Skeletal muscle is developed from multinucleated myocytes formed by the fusion of mononucleated myoblasts. The fusion of myoblasts is associated with many changes in muscle biology such as cessation of DNA synthesis, production of contractile proteins, and marked alterations in enzymatic activity. Before fusion, myoblasts irreversibly withdraw from the cell cycle. This cell cycle exit is required for the normal progression of fusion, and the development of the contractile machinery. Recent report [Chen et al., JBC 277:4324, 2002] suggests that protein arginine methyltransferase (PRMT) 4 is involved in the chromatin remodeling and gene expression related to the muscle differentiation in C2C12 cells, suggesting a possible role as one of the controlling mechanisms of the cell cycle exit of myoblasts. In this study the expression of PRMT1 and PRMT5 during the myoblast fusion in primary muscle culture was investigated. Rat myoblasts isolated from E21 SD rats were cultured as reported previously [Daniels et al., Micr Res Tech 49:26, 2000]. Spontaneous myoblast fusion was blocked by adding EGTA into the culture media, and the fusion burst was induced by changing with normal media. Proteins were extracted at the stages of prefusion, fusion arrest, fusion burst, and postfusion. The extracted proteins were incubated with *S*-adenosyl-L-[*methyl*-$^{3}$H]methionine, and subjected to SDS-PAGE followed by fluorography. Western immunoblot using antibodies against PRMT1 and 5 were performed. Expressions of both PRMT1 and PRMT5 were increased during the fusion burst, which decreased to the prefusion level after fusion. Western immunoblot data was similar to the fluorographic results. The present study suggests that PRMT1 and PRMT5 may also play an important role in the myoblast fusion similar to PRMT4. Especially PRMT1 and *S*-adenosyl-L-[*methyl*-$^{3}$H]methionine(AdoMet)-dependent methylation are necessary for the biochemical and morphological changes of myoblasts during the fusion stage.

**Mild Heat Shock Induces Differentiation of Mammalian and Avian Myoblasts**

T. Yamaguchi, Y. Atomi; University of Tokyo, Art and Science, Atomi's Laboratory, Tokyo, Japan

Skeletal myogenesis is a well-orchestrated cascade of events regulated by multiple signaling pathways. Heat shock response is one of the intracellular defense mechanisms against stressful conditions, which leads to the preferential transcription and translation of heat shock proteins (Hsps). In this study, we investigated the direct effects of temperature on differentiation of cultured C2C12 myoblasts. Compared with the control cultures at 37°C, incubation at 39°C increased myotube diameter. Although the myotube formation at 41°C appeared earlier, their diameters were reduced. The levels of the Hsps (Hsp70 and alphaB-crystallin) were up-regulated with increased temperature. Muscle specific transcription factors, MyoD and myogenin, and extracellular signal rgulated protein kinase (ERK) were induced above at 39°C culture, relative to the 37°C. Moreover, inhibitition of mitogen-activated protein kinase/ERK kinase (MEK) activation by PD98059 suppressed myotube formation. These data suggest that treatment with a mild heat shock might induce C2C12 myotube enlargement via the MEK/ERK pathway. The similarity of the response to mild heat shock was observed in chick and human myoblasts in primary culture of skeletal muscle.The delicate balance of signaling pathway due to a slight change of temperature might be involved in myotube enlargement.

**Axial Elongation in Mouse Embryos Involves Mediolateral Cell Intercalation Behavior in the Paraxial Mesoderm**

W. Yen,[1] C. Burdsal,[2] A. Periassamy,[3] A. E. Sutherland[1]; [1]Cell Biology, University of Virginia, Charlottesville, VA, [2]Biology, Tulane University, New Orleans, LA, [3]Biology, University of Virginia, Charlottesville, VA

The cell mechanical and signaling pathways involved in gastrulation have been studied extensively in invertebrates and amphibians, such as *Xenopus*, and more recently in non-amniote vertebrates such as zebrafish and chick. However, because culturing mouse embryos extra-utero is very difficult, this fundamental process has been least characterized in the mouse. As the primary mammalian model for genetics, biochemistry, and the study of human disease and birth defects, it is important to investigate how gastrulation proceeds in murine embryos. We have developed a method of using 4D multiphoton excitation microscopy and extra-utero culture to visualize and characterize the morphogenetic movements in mouse embryos dissected at 8.5 days of gestation. Cells are labeled by expression of an X chromosome-linked EGFP transgene. This method has provided a unique approach, where, for the first time, patterns of cell behavior in the notochord and surrounding paraxial mesoderm can be visualized and traced quantitatively. Our observations of mouse embryos reveal distinct differences in patterned cell motility relative to other vertebrate models such as *Xenopus*, where axial extension is driven primarily by mediolateral oriented cell behaviors in the notochord and paraxial somatic mesoderm. Unlike *Xenopus*, cells within the mouse notochord are not aligned, although they are elongate. In contrast, cells within the paraxial mesoderm are both elongated and aligned perpendicular to the midline. In addition, these cells are observed to translocate towards the midline, consistent with a role for paraxial mesoderm in driving convergence and extension. These cell behaviors are similar to those characterized in the axial mesoderm of frog embryos during convergence and extension, and suggests that tissues may play different roles in axial elongation between the frog and the mouse.

**Potential Role of Pinin in Regulation of Wnt Signaling and Neural Crest Cell Migration during Mouse Development**

J. Joo,[1] Y. Lee,[2] M. R. Jackson,[1] P. Oh,[2] S. P. Sugrue[1]; [1]Anatomy and Cell Biology, University of Florida, Gainesville, FL, [2]Physiology and Functional Genomics, University of Florida, Gainesville, FL

Numerous studies have demonstrated that Pinin (Pnn), a nuclear and cell adhesion-related protein, functions as a critical mediator of various multiprotein complexes involved in regulation of gene expression, pre-mRNA splicing, and cell adhesion. To investigate biological role of Pnn, we generated conditional Pnn knockout mice with three *loxP* sites (3f) flanking exon 3 to exon 8 of *Pnn* as well as a neomycin resistance cassette. EIIa-Cre mice were utilized to generate constitutive *Pnn*-null (1f) and *Pnn*-conditional (2f) alleles. The *Pnn*$^{1f/1f}$ embryos exhibited lethality at peri-implantation stages. Interestingly, *Pnn*$^{3f}$ appeared to be a hypomorphic allele, which resulted in reduced Pinin protein expression due to incorrect splicing. The *Pnn*$^{3f/3f}$ mice die around birth and exhibit pleiotropic phenotypes, including disorganized epidermis, subepidermal blisters, cleft palate, axial skeletal defects, cardiac outflow tract defects, and anterior eye segment dysgenesis. Since most of these phenotypes are related to

defective neural crest cells (NCC) of which Wnt signaling is critical for the proliferation and migration, we investigated whether Wnt activities are affected in *Pnn*$^{3f/3f}$ ES cells. We found that the activity of Wnt downstream transcription factors, TCF/LEF, is greatly upregulated in *Pnn*$^{3f/3f}$ ES cells. Furthermore, the TCF/LEF activity was also observed to be altered in *Pnn*$^{3f/3f}$ mice. Finally, NCC-specific ablation of *Pnn* by Wnt1-Cre mice revealed severe cardiac and craniofacial defects similar to those of DiGeorge Syndrome, suggesting an essential role of Pnn in the proliferation and/or migration of NCCs. In summary, the results suggest that Pnn is involved in the regulation of Wnt signaling pathway and NCC migration.

**Isolation, Characterization and Secretion of *Xenopus laevis* Embryonic Epidermal Lectin**

S. Nagata,[1,2] N. Fujita[2]; [1]Animal Science, University of California at Davis, Davis, CA, [2]Chemical and Biological Sciences, Japan Women's University, Tokyo, Japan

The *Xenopus laevis* embryonic epidermal lectin (XEEL) is a novel member of a chordate lectin family including mammalian intelectins, frog oocyte cortical granule lectins and plasma lectins in lower vertebrates and ascidians. To elucidate roles of XEEL in embryonic development, we isolated XEEL from tailbud embryos by affinity chromatography on a galactose-Sepharose column. The XEEL protein is a homohexamer of 43-kDa N-glycosylated peptide subunits, requires $Ca^{2+}$ for saccharide binding and shows a higher affinity to pentoses than hexoses and disaccharides. The recombinant XEEL (rXEEL) produced by transfected HEK-293T cells is similar to the purified XEEL in its molecular nature and saccharide-binding properties. Substitution of Asn-192 to Gln removed the N-linked carbohydrate and inhibited secretion of rXEEL, but did not abolish the activity to bind to galactose-Sepharose. Examination of chimeric proteins between rXEEL and rXCGL suggests that the C-terminal segment of XEEL is also important for secretion. The XEEL content of embryo, as estimated by Western blot analyses, increases during neurula/tailbud stages and declines after one week post-fertilization. Immunofluorescence and immuno-electron microscopic analyses showed localization of the XEEL protein in a typical secretory granule pathway of non-ciliated epidermal cells. When tailbud embryos were cultured in the standard medium, XEEL was accumulated in the medium, indicating secretion of XEEL into the environmental water. The rate of XEEL secretion greatly increased at around the hatching stage and stayed at a high level during the first week after hatching. Mammalian intelectins with similar molecular nature and carbohydrate specificity have been implicated in anti-microbial innate immunity in intestinal mucosa. XEEL may have a similar role to protect hatched embryos and early larvae against pathogenic microorganisms in the environmental water.

**Ena/vasp Proteins are Required for Cortical Organization, Neuritogenesis and Axonal Outgrowth During Vertebrate Development**

A. V. Kwiatkowski,[1] D. A. Rubinson,[1] E. W. Dent,[1] J. D. Leslie,[2] F. B. Gertler[1]; [1]Biology, Massachusetts Institute of Technology, Cambridge, MA, [2]Cancer Center Research UK, London, United Kingdom

Ena/VASP proteins regulate actin dynamics, and previous studies have implicated Ena/VASP proteins in neuronal migration and axon guidance. To investigate the requirement of Ena/VASP proteins in nervous system development, we disrupted the remaining Ena/VASP protein, EVL, in the mouse and crossed it to existing Mena (Lanier et al., 1999) and VASP (Aszodi et al., 1999) mutant lines. Within the peripheral nervous system, deletion of all three Ena/VASP proteins resulted in poorly formed trigeminal and spinal nerves that exhibited reduced outgrowth and guidance defects. Histological analysis of the cortex revealed a disorganized intermediate zone with poorly formed or absent fiber tracts, suggesting a defect in axonal formation or extension from cortical neurons. Strikingly, Ena/VASP-deficient brains exhibited a severe form of cobblestone (type II) lissencephaly, in which cortical neurons migrated beyond the marginal zone and established ectopias within the subarachnoid space. The severity of these ectopias reflect possible defects in pial membrane formation and neuronal migration. Surprisingly, in contrast to neurons in the cortical plate, axonal outgrowth was observed from ectopic neurons, suggesting that factors present outside the cortex, possibly in the pial membrane, induce outgrowth in the absence of Ena/VASP. When cultured in vitro, cortical neurons from Ena/VASP-deficient brains fail to undergo neuritogenesis (see accompanying abstract by Dent et al.), consistent with outgrowth defects observed in vivo. However, this defect was rescued when neurons were plated onto laminin, the predominant matrix protein of the pial membrane that is absent from the cortical plate. These results suggest Ena/VASP proteins and laminin function in independent pathways to promote neurite initiation. This study defines new roles for Ena/VASP proteins in neuritogenesis, axonal outgrowth, and cortical organization during vertebrate nervous system development.

**Tbx1 is Required for Epithelial-mesenchymal Interactions Necessary for Inner Ear Development**

E. M. Braunstein,[1] J. S. Arnold,[1] T. Ohyama,[2] A. Groves,[2] E. B. Crenshaw,[3] J. Adams,[4] B. Morrow[1]; [1]Molecular Genetics, Albert Einstein College of Medicine, Bronx, NY, [2]House Ear Institute, Los Angeles, CA, [3]Childrens' Hospital of Philadelphia, Philadelphia, PA, [4]Massachusetts Eye and Ear Infirmary, Boston, MA

Epithelial-mesenchymal interactions between cells of the otic vesicle and periotic mesenchyme are necessary for normal patterning of the inner ear. The T-box transcription factor, *Tbx1*, is required for proper ear development and is expressed both in the otic vesicle and surrounding periotic mesenchyme (POM) during embryogenesis. To determine the role of *Tbx1* in each tissue, we have generated a conditional allele of this gene. Pax2-Cre was used to drive otic vesicle specific ablation of *Tbx1*, while Brn4-Cre was used to ablate *Tbx1* in the POM. Inactivation of *Tbx1* in the otic vesicle resulted in hypoplasia of the inner ear sensory structures and duplication of the cochleovestibular ganglion, similar to *Tbx1* null mice. Ablation of *Tbx1* in the POM resulted in severe structural malformations of the both otic capsule and cochlea. Because the endogenous *Brn4* gene is also inactivated in this conditional mutant, we are currently comparing our phenotype to that of the Brn4 null mouse. These data suggest that *Tbx1* plays a role in signaling between the epithelial and mesenchymal cells responsible for proper patterning of the inner ear. Based on a yeast-2-hybrid screen for binding partners of Tbx1, we hypothesize that Tbx1 may mediate reciprocal signaling between these cells via interaction with proteins localized to focal adhesions and the actin cytoskeleton.

**Immunocytochemical Distribution of Somatotrophs, Mammotrophs, and Mammosomatotrophs in Porcine Anterior Pituitary**

J. Lee,[1] M. H. Stromer,[2] S. Jeftinija,[3] K. Jeftinija,[3] C. G. Scanes,[4] L. L. Anderson[1,3]; [1]Department of Animal Science, Iowa State University, Ames,

IA, [2]Department of Biochemistry, Biophysics and Molecular Biology, Iowa State University, Ames, IA, [3]Biomedical Sciences, College of Veterinary Medicine, Iowa State University, Ames, IA, [4]Department of Poultry Science, Mississippi State University, Starkville, MS

The existence of a novel anterior pituitary cell type, the mammosomatotroph (MS), secreting both growth hormone (GH) and prolactin (PRL) was proposed to function as transitional cells or progenitor cells between somatotrophs (GH cells) and mammotrophs (PRL cells). Age-associated changes were found in the spatial distribution patterns of GH cells both radially and at different axial levels in the porcine pituitary. Fluorescence immunocytochemistry was used to identify GH, PRL, and MS cells and compare their distribution patterns in anterior pituitary glands from newborn and prepubertal stages of pigs. Anterior lobes were sampled at 3 positions in each of 5 radial regions in each of 3 levels perpendicular to the gland axis. While GH cells were densely populated in regions 1, 3, and 5, PRL cells had a high number and immunointensity of fluorescence along all regions close to the intermediate lobe. There were gradually increasing numbers of GH and PRL cells in region 3 from proximal to distal levels at all ages. Double immunofluorescence positive MS cells were distributed in regions 1, 3, and 5 near the intermediate lobe at the proximal level. Furthermore, there was a high population of Connexin 43, a known gap junctional protein, in region 3 at the all levels of depth. Differential immunoreactivity of GH, PRL, and MS cells across regions and ages may reflect heterogeneity or transitional status of these endocrine cells. From these results, we suggest that there may be regional specificity of cellular differentiation and transformation involving cell-to-cell communication through gap junctions to facilitate GH and PRL secretion in the need for endocrine regulation during the rapid growing period in the young pig. Supported by research grant USDA/CSREES NRI 2003-35206-12817 (L.L.A., S.J., and C.G.S).

**Lineage Analysis of the Atrioventricular Myocardium during Cardiac Valve Development**

V. Gaussin,[1] L. Emile,[1] J. B. E. Burch[2]; [1]Cell Biology and Molecular Medicine, UMDNJ-New Jersey Medical School, Newark, NJ, [2]Fox Chase Cancer Center, Philadelphia, PA

The formation of the atrioventricular (AV) valves is a complex event, reflected by the high incidence of congenital valvular defects. Several lineage studies in the mouse indicated that the AV leaflets derive mostly from the mesenchymal cushions in the AV canal. These cushions are in contact with AV myocardium during development suggesting a role for this myocardium during valvulogenesis. Here, we analyzed the contribution of AV myocardium to the formation of the AV valves. For this, we used transgenic mice expressing Cre under the control of a cGATA6 heart-specific enhancer and LacZ-reporter mice for Cre activity (R26R). In E11.5 cGATA6-Cre/R26R mice, Cre-mediated DNA recombination was largely confined to the myocardium in the AV canal and was more robust on the right and posterior sides. At E14.5, LacZ-positive cardiac myocytes were found in the myocardial layer present in the tricuspid mural and posterior leaflets, and in the myocardium in contact with the septal leaflet of the mitral valve. They were also identified in the myocardium at the atrial border of the developing annulus fibrosus. One week postnatal and in adult hearts, LacZ-positive cells contributed to the tricuspid mural and posterior leaflets, the mitral septal leaflet, and the atrial border of the annulus fibrosus. We previously reported that when Alk3, the type Ia receptor for bone morphogenetic proteins, was deleted in these cells, defects were seen in the same leaflets, i.e. the tricuspid mural leaflet and mitral septal leaflet were longer, the tricuspid posterior leaflet was displaced and adherent to the ventricular wall, and the annulus fibrosus was disrupted resulting in ventricular preexcitation. In conclusion, AV myocardium is essential for AV canal development, and contributes to the morphogenesis of AV valves and annulus fibrosus.

2032

**Identification of Candidate Genes in a Transgenic Mouse Model of Urogenital Development and Obstruction**

K. M. McHugh, S. Singh, M. Chilton, A. Bailes, D. Pitre, B. Coley, H. Auer, K. Kornacker, C. M. Bates, M. L. Robinson; Pediatrics, Columbus Children's Research Institute, Columbus, OH

Diseases of the urinary bladder affect an estimated 35 million people in the United States, with end-stage renal failure in children alone estimated to cost over 15 billion dollars annually. Despite the prevalence of bladder disease, little is currently known regarding the mechanisms controlling these processes. We have identified a unique insertional mutant mouse model, designated *mgb,* that develops *in utero* megabladder resulting in variable hydroureteronephrosis and chronic renal failure secondary to obstructive uropathy. Homozygous *mgb* mice possess a primary defect in bladder smooth muscle development that is apparent by embryonic day 15, and whose functional outcome appears gender-specific. Interestingly, heterozygous *mgb* mice possess an intermediate phenotype that appears to result in altered bladder function. FISH analysis indicates that the *mgb* phenotype is the result of a translocation of a defined segment of chromosome 16 into chromosome 11. Using a unique microarray approach, we have identified a subset of genes from the translocated piece of chromosome 16 that are consistently over-expressed in *mgb* mice. This approach has permitted the rapid identification of two primary candidate genes, and represents a potentially exciting technique for the identification of target genes involved in insertional mutagenesis. In conclusion, we have utilized a novel microarray-based approach to rapidly identify the potential candidate gene(s) involved in the production of the *mgb* phenotype. *Mgb* mice represent an excellent model for the study of normal and pathogenic bladder development, including the postnatal progression of chronic renal failure resulting from obstructive uropathy.

2033

**Regulation of Pocket Protein Expression by Activating Transcription Factor-2 (ATF-2)**

D. S. Vale-Cruz, Q. Ma, P. A. LuValle; Anatomy and Cell Biology, University of Florida, Gainesville, FL

Longitudinal bone growth occurs through endochondral ossification, where cartilage provides the template for ossification into bone. This process is dependent on the proliferation and differentiation of chondrocytes, cartilage cells, to form the ossification template. Activating transcription factor-2 (ATF-2) deficient mice exhibit abnormal growth plates, implicating this protein in modulation of cellular processes necessary for normal bone growth. ATF-2 regulates gene expression by binding the cyclic-AMP response element (CRE) located within promoter regions of target genes. The pocket proteins, retinoblastoma (Rb), p107, and p130, are cell cycle regulators that are potential targets of ATF-2 gene regulation. This study focuses on investigating the expression of the pocket proteins within growth plate chondrocytes and the role of ATF-2 in the regulation of the pocket proteins. Pocket proteins display varying levels of expression within the growth plate as determined by immunohistochenistry. Rb and p130 are expressed at high levels within the wild type mouse growth plate. p107 is expressed at lower levels within the growth plate. Expression of pocket proteins in ATF-2 knockout ($ATF^{m/m}$) mice is altered. Western analysis of protein form wild-type, heterozygous and $ATF^{m/m}$ chondrocytes showed expression of Rb in $ATF^{m/m}$ mice is decreased, while expression of p107 and p130 are increased. Levels of pocket protein mRNAs are also

altered in $ATF^{m/m}$ mice. Transfection of a dominant negative ATF-2 plasmid alters levels of pocket protein mRNAs similar to those observed in $ATF^{m/m}$ mouse chondrocytes. Chromatin immunoprecipitation assays were used to show ATF-2 regulation of pocket protein promoter regions. The loss of ATF-2 leads to abnormal pocket protein expression which may, in turn, lead to cell cycle deregulation, more rapid cell cycle progression and, ultimately abnormal growth plate development.

2034

**Design and Creation of a Floxed Mouse Flightless Gene Targeting Vector**

R. K. Judge,[1] K. Matthei,[2] A. J. Cowin,[3] H. D. Campbell[1]; [1]RSBS, Australian National University, Canberra, Australia, [2]JCSMR, Australian National University, Canberra, Australia, [3]Child Health Research Institute, Adelaide, Australia

The flightless protein is an important member of the gelsolin family of proteins involved in actin remodeling, a process that is central to changes in cell adhesion and motility as well as wound repair processes. Recent studies have demonstrated the primary expression of flightless in proliferative basal and suprabasal keratinocytes. These cell types are responsible for the repair of the epidermis in response to injury. Thus, the objective of this study was to determine the effects of altering the quantity of the flightless protein on wound repair in a gene knockout model through the creation and design of a targeting vector using the Red/ET recombination system. A region of the flightless gene encompassing exons 4 and 5 was flanked by *loxP* sites cloned into adjacent introns. A *Neo* gene cassette for positive selection, flanked by *FRT* sites, was introduced adjacent to the *loxP* site upstream of exon 5, whilst a thymidine kinase cassette for negative selection was introduced downstream of exon 2. Induction of the *Cre* recombinase resulted in the deletion of exons 4 and 5 and the subsequent cryptic splicing of exons 1, 2 and 3 to the downstream introns to produce a null allele. These results demonstrate the successful generation of the flightless null allele. The production of this allele is also the first step towards the construction of a flightless conditional knockout targeted to the epidermis.

2035

**Smooth Muscle Cells (SMC) and Activated Myofibroblasts Employ Distinct but also Common Transcription Control of SM α-Actin Expression**

Q. Gan, T. Yoshida, G. K. Owens; University of Virginia, Charlottesville, VA

SMC and activated myofibroblasts express several common cell selective marker genes such as smooth muscle α-actin (SMα). Indeed, based on these observations, there has been considerable controversy regarding the lineage relationship of these two cell types. Interestingly, results of previous cell culture studies in our lab provided evidence for distinct transcriptional regulatory mechanisms in these cells in that we found mutation of two MCAT elements located at -184 bp and -320 bp in the SMα promoter increased transcriptional activity in cultured rat aortic SMC but had the complete opposite effect of decreasing activity in myofibroblasts. The aim of present study was to determine the role of MCAT elements in control of the SMα transcription in vivo in various cell types. Comparison of transgenic mice containing double-MCAT-element mutant SMα promoter-enhancer LacZ reporter gene (dMCAT-SMα-LacZ mice) versus the wild type SMα promoter-enhancer LacZ (SMα-LacZ) showed no differences of transgene expression in SMC tissues in adult mice. However, of major interest, SMα-LacZ but not dMCAT-SMα-LacZ mice showed induction of transgene within activated myofibroblasts after skin wound injury. In addition, the transgene expression in dMCAT-SMα-LacZ embryos showed a remarkably distinct staining pattern as compared to SMα-LacZ embryos, in that induction of this mutant transgene was developmentally delayed in SMC and completely abolished in cardiac, and skeletal myoblasts, which transiently express SMα during embryonic development. Taken together, these results provide clear evidence that although multiple cell types other than SMC express the SMα gene, they employ distinct transcriptional regulatory controls as compared to mature SMC within adult animals. However, of interest, initial induction of SMα within SMC during early embryonic development appears to require common regulatory controls as in non-SMC including complete dependence on MCAT elements.

2036

**Pitx2, Which Implicated in the Formation of Brachial Arch Arteries, Potently Activates Transcription of Smooth Muscle Marker Genes**

Y. Shang, T. Yoshida, G. K. Owens; Physiology, University of Virginia, Charlottesville, VA

The mechanisms that control early stages of smooth muscle cell (SMC) differentiation are relatively poorly understood. We previously developed an inducible SMC lineage system, an A404 SMC progenitor cell, which activated all of the SMC marker genes after the treatment with retinoic acid (RA). The goal of the present study was to identify novel transcription factors that control early stages of SMC differentiation based on subtraction hybridization screening of RA-treated A404 cells versus untreated A404 cells. Of major interest, we identified over 40 genes that were induced within 48 hours of treatment of RA in differentiated A404 cells. One of these, Pitx2, a homeodomain-containing transcription factor previously shown to play a role in the formation of brachial arch arteries, was transiently induced by 6-fold following RA treatment of A404 cells. Expression of Pitx2 was also induced by 8-fold in an embryonic stem cell-derived embryoid body model of SMC differentiation. Moreover, over-expression of Pitx2 activated transcription of SMC marker genes including smooth muscle (SM) α-actin by 10-fold. In contrast, short interfering RNA-induced suppression of Pitx2 in differentiated A404 SMC cells decreased SM α-actin transcription. Site-directed mutagenesis analysis revealed that the effect of Pitx2 on SM α-actin transcription was mediated by a TAATCC cis-element located at -145 bp and CArG B element at -112 bp of the SM α-actin promoter. Electrophoresis mobility shift assays showed binding of Pitx2 to a TAATCC element. In addition, the interaction between Pitx2 and serum response factor (SRF) was seen by co-immunoprecipitation assays, and co-expression of Pitx2 and SRF synergistically induced SMC marker gene transcription. Taken together, these results suggest that Pitx2 is a novel factor involved in SMC marker gene expression in the early stages of SMC differentiation.

2037

**The Ternary Complex Factor, Elk-1, Plays a Key Role in Modulating Transcriptional Activation of Single and Multiple CArG-Containing Smooth Muscle Cell Marker Genes by Myocardin and MKL Factors**

T. Yoshida, Q. Gan, G. Owens; Physiology, University of Virginia, Charlottesville, VA

Myocardin and its related factors, MKL1 and MKL2, are potent co-activators of serum response factor (SRF). The aims of the present studies were to determine: 1) the role of MKL factors in expression of single CArG-containing, multiple CArG-containing, and CArG-independent smooth

muscle cell (SMC) marker genes; and 2) the mechanisms whereby myocardin and MKL factors selectively induces expression of single CArG-containing SMC marker genes, but not a single CArG-containing c-fos gene. Results showed that expression of MKL1 and MKL2 was unaltered during the induction of SMC differentiation in a novel embryonic stem cell-derived embryoid body model and A404 SMC progenitor cells. Results from gain- and loss-of-function experiments showed that MKL1 and MKL2 regulated the expression of single CArG-containing (e.g. telokin) and multiple CArG-containing (e.g. smooth muscle (SM) α-actin, SM-myosin heavy chain, and SM22α), but not CArG-independent (e.g. aortic carboxypeptidase-like protein and focal adhesion kinase-related nonkinase) SMC marker genes. Mutational analyses of single CArG-containing genes showed that the presence of ternary complex factor (TCF)-binding site adjacent to the CArG element attenuated the responsiveness to myocardin and MKL factors. Chromatin immunoprecipitation assays revealed that one of the TCFs, Elk-1, constitutively bound to the CArG-containing region in the c-fos gene, but not to the CArG-containing region in the telokin gene, and that myocardin selectively enhanced SRF binding to telokin CArG element as compared to c-fos CArG element in SMCs. Results provide novel evidence that MKL factors regulate single and multiple CArG-containing SMC marker genes and that Elk-1 plays a key role in modulating the response of single CArG-containing genes to myocardin and MKL factors. (Supported by grants NIH R01 HL38854, R37 HL57353, and P01 HL19242.)

**Changes in the Muscle Fiber Characteristics of the Anterior Belly of the Digastric Muscle Before and After Weaning in Mice**

K. Sakiyama, M. Yoshii, N. Yanagisawa, S. Abe, Y. Ide; Anatomy, Tokyo Dental College, Chiba, Japan

During the process of growth and development, the digastric muscle is subjected to marked functional changes, including the change from suckling to mastication. In particular, because the anterior belly of the digastric muscle, which is one of suprahyoid muscles, plays an important role in mastication. Therefore, thie muscle seems to be a marked functional change before and after weaning. However, the details remain unknown. Here, in order to clarify the changes in the muscle fiber characteristics of the anterior belly of the digastric muscle before and after weaning, we examined myosin heavy chain (MHC) isoforms at the protein (immunohistochemistry) and mRNA (transcription) levels. As a control, the changes in the muscle fiber characteristics of the sternohyoid muscle, which is anatomically aligned in the same direction as the anterior belly of the digastric muscle, were analyzed. The results showed that, in the anterior belly of the digastric muscle that is involved in mandibular movements in mice, the ratio of a fast-contraction isoform with strong contractile force increased after weaning. We believe that this occurred in response to a functional change from suckling to mastication. On the other hand, there was little change in the composition of sternohyoid muscle.

2039

**Barx2 Regulates Muscle Cell Plasticity**

R. Meech,[1] K. Gonzalez,[1] H. Makarenkova[2]; [1]The Scripps Research Institute, San Diego, CA, [2]The Neurosciences Institute, San Diego, CA

Differentiation and dedifferentiation are fundamental cellular processes mediating muscle development and repair. Recent work has shown that the homeodomain protein Barx2 plays important roles in both of these processes. Overexpression of Barx2 in myoblasts increases expression of some muscle specific genes and accelerates myotube formation, while overexpression in myotubes downregulates muscle genes and promotes dedifferentiation. One potential explanation for this dichotomy is suggested by the domain structure of Barx2: the protein contains both repressor and activator domains that may recruit either co-activator or co-repressor complexes to muscle specific genes in different contexts. Preliminary data suggest that Barx2 helps coordinate cell cycle regulation, cytoskeletal remodeling and muscle specific gene expression during differentiation and dedifferentiation. Thus Barx2 may play an important role in the cellular mechanisms of muscle repair after injury or degenerative disease.

2040

**Properties of Myosin Heavy Chain in Tongue Muscle of Microphthalmic (*mi/mi*) Mice Before and After Weaning**

N. Yanagisawa, K. Sakiyama, S. Abe, Y. Ide; Anatomy, Tokyo Dental College, Chiba City, Japan

To elucidate the effects of teeth on muscle fibers in tongue during the development process, we examined the expression of muscle contractile proteins and the genes for those proteins in normal mice and microphthalmic (*mi/mi*) mice with impaired tooth eruption. The mice were observed during the growth period, including weaning, which is when feeding movements undergo major changes. Expression of the myosin heavy chain (MyHC)-2a protein, whose contraction speed is relatively slow, disappeared after weaning in normal mice, while it remained in high concentrations even after weaning in *mi/mi* mice. The presence of MyHC-2a after weaning in mice with no tooth eruption was attributed to a compensation for lack of proper masticatory function and sucking-like movements, as MyHC-2a is necessary for these movements.

2041

**Role of Laminin-10 in Hair Development**

J. Gao,[1] C. Chen,[1] N. Nguyen,[1] J. Miner,[2] A. E. Oro,[1] M. P. Marinkovich[1]; [1]Epithelial Biology, Stanford University, Stanford, CA, [2]Medicine, Washington University, St. Louis, MO

In the current study we sought to determine the role that laminin-10 plays in hair follicle formation. Lama5 -/- transgenic mice, which lack laminin-10, do not survive beyond E16.5, however development of lama5 -/- skin can be studied after grafting E16.5 day skin to nude mice. While lama5 -/- skin showed a complete lack of hair development after grafting, incubation of lama5 -/- skin in a solution of wild type laminin-10 or recombinant laminin-10 lacking alpha 5 G45 domain prior to grafting restored the development of fully formed hair. However recombinant laminin-10 lacking G3-5 domain showed no ability to support hair follicle formation. These results suggest that the heparin binding domain on the G45 region is dispensable but the integrin binding domain on the G3 region is essential for hair follicle development. E16.5 lama5 -/- skin showed deficient noggin, Msx1 and Lef-1 expression, however Wnts, BMPs, and Msx2 were normal by rt-PCR. By IDIF E16.5 lama5 -/- skin completely lacked noggin expression and failed to show decreased e-cadherin or p-SMAD expression, in marked contrast to wild type skin. Lama5 -/- skin treated with SHH or noggin prior to grafting formed hair follicles, however Wnt3a failed to have any effects. These findings suggest that laminin-10 plays a role in promoting the expression of noggin upon which subsequent steps of phosphoSMAD downregulation, ecadherin downregulation and SHH upregulation occur in the hair morphogenic signaling cascade. Finally, we also found that lama5 -/- epithelial cells failed to support hair development, when mixed with wild type purified dermal papillae cells in hair reconstitution assays. These results implicate laminin-10 as an epithelial derived signal which is required for the hair inducing effects of the dermal papillae.

**A New Chemical Inhibitor of Steroid Biosynthesis**

J. M. Gendron,[1] A. Haque,[2] T. Chang,[1] Z. Wang[2]; [1]Biological Sciences, Stanford/Carnegie Intstitution, Stanford, CA, [2]Plant Biology, Carnegie Intstitution, Stanford, CA

Brassinosteroids (BRs) are ubiquitous plant hormones that control many aspects of plant growth and development. Molecular and genetic tools have been used to delineate the BR biosynthesis and signaling pathways that transduce the BR signal. One important tool that has been used widely in BR research is the small molecule brassinazole (BRZ), which is a triazole-based compound that is thought to inhibit the action of at least one cytochrome p450 enzyme involved in BR biosynthesis. Plants grown on BRZ display typical BR-deficient dwarf phenotypes and can be rescued by exogenous application of BRs, suggesting the compound decreases BR biosynthesis. To identify new inhibitors of BR biosynthesis or signaling, a chemical genetics screen was done using a library of 10,000 small molecules. Dark grown hypocotyl length and expression of a BR signaling marker were assayed to find molecules specifically regulating BR processes. 90 compounds were identified that cause typical BR-deficient phenotypes and affect expression of the BR marker. One of the compounds identified (17) causes phenotypes that can be rescued by application of BR. Compound 17 contains a cyclopropyl side group that is known to react with cytochrome p450s and inhibit their function. Removal of the cyclopropyl group results in loss of activity of the compound, suggesting that the cyclopropyl is necessary for proper function of compound 17. This is the first non-triazole based small molecule identified that inhibits BR biosynthesis. This compound will be a valuable tool to investigate BR signaling.

**Studies on the Expression of SIRT1 (the Human Homologue of SIR2) in HaCaT Cells After Exposure to Caloric Restriction and UV Stress**

C. Dal Farra, E. Roux, E. Bauza, J. Botto, N. Domloge; Vincience, Sophia antipolis, France

Recent studies have established that SIRT1, the human homologue of Sir2, plays an important role in cellular response to stress and aging. It has also been shown that SIRT1 deacetylates p53, preventing cellular senescence and apoptosis induced by stress. Hence, we were interested in studying SIRT1 expression in HaCaT cells, as these cells are commonly used in skin research. SIRT1 and p53 expression in HaCaT cells was evaluated after cells were exposed to caloric restriction or UVB stress. Evaluations were performed through immunostaining, immunoblotting, and mRNA studies. In HaCaT cells irradiated with different doses of UVB, immunoblotting studies revealed an increase in SIRT1 in a dose-dependent manner, up to 40mJ/cm2. Maximum expression of SIRT1 was seen at 30mJ/cm2. Interestingly, p53 expression did not vary significantly, which is consistent with the immortal nature of the cell line. Immunostaining studies revealed the nuclear expression of SIRT1 and confirmed the above results. Furthermore, an increase in SIRT1 mRNA was observed after low UVB doses in mRNA cell studies, and this effect lasted up to 48h after irradiation. Caloric restriction studies showed an increase in SIRT1 expression in a dose-dependent manner with glucose deprivation, and this effect was seen after 48h of deprivation. Interestingly, a significant variation in p53 expression was not observed. These studies demonstrate the expression of SIRT1 in HaCaT cells and reveal the correlation between this expression and UVB and caloric stress. Consequently, these findings strongly suggest that SIRT1 plays an important role in defense against stress and aging in HaCaT cells.

**OsDREB1-A Transcription Factor Gene from Rice, Enhances Cold Tolerance in Tobacco**

G. Zhang, P. Li, F. Chen, C. Quan; Department of Biological Sciences and Biotechnology,Tsinghua University, Beijing, China

The OsDREB1 gene from rice encodes a transcription factor belonging to the DERBP transcription factor subfamily. Many DREBP transcription factors regulate gene expression in response to drought, high-salt, and cold stresses by binding specifically to the dehydration-responsive element (DRE). DRE-binding proteins such as CBF1, DREB1A, and DREB2A have been cloned from Arabidopsis thaliana and have proved to play an important role in stress response of Arabidopsis and several other plants. In this study the OsDREB1 gene was transferred to tobacco plants by the Agrobacterium-mediated transfer method, and 16 transgenic plants were identified, PCR analysis demonstrated that the foreign genes had been integrated into the tobacco genome. Results of freezing stress experiments indicated that the transgenic plants had enhanced cold tolerance.

**Detailed Understanding of Thioredoxin-Linked Redox Regulation by Disulfide Proteome**

H. Yano, S. Kuroda; National Institute of Crop Science, Tsukuba, Japan

Evidences are accumulating to suggest that redox regulations play critical roles in a broad spectrum of biology. Thioredoxin, a ubiquitous 12kDa protein with a catalytically active disulfide bond, plays a central role in controlling the redox status of disulfide bonds in proteins that regulate a range of physiological processes. Recently, Yano *et al.* (Yano, H., Kuroda, S. and Buchanan, B. B., *Proteomics* 2002, *2*, 1090-1096) developed a disulfide proteome technique that visualizes redox change in proteins comprehensively. In this presentation, using disulfide proteome, we examined rice bran and identified embryo-specific protein and dienelactone hydrolase (DLH) as putative targets of thioredoxin. Monitoring both endogenous and recombinant thioredoxin's effects on rice bran proteins and supporting *in vivo* observations propose a mechanism of redox regulation in seed germination, in which thioredoxin activates cysteine protease with a concurrent unfolding of its substrate, the embryo-specific protein, to facilitate degradation. Our findings suggest that thioredoxin controls the lifetime of specific proteins effectively by regulating the redox reactions coordinately. These findings, with the previous observations, suggest the presence of thioredoxin-linked exquisite mobilization mechanisms, in which specific seed proteins are degraded in the respective stages of germination and early seedling development. Also, the regulatory mechanism of rice DLH was found to be different from that of bacterial DLH. The model study demonstrates that the disulfide proteome technique is useful not only to identify targets of thioredoxin, but also to clarify the detailed mechanism of redox regulation. Proteome analysis of regulatory mechanisms, such as those based on phosphorylation and thiol redox status, will add a new dimension to biology.

**Expression and Auxin Effects on the RACK 1 Homolog from Common Bean (*Phaseolus vulgaris*)**

M. A. Villanueva,[1] T. T. Islas-Flores,[1] I. R. Islas-Flores,[2] E. L. Bearer[3]; [1]Plant Molecular Biology, Institute of Biotechnology-UNAM, Cuernavaca, Morelos, Mexico, [2]Plant Biochemistry, Centro de Investigación Científica de Yucatán, A.C., Mérida, Yucatán, Mexico, [3]Biology and Medicine,

Brown University, Providence, RI
Germination and growth in plants is a natural event that involves multiple molecular reactions within complex and highly regulated biochemical cascades which will eventually develop into a photosynthetic, autotrophic plant. The cytoskeleton and signal and adaptor proteins play key roles during these early stages and most of the plant life cycle. One of these proteins of the adaptor type is the receptor for activated protein kinase C (RACK1). The plant homolog was partially sequenced by RT-PCR using mRNA from common bean embryo axes, and an antibody against an internal peptide was raised in rabbits. Western blot analyses indicated that the protein was present in detectable amounts in the embryo axes, and that the protein was present in both microsomal and soluble fractions from this tissue. Expression analysis during germination revealed that the protein was present at relatively constant levels from 0 to 96 h. However, the mRNA showed a peak of maximal expression at 36h. The presence of auxin during germination only delayed the maximal peak of expression of the mRNA to 48 h but had no effect on the protein level. An auxin blocker, naphtylphtalamic acid had no effect on either mRNA or protein expression levels. Southern blot analysis showed the presence of a small gene family with only one or two members. These data indicate that the RACK1 homolog from bean is present in soluble and insoluble forms in the bean embryo axis, and that its mRNA has an important peak of expression at times when germination stops and growth and elongation start in the seedling, but external auxins or auxin blockers have a minimal effect on this phenomenon.

## Growth Factors in Development (2047-2057)

2047

### Epidermal Growth Factor (EGF) Regulates Differentiation of Small Gaba-ergic Cortical Neurons

E. C. Walcott,[1] K. Crossin,[1,2] H. Makarenkova[1]; [1]The Neurosciences Institute, San Diego, CA, [2]The Scripps Research Institute, San Diego, CA
The mechanisms underlying the development of neuronal diversity are largely unknown. In the mammalian cerebral cortex Gamma-aminobutyric acid (GABA) neurons represent 10-25% of all neurons. Neuronal cultures prepared from rat embryonic cerebral cortex at E 16-18 form two different populations of GABA-ergic neurons. A distinct population of large GABA-ergic neurons was found in the cultures just after the plating. This population differentiates into large neurons with extensively developed and branched dendritic trees and is responsible for generation of synchronous oscillatory network activity. The ability of these neurons to differentiate even in the presence of mitogen inhibitor ARAC suggests that most of these neurons are post mitotic. Neurons in the second population of GABAergic cells are much smaller, predominantly bipolar in appearance and they form clusters between large neurons. Small GABA-ergic neurons are generated in culture during the first week and their function and mechanisms underlying their differentiation are unknown. A further characterization of small GABA-ergic neurons shows that they extensively express epidermal growth factor receptor (EGFR), while the expression of fibroblast growth factor receptors FGFRs is low. In correlation with this finding the application of FGFR inhibitor SU5402 to the cortical cultures just after plating had little effect on differentiation of small GABA-ergic neurons while treatment with EGFR inhibitors PD153035 and ZD 1839 almost completely eliminated population of small GABA-ergic neurons. These treatments did not affect the differentiation of large GABA-ergic neurons however application of FGFR inhibitor disturbed synchronous oscillatory network activity of these cells. These findings suggest that EGF may be involved in differentiation of cortical neuronal subpopulations later in development.

2048

### Brain-Derived Neurotrophic Factor Potentiates EphrinA2-Induced Neuronal Growth Cone Collapse

C. Mays, D. S. Ice, E. V. Wong; Biology, University of Louisville, Louisville, KY
Ephrin ligands and their cognate Eph receptor tyrosine kinases play an important role in many developmental processes including angiogenesis, early tissue organization, and axon guidance. Within one of the classic models for the study of axon guidance, the developing chick retinotectal projection, ephrinA2 and ephrinA5 have well-described expression patterns and roles in the optic tectum. EphrinA2, expressed in a smooth anterior-posterior gradient across the tectum, in combination with graded nasotemporal expression of its receptor in the retina, provides positional cues to aid in precise retinotopic mapping of retiinotectal synapses. EphrinA5, expressed in a sharp gradient in just the posterior third of the tectum may also provide some positional information, but likely acts primarily to prevent overshoot of axons. As the retinal axons approach their targets, they begin to receive trophic support via brain-derived neurotrophic factor (BDNF). It was therefore hypothesized that BDNF may modulate ephrin sensitivity to help direct synaptogenesis at the correct site. By testing chick retinal ganglion cell axons and growth cones in vitro, it was found that 18-hr pretreatment with BDNF potentiates growth cone collapse induced by ephrinA2, but not ephrinA5. Upregulation of EphA receptors for ephrinA2 is one possible mechanism for the potentiation by BDNF. Immunohistochemical investigation of this possibility has revealed a significant increase in EphA3 receptor expression in retinal neurons treated with BDNF compared to those that have grown in a control nutrient medium, suggesting that this is part of a mechanism to regulate ephrin- mediated axon guidance by neurotrophic factors.

### VEGF Acts as a Guidance Signal on Cerebellar Granule Cell

N. G. Thomasset,[1] P. Salin,[2] N. Chounlamountri,[1] M. Belin,[1] C. Ruiz de Almodovar,[3] L. Moons,[3] P. Carmeliet,[3] C. Meissirel[1]; [1]Faculty of Medicine, INSERM 433, Lyon, France, [2]Faculty of Medicine, UMR5167 CNRS, Lyon, France, [3]University of Leuven, Flanders Interuniversitary Institute for Biotechnology, Leuven, Belgium
Migration of undifferentiated neural progenitors is critical for the development and repair of the nervous system. However, mechanisms and factors that regulate migration of these progenitors are not well understood. Our objective is to investigate the role of Vascular Endothelial Growth factor (VEGF-A), a major angiogenic factor, during postnatal cerebellar development when proliferation or migration/axogenesis of granular precursor is extensive. Our results showed that VEGF is strongly expressed in developing Purkinje neurons with VEGFR2 receptor expression restricted to granular cell precursors in the external granular layer. Using purified cultured cells obtained from P5 cerebellar cortices, we studied VEGF effect on cerebellar granule cell proliferation, migration and axonal outgrowth in presence or not of a specific VEGFR2 inhibitor, SU1498. Quantification of proliferating granule cell precursors labelled with Bromodeoxyuridine showed a significant dose effect of VEGF up to a 25% increase in proliferation. We investigated VEGF effect on directed cell migration using an in vitro chemotaxis migration assay and co-cultures. Cell counts and axonal area measurements indicate that axons and cell bodies were chemoattracted to short- and long-range VEGF signals, through stimulation of

VEGFR2. Such directed processes could involve local guidance effects at the growth cone level. Interestingly, we demonstrated using a standard chemotropic assay, that axonal growth cones of isolated granule cells turned towards a VEGF gradient. Furthermore, disruption of local VEGF gradient in the cerebellum of VEGF?/?knockin mice impaired inward migration of granule cells. In conclusion, our results demonstrate that VEGF acts as a regulatory signal to control cell proliferation and directed migration as well as axogenesis during postnatal cerebellar development, emphasizing that common mechanisms underlie vessels and nerves guidance

**Hb-egf Promotes Epithelial Cell Migration In Eyelid Development**

N. Mine, R. Iwamoto, E. Mekada; Cell biology, Microbial desease Osaka University, Suita, Japan

Heparin-binding EGF-like growth factor (HB-EGF) is a member of the EGF family of growth factors that binds to and activates the EGF receptor (EGFR) and ErbB4. Here, we show that HB-EGF-EGFR signaling is involved in eyelid development. HB-EGF expression is restricted to the tip of the leading edge of the migrating epithelium during eyelid closure in late gestation mouse embryos. Both HB-EGF null (HB del/del) and secretion-deficient (HB uc/uc) mutant embryos exhibited delayed eyelid closure due to slower leading edge extension and reduced actin bundle formation in migrating epithelial cells. No changes in cell proliferation were observed in these embryos. In addition, activation of EGFR and ERK was decreased in HB del/del eyelids. Crosses between HB del/del mice and waved-2 mice, a hypomorphic EGFR mutant strain, indicate that HB-EGF and EGFR interact genetically in eyelid closure. Together with our data showing that embryos treated with an EGFR-specific kinase inhibitor phenocopy HB del/del embryos, these data indicate that EGFR mediates HB-EGF-dependent eyelid closure. Finally, analysis of eyelid closure in TGF- a null mice and in HB-EGF and TGF-a double null mice revealed that HB-EGF and TGF-a contribute equally to and function synergistically in this process. These results indicate that soluble HB-EGF secreted from the tip of the leading edge activates the EGFR and ERK pathway, and that synergy with TGF-a is required for leading edge extension in epithelial sheet migration during eyelid closure.

2051

**A Novel G Protein-Coupled Receptor Controls the Cortical Assembly in Early Xenopus Embryos Through Small RhoGTPases**

Q. Tao, C. Wylie; Developmental Biology, Cincinati Childrens Hospital, Cincinnati, OH

The actin skeleton plays critical roles in all multicellular organisms. However, the mechanism that controls the assembly of cortical actin, and its remodeling during embryogenesis, are poorly understood. We have been using early Xenopus embryos to study these processes. We have previously shown that the Armadillo-repeat protein, plakoglobin, is both necessary and sufficient for cortical actin assembly in early Xenopus embryos, and is down stream of a small Rho GTPase, cdc42. In order to find more components of this pathway, we carried out an expression screen, using an egg cDNA library. This screen identified a novel G-protein-coupled receptor (GPCR) related to the GPR4 subfamily. We have named this receptpr Xflop. Both gain- and loss-of-function assays showed that Xflop-mediated signaling is both necessary and sufficient for assembly of the actin skeleton in the early Xenopus embryo. In particular, Xflop is required for regulating the overall amount of cortical actin. Epistasis showed that RhoA, cdc42, and Rac1 are all required for the full function of Xflop in regulating cortical actin assembly in early Xenopus embryos. Our work highlights the importance of intercellular signaling in controlling the overall amount and density of the cortical actin network in early embryos.

2052

**Expression Pattern of Serotonin Signaling Components during Chick Gastrulation**

T. Fukumoto, T. Mikawa; Cell & Developmental Biology, Cornell University Medical College, New York, NY

We have previously shown that both agonists and antagonists of serotoninergic signaling can randomize the expression of laterality genes during early embryogenesis. While the data suggested a novel role of serotoninergic signaling in left-right axis formation, it is unclearwhen and how the lateral patterning is influenced by this signaling. In the present study, we examined expression profiles of enzymes that regulate the level of serotonin (5-HT). These included tryptophan hydroxylases (TPH1 and TPH2), which synthesize 5-HT from tryptophan, and monoamine oxidase (MAO), which degrades 5-HT. Our RT-PCR analysis detected these three enzymes in both pre-gastrula and gastrula stage embryos. Our in situ hybridization analysis detected th preferential expression of these thee enzymes at the posterior region of the embryonic disc, including Koller's sickle, at stage XII/XIII. After H.H.stage 2, their expression was detected in the primitive streak. Consistent with these molecular data, our immunohistochemical analysis detected 5-HT in a posterior midline region of the embryonic disc at stage XIV and in the primitive streak at H.H.stage 3. These results are consistent with a model where serotoninergic signaling plays a regulatory role in laterality patterning. The data also suggest that left-right axis formation begins perhaps at much earlier developmental stage than previously thought. (Supported in part by the NIH)

2053

**Quantitative Assessment of Tubulogenesis in vitro Effects of Growth Factors**

P. Nelson, N. Ratkevicius, S. Sepulveda, C. Araya, J. Garrido; Cell & Molecular Biology, Catholic University of Chile, Santiago, Chile

A rat gastric epithelial cell line (ERG-2) established in our laboratory grows as stable monolayers in high-serum (10% FBS) media. In low-serum (2.5% FBS) media these cells undergo tubular morphogenesis to produce branched structures overlying the monolayer. While characterizing this process we observed that cell subpopulations seen as distinct foci undergo morphological changes that precede tubulogenesis. We have shown such changes accompany epithelial-mesenchymal transition on localized groups of cells that divide more actively than the polygonal cells in the underlying monolayer, and that such increased proliferation is independent of MEK1-2 activity. To understand the possible roles of growth factors in the regulation of this process we developed a method that allowed us to assess tubulogenesis quantitatively. We have employed this method to evaluate the effects of several growth factors and inhibitors of intracellular signaling cascades. Our results show that both EGF and HGF are powerful inductors of tubulogenesis, while incubation with TGFbeta inhibits both spontaneous tubulogenesis and the stimulatory effect of EGF and HGF on this process. On the other hand, inhibition of MEK1-2 results in increased tubulogenesis, while inhibition of PKA, PI3K and ROCK abrogate the stimulatory effects of EGF and HGF. These results indicate that multiple, diverse signaling pathways are involved in the regulation of this process.

2054

**Effect of Thrombin Peptide TP508 on Chondrocyte Differentiation in Mouse Embryonic Limb Bud Cells and Ex Vivo Cultures of Mouse embryo Metatarsals**

S. S. Dong,[1] R. Serra,[1] G. M. Fuller,[1] D. H. Carney[2]; [1]Dept of Cell Biology, Univ. Alabama, Birmingham, AL, [2]Dept Human Biological Chem and Genetic, Univ. Texas Medical Branch, Galveston, TX

The thrombin peptide, TP508 (Chrysalin®), is a synthetic peptide representing the domain of thrombin required for high-affinity binding to a specific class of cell surface thrombin receptors. This peptide has been shown to promote or accelerate repair and regeneration of soft and hard tissues including cartilage. TP508 is now in human clinical trials to evaluate its potential use in fracture repair. Little is known, however, about the mechanisms by which TP508 stimulates repair and regeneration of a specific tissue such as cartilage. We utilized embryonic limb cell micro-mass and metatarsal organ culture models to evaluate the ability of TP508 to stimulate specific phases of osteochondral differentiation. Addition of TP508 to micro-mass cultures of limb cells isolated from 11.5 day embryos resulted in a dose dependent increase in Alcian blue proteoglycan staining after 3 days in culture. An increase in the total number of chondrogenic nodules was not observed suggesting TP508 does not recruit cells to the chondrogenic lineage but directly regulates proteoglycan synthesis. TP508 also resulted in an increase in cell proliferation after 6 days in culture. A scrambled TP508 peptide had no effect on these cells. Metatarsal bones from 15.5 day embryos were then cultured in the presence of 100µg/ml of TP508 or Scrambled TP508. Cultures treated with TP508 demonstrated an expansion of the hypertrophic zone relative to cultures treated with scrambled peptide. Alterations in the total length of the bone were not detected. This observation suggests that TP508 may activate a set of signals that leads to hypertrophic differentiation in chondrocytes. These studies support the potential use of TP508 for applications involving both bone and cartilage repair. (Supported by NIH AR46982, AR45605, and OrthoLogic Corp).

2055

**Wnt5a Exhibits a Growth Inhibitory Effect on the Development of the Mammary Gland**

K. Roarty, R. Serra; Cell Biology, University of Alabama at Birmingham, Birmingham, AL

Postnatal mammary gland development involves a complex interplay between epithelial and stromal components to regulate development and function of the gland. Wnt proteins represent a family of signaling molecules that participate in diverse developmental processes in embryonic and adult tissues. Wnt5a is expressed during multiple phases of mammary gland development; however, its role remains to be elucidated. In vitro studies have suggested Wnt5a mediates adhesion and migration of mammary epithelial cells. To investigate the role of Wnt5a in the development of the mouse mammary gland in vivo, Wnt5a slow-release plastic pellets containing 170ng Wnt5a were implanted into the glands of 3-5 week old virgin Balb/C mice. Control pellets containing BSA were implanted into the contralateral glands. Ten days after implantation mice were injected with 60µg/g body weight BrdU 2 hours before sacrifice, at which point glands were collected for wholemount and histological analysis. Evaluation of Wnt5a-implanted wholemounts revealed an inhibition of the ductal tree through the fat pad vs. those glands receiving BSA implants. In addition, the terminal end buds of the glands receiving the Wnt5a implants were noticeably smaller in size compared to control glands. BrdU analysis revealed that this inhibition and size difference was due to a decrease in proliferation in the terminal end buds in those glands receiving the Wnt5a implants. TUNEL analysis showed no difference in the number of apoptotic cells between Wnt5a and control glands. These results demonstrate that Wnt5a inhibits the progression of the terminal end buds through the fat pad during puberty accompanied by a decrease in size of the end bud, and that this effect is due to a decrease in proliferation and not an increase in apoptosis.

2056

**Lipopolysaccharide Inhibits FGF-10 Expression in Fetal Mouse Lung Mesenchyme**

J. T. Benjamin, R. Smith, N. Davis, L. S. Prince; Pediatrics, University of Alabama at Birmingham, Birmingham, AL

Prenatal exposure to inflammation increases the risk of bronchopulmonary dysplasia in preterm infants. The lungs of infants with bronchopulmonary dysplasia have fewer, more simplified alveoli, possibly due to defective distal airway branching. We have previously shown that *E. coli* lipopolysaccharide (LPS) decreases distal airway branching in fetal mouse lungs. FGF-10 is a master regulator of branching morphogenesis and is expressed in the distal lung mesenchyme. We hypothesized that LPS decreases FGF10 expression leading to altered distal airway branching in the fetal mouse lung. We first demonstrated that FGF-10 could regulate distal airway branching. In our fetal mouse lung explant model, recombinant FGF-10 increased the number of distal airway branches from 40.2 branches/mm$^2$ to 49.6 branches/mm$^2$ ($p<0.05$). Addition of a polyclonal anti-FGF10 antibody inhibited distal airway branching (30.2 branches/mm$^2$, $p<0.01$); anti-FGF-10-treated explants resembled those exposed to LPS. Using real-time PCR, we measured decreased FGF-10 gene expression in LPS-treated fetal lung explants (55 % of control, $p<0.05$). LPS also decreased the expression of the FGF-10-induced genes BMP4, BMPR1a, and PERP. LPS did not alter FGF-10 expression in explants from TLR4 mutant mice. These data suggested that LPS altered gene expression along the FGF-10 signaling pathway. To further test our hypothesis, we restored distal airway branching in LPS-treated explants by adding exogenous FGF-10. TGFβ1 is a known suppressor of FGF-10 expression. However, LPS did not increase TGFβ1 gene expression or increase the amount of soluble TGFβ1 released from cultured fetal lung explants. Therefore, LPS appeared to decrease FGF-10 expression independent of TGFβ1. The decrease in FGF-10 expression resulted in defective distal airway branching and suggests a mechanism by which innate immune signaling can alter lung development.

2057

**Roles of Notch Signaling in Chondrogenesis of Mouse Mesencephalic Neural Crest Cells**

M. Ota, K. Nakanishi, Y. Chan, K. Ito; Department of Biology, Osaka University, Toyonaka, Japan

Neural crest cells respond to various signaling molecules and differentiate into a wide variety of cell types, including melanocytes, peripheral neurons and their glial cells, and smooth muscle cells. In addition, cranial neural crest cells give rise to chondrocytes, osteobalsts, and components of the craniofacial skeleton. It has been shown that FGF2 promotes chondrogenesis of cranial neural crest cells. Furthermore, this signaling molecule activates Notch signaling in development of the nervous system. In the present study, therefore, we have examined the roles of Notch signaling in chondrogenesis of mouse mesencephalic neural crest cells. The activation of Notch signaling by the addition of a Notch ligand, Delta, promoted chondrogenesis in the neural crest cell cultures. Notch activation or FGF2 exposure during the first 24 hours in culture was indispensable for an increase of the number of cells expressing type 2 collagen that is a specific marker of chondrocytes. The expression of SOX9, which is a

member of SRY-like HMG box-containing gene family and a transcription activator of type 2 collagen, was upregulated by FGF2 treatment, while BMP4 had no effects on the expression of type 2 collagen or SOX9. Furthermore, the treatment with Delta induced the expression of Sox9. The present data show that chondrogenesis of the neural crest cells is promoted by the activation of Notch signaling as well as FGF2 treatment. Thus, Notch signaling may play important roles in differentiation of mouse mesencephalic neural crest cells into chondrocytes.

### Nonhuman Primate (NHP) Embryonic Stem Cell Lineage Contributions in Mouse:NHP Interspecific Chimeric Blastocysts

C. Simerly, J. Park, E. Park, D. McFarland, H. Qidwai, E. Jacoby, C. Navara, G. Schatten; Pittsburgh Development Center, Pittsburgh, PA

Embryonic stem (ES) cell pluripotency, convincingly demonstrated in reaggregated embryos in which the resultant offspring have ES cell contributions to all germ layers and tissues, including the germ line, has only been achieved using mouse embryonic stem (mES) cells. Overwhelming ethical concerns preclude attempts with human embryonic stem (hES) cells. Projects utilizing NHP's might address crucial questions surrounding the clinical utility of hES cells. Here, we investigate both intra-specific (NHP-ESC: NHP embryo) and inter-specific (NHP-ESC: Mouse embryo) reaggregated embryos to explore nhpES cell lineage contributions to the resultant chimeric blastocysts. For intra-specific chimera, NHP-ES cells, aggregated either with zona-free, CellTracker™ Orange-labeled fertilized rhesus embryos or injected (<10 ES cells) into the perivitelline space of 6-8 cell stage embryos, were cultured to the blastocyst stage or transferred to timed recipients for offspring production. For inter-specific chimera, NHP-ES cells were aggregated with zona-free fertilized (2N) or tetraploid (4N) mouse 2-cell stage embryos and grown to the blastocyst stage. Mouse embryo +YFP-labeled mouse ESC chimera served as controls. All blastocysts were analyzed dynamically and after fixation using pluripotency markers. Preliminary results show NHP-ESCs integrate into NHP embryos to form chimeric morulae, although a pregnancy has yet to be established. Conversely, NHP-ESCs aggregated with mouse 2N or 4N embryos do not integrate into the inner cell mass (ICM) in resultant blastocysts, suggesting inter-specific primate-rodent aggregations do not form chimeric embryos. We conclude that intra-specific, but not inter-specific, chimera aggregations will be useful for ethically addressing questions of primate chimeric pluripotency.

2059

### Differentiation-Related Changes in Mitochondrial Properties Might be an Indicator of Stem Cell Competence

T. A. Lonergan, C. A. Brenner, S. Rajasekaran, B. D. Bavister; Biological Sciences, University of New Orleans, New Orleans, LA

Several methods can be used to assess stem cell competence, including the expression of cell surface markers and telomerase activity. We hypothesize that mitochondrial characteristics might be a faster way to verify stem cell competence. Several properties of a multipotent monkey mesenchymal cell line, which has previously been shown to differentiate into adipocytes, chondrocytes and osteocytes, change with increasing passage number. Cells from the earliest passage (P11) vs. those from later passages (15 - 17) are characterized by : a) a much higher percentage of cells (85% vs. 18%) with a perinuclear arrangement of mitochondria when labeled with Mitotracker; b) a much lower percentage of cells (1% vs. 57%) with a fused mitochondrial arrangement, in which mitochondria appear to coalesce into larger aggregates; c) a much lower percentage of cells with lipid droplets (1% vs. 36%) indicating differentiation into adipocytes; and d) an eleven-fold increase in ATP content per cell (0.45 vs. 4.49 pmoles ATP/cell, P=0.012). The percentage of cells with lipid droplets correlates positively to the percentage of cells with a fused mitochondrial arrangement ($r^2$ = 0.999, P = 0.019), suggesting that this mitochondrial distribution may be a marker for differentiation into adipocytes. Collectively, these data suggest that the presence of a perinuclear arrangement of mitochondria, accompanied by a low ATP/cell content might be a valid indicator of stem cell competence, while departure from this profile indicates cells are differentiating. Similar mitochondrial properties will be examined in the future using other primate adult and embryonic cell lines.

### Human Embryonic Stem Cells Show Highest BrdU Uptake and Apoptosis on Low Density Feeder Cells in Culture

J. A. Ozolek,[1] E. Jane,[2] P. J. Sammak,[3] G. P. Schatten[3]; [1]Pathology, Children's Hospital of Pittsburgh, Pittsburgh, PA, [2]Neurosurgery, Children's Hospital of Pittsburgh, Pittsburgh, PA, [3]Pittsburgh Development Center, Pittsburgh, PA

During human development and particularly the developing nervous system, cell proliferation and programmed cell death occur in concert as tissue and organogenesis proceed. The objective was to determine cell culture conditions that promote or discourage proliferation and apoptosis of human embryonic stem cells (hESCs). HSF-6 hESCs were grown in Knockout DMEM on CF-1 mouse feeders or U87 glioblastoma cells at densities of 50,000 (low), 100,000 (intermediate), and 150,000 (high) cells per well for 7, 12, and 19 days. Cells were incubated with BrdU one hour prior to fixation. BrdU and TUNEL staining was performed according to manufacturer protocol (Roche Diagnostics Incorporation, Indianapolis, IN) and examined by confocal microscopy. Positive BrdU and TUNEL cells were found primarily at edges and between established colonies. Many positive BrdU cells demonstrated bright intensity signal at edges of nuclei. At day 7, both feeders produced high numbers of BrdU positive and TUNEL positive cells compared to day 12 and day 19. Numerous BrdU positive cells were seen on low density U87 feeder conditions at days 7, 12, and 19 compared to intermediate or high density. Day 7 U87 feeder conditions produced higher numbers of BrdU positive cells at all densities compared to either day 12 or 19. We conclude hESCs grown on U87 feeder conditions demonstrate greater numbers of apoptotic cells than cells grown on CF-1 feeders. HESCs on U87 feeders show greater numbers of BrdU positive cells consistently over time. Independent of the feeder system, proliferation and apoptosis may be positively correlated. We speculate that the lower density feeder systems may induce cell cycle and programmed death sequences due to low amounts of specific factor (s). U87 cells may supply additional factors that promote cell turnover.

### Focused Laser Beams as Versatile Tools for Stem Cell Purification and Clonal Expansion

A. Buchstaller, A. Buchstaller, S. Soria-Lopez, S. Sagebiel, R. Huss; Pathology, University of Munich, Munich, Germany

Stem cells have the potential to differentiate into specialized cells from various lineages. Differentiation is often associated with changes in morphology and cell surface marker expression. To understand the intrinsic molecular events associated with differentiation, it is important to gain pure populations of cells and to analyze their behavior and characteristics. The selection and isolation of cells with specific features also stand at

the center of stem cell therapy and tissue engineering. Heterogeneity of cell preparations poses a serious problem to the molecular analysis and therapeutic use of stem cells. We used "Laser Microdissection and Pressure Catapulting" (LMPC, P.A.L.M. Microlaser Technologies) for the isolation of life stem cells according to cell morphology and marker expression. We first isolated single cells from 1) murine embryonic carcinoma cell lines, 2) murine adult stem cell lines and 3) preparations of human bone marrow mononuclear cells. The recultivated clonal cells expand rapidly, express the same stem cell-specific markers as the originating cells and maintain the same morphology. We then proceeded to sort out and clonally expand single adherent fibroblast-like CD29+/CD44+ mesenchymal stem cells from a complex mixture of bone marrow-derived cells. In a different set of experiments we separated undifferentiated embryonic carcinoma cells from their differentiated progeny after treatment with all-trans retinoic acid. Cells exhibiting a neuronal morphology including neurites and growth cones were isolated with LMPC, recultivated, and analyzed for the expression of the growth-associated molecule GAP-43 and activity of L-type calcium channels. Applied in a high throughput fashion, coupled to single cell manipulation and high content single cell analysis, LMPC will prove itself as an important tool in basic research, drug development, and regenerative medicine.

**Chromatin-related Proteins in Pluripotent Mouse Embryonic Stem Cells Are Downregulated after Removal of Leukemia Inhibitory Factor**

A. Kurisaki,[1] T. S. Hamazaki,[2] M. Asashima,[3] H. Sugino[1]; [1]Division of Molecular Cytology, The Institute for Enzyme Research, The University of Tokushima, Tokushima, Japan, [2]Department of Tissue Regeneration, Research Institute International Medical Center of Japan, Tokyo, Japan, [3]Department of Life Sciences, The University of Tokyo, Tokyo, Japan

Embryonic stem (ES) cells have generated enormous interest due to their capacity to self-renew and the potential for growing many different cell types in vitro. Leukemia inhibitory factor (LIF), bone morphogenetic proteins, octamer binding protein 3 or 4, and nanog are important factors in the maintenance of pluripotency in mouse ES cells. However, the mechanisms by which these factors regulate the pluripotency remain poorly understood. To identify other proteins involved in this process, we did a proteomic analysis of mouse ES cells that were cultured in the presence or absence of LIF. More than 100 proteins were found to be involved specifically in either the differentiation process or the maintenance of undifferentiated state. Among these, chromatin-related proteins were identified as the major proteins in nuclear extracts of undifferentiated cells. In contrast, endothelial and mesenchymal markers, as well as some actin-related proteins were induced during the differentiation following LIF withdrawal. These results suggest that specific chromatin-related proteins may be involved in maintaining the unique properties of pluripotent ES cells. And moreover, we could demonstrate that the proteomic approach is a powerful method to elucidate the mechanism of pluripotency and differentiation process in the stem cell.

2063

**Response of Human Embryonic Stem Cells [hESCs] to Ionizing Radiation-induced DNA Damage Includes Rapid Cell Death or Immediate Differentiation**

O. Momcilovic,[1,2] J. Mich-Basso,[3,2] C. J. Redinger,[3,2] A. Ben-Yehudah,[3,2] G. Schatten,[3,2] C. S. Navara[3,2]; [1]Human Genetics, University of Pittsburgh, Pittsburgh, PA, [2]Pittsburgh Development Center, Pittsburgh, PA, [3]Ob/Gyn and Reproductive Sciences, University of Pittsburgh, Pittsburgh, PA

Human embryonic stem (hES) cells exhibit heterogeneous and exaggerated responses to ionizing radiation induced DNA damage. In our study we employed gamma irradiation of hES cells and somatic cells, followed by live cell imaging, time course recoveries and immunocytochemistry by confocal microscopy. After gamma irradiation WI-38 human embryonic lung fibroblast cells halted progression through the cell cycle and continued with normal mitotic divisions one-day post-irradiation. Conversely, pluripotent hES cells responseded in a varied fashion with cells in the center of large colonies dying beginning within 2 h, so that the center of colonies appeared hollow by 6 h after irradiation. Cells on the periphery of the colony did not undergo cell death but adopted a differentiated phenotype. In contrast, small colonies retained their integrity at all times and seemed only to differentiate. Human embryonic cells returning to mitosis after one day displayed mostly abnormal mitotic spindle morphologies. Expression of the pluripotency marker Oct-4 began disappearing almost immediately after irradiation and did not return until about 1 week later as detected by confocal microscopy. At approximately the same time normal colonies reappear, suggesting that some cells escape either cell death or differentiation fates and can return to an undifferentiated phenotype. Nuclear localization of phopho-p53 increased dramatically after irradiation. This effect was much more pronounced than in WI-38 cells and contrasts reports of poor nuclear localization of p53 in mouse embryonic stem cells. These results suggest that even colonies expressing uniform markers of pluripotency are heterogeneous and that hESCs human embryonic stem cells have alternative responses to DNA damage as compared to than do somatic cells.

2064

**Isolation and Characterization of STAT3 Target Genes in Mouse Embryonic Stem (ES) Cells**

Y. Na,[1] Y. Song,[2] S. Hong[1,2]; [1]Institute of Molecular Biology and Genetics, Seoul National University, Seoul, Republic of Korea, [2]School of Biological Sciences, Seoul National University, Seoul, Republic of Korea

Mouse ES cells can be maintained as a pluripotent, self-renewing population in the presence of leukemia inhibitory factor (LIF). It has been reported that STAT3 activation is sufficient to maintain an undifferentiated state of mouse ES cells. However, the downstream effectors of LIF/STAT3 pathway are poorly understood. To isolate and characterize the genes that are regulated by STAT3 in undifferentiated ES cells, we performed chromatin immunoprecipitation (X-ChIP). We were able to isolate several candidates whose expressions are regulated by STAT3. The expression of FoxJ1, a member of forkhead box family of transcription factor, was increased after the removal of LIF or the treatment of Jak2 inhibitor, AG490. Using EMSA analysis, it was found that STAT3 could bind to the promoter region of FoxJ1. These suggest that FoxJ1 is regulated by LIF/STAT3 signaling pathway. Another candidate gene, ZFP-57, a putative zinc finger protein, was decreased after the induction of differentiation. Using EMSA analysis, we found that STAT3 could bind to the promoter region of ZFP-57 and regulate directly the expression of ZFP-57. Mouse ES cells transfected with ZFP-57 could maintain an undifferentiated state a little bit longer than the wild type counterpart in the absence of LIF, which suggests that ZFP-57 might be the key regulator of ES cell self-renewal.

2065

**STAT3 Regulates the Differentiation of Mouse ES Cells into Neural Precursor Cells**

K. M. Foshay, G. Gallicano; Cell Biology, Georgetown University, Washington, DC

While the JAK/STAT signaling cascade plays a major role in the onset of gliogenesis, its functions during early neuronal development and differentiation of neural precursor cells are unclear. STAT3 is both present and active as early as E10.5 in the developing mouse CNS. Because gliogenesis does not begin until several days later, E14, the presence of STAT3 at E10.5 suggests that JAK/STAT signaling is functioning earlier in neural development. However, data produced by a neural specific STAT3 knockout mouse contradict the idea that STAT3 functions early in neural development, as these mice do not exhibit any overt neural phenotypes. We suggest a possible solution to the ambiguity of STAT3 function in neural development by demonstrating that the true function of STAT3 lies in regulating the differentiation of embryonic stem cells into neural precursor cells. This fate choice occurs prior to E10.5 and prior to the deletion of STAT3 in the neural specific knockout model. To test our hypothesis, we generated STAT3 dominant negative stem cells and subjected them to neural differentiation induced by retinoic acid. When compared to controls, STAT3 dominant negative ES cells differentiated into significantly fewer neural precursor cells, as determined by expression of nestin. Due to the decrease in neural precursor cells, STAT3 dominant negative cultures also expressed drastically lower levels of neural specific markers, such as Emx2, Synaptophysin, and the astrocyte marker, s100b.

**Feasibility of RNAi Mediated Inhibition of BMP Signaling During Maintenance and Neural Differentiation of Mouse Embryonic Stem Cells**

L. Bjorklund, T. Andersson; Karolinska Institute, Center for Genomics and Bioinformatics, Stockholm, Sweden

BMP signaling has been shown to regulate stem cell maintenance and proliferation as well as differentiation of mouse embryonic stem cells (mESC). Furthermore, BMP-antagonism is essential for neuronal differentiation within the adult neural stem cell niche. However, the ESC response to BMPs may vary at different time-points during differentiation. Thus, it is of importance to be able to study the effects of BMP inhibition at various stages of neural differentiation from mESCs. Using lipid based transfection of undifferentiated ES cells, we were able to achieve over 90% decrease in the expression level of the Bmp4 gene at 24 hrs post-transfection. To achieve transfection of adherent cells undergoing neural differentiation as monolayers, we used a capillary based electroporation system to deliver the siRNA molecules. Preliminary results suggest that it is possible to deliver siRNA also to adherent mESCs undergoing neural differentiation as monolayers. We conclude that it is possible to introduce siRNA against molecules such as BMPs into mESCs both as undifferentiated cells undergoing passage as well as during differentiation into neurons.

2067

**Wnt Drives In Vitro Development of Dorsal Mesoderm from Embryonic Stem Cells in the Absence of BMP**

M. Tanaka,[1] Y. Wang,[1] C. Wood,[1] N. Brouard,[1] D. Haylock,[2] P. Simmons,[1] N. Nakayama[2]; [1]Peter MacCallum Cancer Institute, Melbourne, Australia, [2]Australian Stem Cell Centre, Peter MacCallum Cancer Institute, Melbourne, Australia

Various mesodermal cell-types, defined by the expression of VEGFR2 (Flk-1), PDGFRα and/or N-cadherin (Ncad), are induced in vitro from embryonic stem (ES) cells in a serum-free medium with or without BMP4. BMP4 affects regional specificity during early embryogenesis. Therefore, we investigated the effect of BMP4 on region-specific mesoderm formation during ES cell differentiation. $Ncad^+Flk\text{-}1^-PDGFR\alpha^+$ cells, phenotypically identical to those previously isolated from BMP4-containing culture and determined to be osteochondrogenic and non-hemogenic, were produced without BMP4 or even in the presence of BMP-inhibitor, noggin. They were also osteochondrogenic and non-hemogenic. T and Tbx6 genes were transcribed in both $Ncad^+Flk\text{-}1^-PDGFR\alpha^+$ cells, suggesting BMP4-independent mesoderm formation. On the contrary, BMP4 was essential for the hemogenic $Ncad^+Flk\text{-}1^+PDGFR\alpha^-$ cell-genesis. Regardless of the exogenous BMP4, production of $Flk\text{-}1^+$ and $PDGFR\alpha^+$ mesodermal cells was completely abolished by Wnt-inhibitor, Dkk1 or Fzd8CRD-Fc, and was upregulated by purified Wnt3a protein. Global gene-expression profiling suggested that the $Ncad^+Flk\text{-}1^-PDGFR\alpha^+$ cells developed without BMP4 contained somitic mesodermal cells (expressing Meox1/2, Pax1/3, Praxis), but those generated with BMP4 did not. Transcripts of marker genes for the anterior-distal region of the embryo appeared during the first 5 days of differentiation without BMP4, while many of them did not with BMP4. In fact, without BMP4, neural tube marker genes (Pax6, Sox1), and anterior visceral endoderm marker genes (Cer1, sFRP1) were detected. However, posterio-proximal site marker genes (Wnt3, T, MesP1) were expressed preferentially in the presence of BMP4. Thus, 1) Wnt signaling appears to be essential for $Flk\text{-}1^+$ and $PDGFR\alpha^+$ mesoderm formation from ES cells, 2) exogenous BMP4 seems to impose proximal region-specific characteristics on the developed progenitor cells, and suppresses anterior-distal characteristics, and 3) thus, paraxial (dorsal) mesoderm-like cells are selectively generated in the absence of BMP4.

2068

**Molecular Commitment to Osteogenic Lineage of Human Umbilical Cord Blood Derived Mesenchymal Stem Cells**

P. A. Jaramillo,[1] J. P. Morales,[1] J. J. Minguell,[2] A. A. Erices[1,2]; [1]Departamento de Ciencias Biológicas, Universidad Andrés Bello, Santiago, Chile, [2]Clínica Las Condes, Santiago, Chile

Mesenchymal stem cells (MSC) represent a subpopulation of cells present in the bone marrow stroma (BM-MSC) and umbilical cord blood (UCB-MSC). They are characterized for their capacity to differentiate along the osteogenic, adipogenic, chondrogenic and myogenic differentiation pathways, among others. The aim of this work was to characterize the expression of osteogenic markers in MSC obtained from BM and UCB, and to evaluate comparatively their ability to respond to an osteogenic differentiation stimuli. It was found that cultures of both cellular populations express early differentiation markers towards the osteogenic (Runx-2/Cbfa-1, Msx-2), adipogenic (PPAR-γ), condrogenic (Sox-9), miogenic (MyoD, Myf-5), pancreatic (Pdx-1, Ngn-3, Isl-1) and neural (NeuroD, Nestin) differentiation pathways. When osteogenic differentiation was induced, both cell types did not show significant variations in the expression levels of Runx-2/Cbfa-1 and Msx-2. However, after this induction, Msx-2 expression showed a translocation to cytoplasmatic domains, which was increased with the progression along the osteogenic differentiation. This pattern was more accentuated in UCB-MSC than in BM-MSC. When analyzing the expression and/or activation of intermediate/late osteogenic markers, it was found that UCB-MSC showed a smaller proportion of alkaline phosphatase positive cells and absence of expression of

osteopontin in comparison to BM-MSC. In response to the osteogenic stimuli, UCB-MSC increased alkaline phosphatase activity to a greater degree in comparison to BM-MSC. On the other hand, both cellular populations express osteopontin in response to the osteogenic differentiation stimuli. These results suggest that both UCB-MSC and BM-MSC represent multipotential cellular populations and that UCB-MSC have a greater proportion of immature osteoprogrenitor cells, with a different potential to the osteogenic differentiation pathway.

2069

**Isolation, Growth and Differentiation Characteristics of a Novel Human Mesenchymal Stem Cell Source from Umblical Cord Stroma**

S. Karahuseyinoglu,[1] O. Cinar,[1] F. Kara,[2] A. Can[1]; [1]Histology-embryology, Ankara University School of Medicine, Ankara, Turkey, [2]Zubeyde Hanim Maternity Hospital, Ankara, Turkey

Mesenchymal stem cells are of great interest in the past decades although they are far from being well-characterized cells unlike the hematopoietic ones. Few studies revealed a potential source of mesenchymal stem cells in the connective tissue stroma of the umbilical cord (UC). The purpose of this study is to isolate stem cells from human UC stroma and to assess the cellular characterization of these cells throughout their differentiation into different lineages. UCs were obtained from Cesarian sections (n=6) performed following uncomplicated, term pregnancies. Stromal tissues excluding blood vessels was digested and then resuspended pellet was plated into culture dishes as 20 cells/cm$^2$. Upon reaching to 80-90 % confluency (4000 cells/cm$^2$), cells were subcultured and used for cell dynamics (viability, doubling time, mitotic index), differentiation experiments and microscopic observations at certain time points. Synchronously, cells in culture were used for certain protein quantification. Morphological appearance of cells differed in concordance with the number of subcultures. While during the first 10-20 division cycles cells were strongly positive for vimentin (marker for mesodermal origin) and pancytokeratin (marker for epidermal origin), pancytokeratin positivity gradually declined and totally diminished when cells began to form multicellular bodies usually after 60-70 division cycles. Contact inhibition, anchorage dependency and arrest in mitosis after serum deprivation strongly ruled out the possibility of a tumorigenic phenotype. Cells at early division cycles subjected to neuronal differentiation gained typical neuronal appearance. Additionally, they successfully differentiated into mesenchymal lineages such as osteogenic, chondrogenic and adipogenic cells in conditioned cultures. Taken together, overall data led us to suggest that human UC stromal cells bear multi-germ layer characteristics, therefore have a great range of differentiation capacity and may be considered as a new source for stem cells.

2070

**Neuroendocrine Potential of Human Umbilical Cord Blood Derived Mesenchymal Stem Cells**

J. P. Morales,[1] N. McConnell,[1] P. Jaramillo,[1] A. Fierro,[2] J. J. Minguell,[2] A. A. Erices[1,2]; [1]Departamento de Ciencias Biológicas, Universidad Andrés Bello, Santiago, Chile, [2]Clínica Las Condes, Santiago, Chile

Adult pancreas neogenesis and embryonic stem cell differentiation to insulin producing cells (IPC) require cells expressing neuroendocrine genes like *nestin*, *neuroD*, and *neurogenin-3*. Both postnatal bone marrow and umbilical cord blood contain mesenchymal stem cells (MSC) expressing nestin, suggesting a neuroendocrine potential, but this capacity is unknown. With the purpose of generating new cellular therapies for diabetes, it has been our principal interest to study the differentiation potential of mesenchymal stem cells (MSC) derived from human umbilical cord blood or bone marrow as possible progenitors of pancreatic endocrine tissues or IPC. We focused on characterizing the presence of molecular markers of endocrine pancreas lineage in MSC such as Nestin, Pdx-1, Neurogenin-3, Islet-1, Pax-4, and Insulin that suggests these cells as good candidates to generate IPC. In addition, we study the characterization of cells of pancreatic acinar tissue since it has been documented that cells derived from this fraction could also participate in the generation of IPC. MSC were characterized on expression of mesenchymal markers as SH2, SH3, SH4, and smooth muscle actin-α and their capacity to differentiate to osteogenic, chondrogenic and adipogenic lineages. Through analysis by RT PCR, immunoflorescence, and western blot, the results of this first stage are promising and showed that both MSC and acinar cells express pancreatic markers with a slight variation in the expression levels. Coculture of MSC on acinar cells increased expression level of markers as Pdx-1 in MSC, a essential gene for pancreas development and regeneration. Based on this, we propose that under the appropriate stimuli our MSC could differentiate in cells that generate insulin. We can conclude that MSC unbilical cord blood and bone marrow represent, at a molecular level, a potential precursor of IPCs under the correct stimuli.

2071

**Inhibition of Osteogenic Differentiation in Human Mesenchymal Stem Cells by Exogenous c-myc-tagged Focal Adhesion Kinase**

W. A. Williams, N. E. Schapiro, S. R. Christy, R. F. Klees, G. L. Weber, G. E. Plopper; Biology, Rensselaer Polytechnic Institute, Troy, NY

Osteogenic differentiation of human mesenchymal stem cells (hMSC) occurs in vitro upon binding to collagen I in the absence of soluble osteogenic stimuli. We hypothesize that activation of integrin-associated protein focal adhesion kinase (FAK) via phosphorylation of its tyrosine-397 is one of the primary intracellular signals that leads to osteogenic differentiation of hMSC. To test our hypothesis, we infected hMSC with a retrovirus containing a c-myc epitope-tagged FAK wild type gene (c-myc-FAK) or a c-myc epitope-tagged FAK Y397F mutant gene (c-myc-FAK F397), and identified and isolated infected hMSC by their resistance to the antibiotic G418. A statistically significant increase in the phosphate mineral-to-matrix ratio was observed in hMSC infected with a virus containing the gene coding for c-myc-FAK when plating on collagen I as compared to cells infected with a virus containing the gene coding for c-myc-FAK F397 or a virus containing no c-myc-FAK gene. Variable results were obtained when immunoblotting for the c-myc epitope tag. However, expression of c-myc-FAK and c-myc-FAK F397 in infected hMSC was investigated using immunofluorescence and RT-PCR. Moreover, expression of phenotypic markers of osteogenesis in these cells was investigated using immunoblotting, immunofluorescence, and RT-PCR. These data could demonstrate a key role for ECM-induced FAK signaling in osteogenic differentiation of hMSC.

2072

**Differentiation of Human Embryonic Stem Cells into Neuroblasts Expressing the Migration Marker, Doublecortin**

J. A. Ozolek,[1] E. Jane,[2] P. J. Sammak,[3] G. P. Schatten[3]; [1]Pathology, Children's Hospital of Pittsburgh, Pittsburgh, PA, [2]Neurosurgery, Children's Hospital of Pittsburgh, Pittsburgh, PA, [3]Pittsburgh Development Center, Pittsburgh, PA

In the context of brain regeneration and repair, in particular damage to the fetal brain or premature infant brain, it will be useful to know how

culture conditions can produce specific phenotypes of cells. In the developing nervous system, the expression of doublecortin (DCX) signifies the presence of migrating neurons. Doublecortin is a microtubule binding protein required for normal neural migration and cortical layering during development. The objective of this study was to determine if differentiation into neuronal and glial phenotypes is promoted by 1) varying feeder density, 2) using different feeder layers and 3) to determine phenotypic changes over time in culture. HSF-6 hESCs were grown in cell culture on CF-1 mouse feeder layers or U87 glioblastoma cells at densities of 50,000, 100,000, and 150,000 cells per well. Cells were grown in Knockout DMEM media, fixed and double-labeled with antibodies to nestin (intermediate filament expressed in neuroepithelium) and doublecortin and examined by confocal microscopy. Comparison of DCX expression was done between HSF-6 on CF-1 and U87 at day 19 only. At day 19, hESCs grown on CF-1 feeders at 100,000 cells/well demonstrated numerous cells primarily at the edge of colonies with strong DCX and nestin coexpression compared to U87 at 100,000 cells/well that showed weaker expression, fewer colonies, and some loss of nestin coexpression. Comparing expression of hESCs grown on U87 only, cells at 100,000 cells/well and fixed on day 12 demonstrated the most cells at the edge of colonies expressing both nestin and DCX compared to day 7 or 19. We conclude that intermediate density feeder cell conditions promote the differentiation of hESCs in culture into cells with neuroblast/neuroepithelial qualities. CF-1 feeders may promote this differentiation more efficiently than U87 glioblastoma cells.

2073

**Differentiation of Human Adult-Derived Stem Cells into Neuronal Cells**

D. Coffey, J. M. Thompson; Biology, California State University, San Bernardino, CA

Stem Cells are characterized by their ability to reproduce themselves for extended periods, and by their unique ability to give rise to cells of distinct and varying lineages. This ability to transform into disparate cells and subsequent tissue holds great promise for clinical application of stem cells in both replacement and restorative therapies. In 1998, Human Embryonic Stem Cells (ESC) were isolated and shown to be pluripotent, as they were capable of differentiation into all tissues types. More recently, stem cells have been isolated from adult tissues. Adipose, blood, muscle and bone tissue have all been found to contain a subset of undifferentiated cells which can be directed by endogenous growth factors to restore function or regenerate tissue. In our study, we have employed adult-derived stem cells obtained from Human bone marrow stromal cells. These Mesenchymal Stem Cells (MSC) have been maintained in vitro as undifferentiated cells for multiple passages, demonstrating the proliferative abilities ascribed to stem cells. Further, we have used specific induction protocols to produce differentiation, or possibly an initial de-differentiation into a precursor cell and subsequent differentiation, of these MSCs into cells displaying a distinctly neuronal phenotype. These cells exhibit morphologies that are, at once, drastically different from their stromal cells progenitors and strikingly reminiscent of neuronal phenotypes complete with long neuritic processes. Immunocytochemical analysis revealed expression of the neural stem cell marker Nestin and the presence microtubule associated protein (MAP) in the post-induction population and a lack of these results in the pre-induction population. These results indicate that there exists an endogenous population of adult stem cells in many different mesenchymal tissue types that can be induced to differentiate into cells similar to those tissues or into cells of endodermal or even ectodermal origin.

2074

**Electron Microscopic Observation of Rat Perirenal Adipose Tissue and Adipogenesis in Vitro**

K. Han,[1,2,3] S. Kim,[1,2,3] C. Park,[4] C. Uhm[1,2,3]; [1]Department of Anatomy, Korea University College of Medicine, Seoul, Republic of Korea, [2]Brain Korea 21 Biomedical Sciences, Seoul, Republic of Korea, [3]Korea Lung Tissue Bank, Seoul, Republic of Korea, [4]Electron Microscope Facility, Korea University College of Medicine, Seoul, Republic of Korea

Adipose tissue contains many stem cells of mesenchymal origin that are able to self-renew and capable of differentiation along multiple lineages. To obtain the basic structural information of the adipose tissue and adipogenic stem cells, we observed perirenal adipose tissue and cultured adipocytes of rats by electron microscopy. After anesthetization of male Sprague-Dawley rats, perirenal adipose tissues were dissected out, and stem cells were isolated and cultured with DMEM with 10% FBS and antibiotics at 37°C in 5% $CO_2$ incubator. Formation of fat droplets was observed after Oil-Red-O staining. For electron microscopy, cultures and adipose tissues were fixed in 2.5% glutaraldehyde buffered with 0.1M phosphate buffer (pH 7.4), postfixed with 1% osmium tetroxide and processed for scanning and transmission electron microscopy according to the routine protocols. Platinum-coated samples were observed with a FE-SEM (Hitachi S-4700), double-stained with uranyl acetate and lead citrate sections were observed with a TEM (Hitachi H-7500). In adipose tissue, adipocytes formed a group separated by intervening connective tissue septa. Each adipocyte was surrounded by a meshwork of fine reticular fibers, and adjacent cells were connected by a dense network of fibers. Capillaries were present in the connective septa. Measurements of diameter revealed two populations of adipocytes; small of 18.4 um in diameter and large of 73.8 um in diameter. The nature of this subpopulation is not known. Preadipocytes were mainly spindle-shaped at first and became round as small lipid droplets were accumulated. The small fat droplets gradually fused together to form one large fat droplet filling up to 80% of the cytosol in the mature adipocyte. Our results confirmed the general architecture of the adipose tissue and the differentiation of preadipocytes into adipocytes. Further study in the obesity and metabolic diseases is needed.

2075

**Adult Stem Cells from Adipose Induce Neural Differentiation of Human Embryonic Stem Cells**

L. E. Kokai,[1] K. G. Marra,[1] J. P. Rubin,[2] E. Jane,[3] J. A. Thaller,[3] G. P. Schatten,[3] P. J. Sammak[3]; [1]Bioengineering, University of Pittsburgh, Pittsburgh, PA, [2]Surgery, University of Pittsburgh Medical Center, Pittsburgh, PA, [3]Ob/Gyn/Reproductive Sciences, Pittsburgh Development Center of Magee-Women's Research Institute, Pittsburgh, PA

A current barrier for human embryonic stem cells (hESCs) in clinical use is the requirement of animal products for differentiation to defined fates with exposure to nonhuman pathogens and immunogens. This study used human adipose stem cells (hASCs) as feeder cells in lieu of animal cells, thus providing a xeno-free co-culture system. hASCs are adult meshenchymal stem cells, are easily obtained, have a known immunosuppressive ability and are similar to currently employed mouse preadipocytic stromal cells used for neuronal differentiation. hASCs were isolated from adipose tissue collected from patients undergoing elective surgical procedures and characterized by fluorescence activated cell sorting. hESCs, line HSF-6 and H7 were maintained following the provider's recommendations and then co-cultured for 19 days on either mitomycin-C treated hASCs or human fibroblasts. Immunocytochemical analysis showed hESCs cultured with hASCs were Oct4 negative and Pax6, A2B5, GFAP, nestin, and

beta-III tubulin positive in a density dependent manner. Astrocytes (GFAP) were dominant at low hASC density and neurons (nestin, beta-III tubulin) increased at higher hASC density. Results were similar for two hESC cell lines on hASC lines derived from three unique patients. hESCs cultured with fibroblasts as a control sporadically expressed mature neural markers, few astrocyte markers and retained undifferentiated cell populations. At 60 days, complex neural networks were produced on high-density hASCs. hASCs have several advantages: Teratoma forming cells were not detected past 19 days. hASC produced either high yield astrocytes or supported extensive neuronal outgrowth. Patient-specific hASCs transplanted with neural stem cells may reduce graft vs. host rejection, or modify the endogenous neural stem cell niche to promote neurite outgrowth. These findings recommend hASCs as in vitro feeder layers or in vivo niche support cells in the treatment of neurodegenerative diseases by cell therapy.

2076

**Differentiation of Human Adult Adipose-derived Stem Cells into Neurons *in vitro***

V. Nguyen,[1] J. M. Thompson,[1] J. Shores[2]; [1]Biology, California State University, San Bernardino, CA, [2]Plastic Surgery, Loma Linda University Medical Center, Loma Linda, CA

One of the hottest areas in research today is stem cell research. Stem cells are undifferentiated cells that can develop into any type of cell in the body. Researchers believe that stem cells can revolutionize medicine by enabling physicians to repair or replace damaged organs or tissues. Adipose tissue has been shown to contain multipotent stem cells called human adipose-derived stem cells (HuADSC). These cells are capable of differentiating into any of the three germ layers: ectoderm, endoderm and mesoderm. In our research, we isolated the HuADSC's that were obtained from human liposuction debris. HuADSC cultures were established and grown for 4 passages in RPMI medium with 10% fetal calf serum and 1% antibiotic/antimycotic. We treated our cells with 20 ng/ml basic fibroblast growth factor (bFGF), 0.5 µM retinoic acid (RA) or combinations of these in hoping to differentiate them into neurons that can be used as therapeutic treatments for diseases involving the central nervous system (CNS) or the peripheral nervous system (PNS). RA is commonly used in embryonic stem (ES) cell differentiation. ES-cell-derived 3D cell aggregates called embryoid bodies treated with RA have been shown to give rise to excitable and functional neurons. Other studies showed that induction of ES cells with FGF can differentiate into specific neurons such as dopaminergic neurons. Morphological changes were analyzed with a Nikon Eclipse TS100 microscope and captured with NIH Image. Our results show that bFGF is the best inducing factor. Morphological changes including neurite-like branching were observed in our treated cultures. Furthermore, anti-MAP (marker for mature neurons) and anti-Nestin (marker for neural stem cells) antibodies were used to confirm the differentiation of cells.

**Osteogenic Differentiation of Adipose Derived Mesenchymal Stem Cells from Adult Human Lipoplasty**

D. Williams,[1] J. M. Thompson,[1] J. Shores[2]; [1]Biology, California State University, San Bernardino, CA, [2]Plastic Surgery, Loma Linda University Medical Center, Loma Linda, CA

Stem cells are undifferentiated cells that during embryogenesis give rise to the three germ layers ectoderm, mesoderm, and endoderm. The ability to recover and manipulate these cells has become a major focus of research in the scientific community. Recent studies have demonstrated the presence of adult mesenchymal stem cells (MSC) in the supportive matrix of bone marrow and adipose tissues. The ability of adult stem cells to regain their plasticity by differentiating into multiple tissue types including osteogenic, chrondrogenic, myogenic and adipogenic tissue, promises to be powerful force for treatment of disease pathology. The procedures for inducing differentiation have not been fully established, nor have methods of inoculation *in vivo* for the purpose of tissue engineering and vascular regeneration. In this study we propose to establish a successful induction medium for osteogenic differentiation. Adipose derived stem cells (ASC) were isolated from human lipoplasty (liposuction). Lipoaspirate cells were harvested by washing with phosphate buffered saline followed by treatment with collagenase. Cells were then grown to confluence in a control medium of RPMI, 10% fetal calf serum and 1% antibiotic/antimycotic. Induction of cells was initiated by replacing control medium with an osteogenic medium consisting of RPMI, 10% FCS, 1% antibiotic/antimycotic, 0.1 µM dexamethasone, 50 µg/ml ascorbic acid, and 10mM β-glycerophosphate. Following differentiation, cells were analyzed for morphological changes. Images were viewed using bright field and phase contrast microscopy. Alzarin red stain was used confirm the presence of extracellular matrix calcification. Immunochemistry was performed to demonstrate the production of alkaline phosphate. The ultimate goal of this research is to develop not only a standard for the induction medium but also to develop a 3-dimensional scaffold combining multiple tissue types capable of successful inoculation *in vivo* in a clinical setting.

**Cord Blood Derived Embryonic Stem Cells**

C. P. McGuckin,[1] L. Denner,[2] M. Baradez,[3] S. Navran,[4] J. Zhao,[2] R. Urban,[2] R. Tilton,[2] N. Forraz[1]; [1]Regenerative Medicine, Clinical Laboratory Sciences, University of Newcastle, Newcastle upon Tyne, United Kingdom, [2]Internal Medicine-Endocrinology & Stark Diabetes Center, University of Texas Medical Branch, Galveston, TX, [3]Stem Cell Therapy Programme, Kingston University, Kingston upon Thames, London, United Kingdom, [4]Synthecon Corporation, Houston, TX

**OBJECTIVES**: The lobby for Embryonic Stem Cells (ES) is strong and highly visible. But when will these cells be a routine clinical intervention? ES limitations are clearly cellular immunogenicity and amount of producible homogeneous tissue - and without feeder layers! Adult stem cells (ADS) from Umbilical Cord Blood (UCB) however, propose a huge untapped source with the global yearly birth rate at 100 million, with added advantage of long telomere and ontogenically. We report here reproducible harvest and development of UCB cells with ES cell markers ["Cord Blood derived embyonic-like stem cells" (CBE's)] and developed them for defined Tissue Engineering. **METHODS**: A CBE harvest and expansion: UCB [elective caesarian birth] was separated by sequential immunomagnetic removal [nucleated granulocytes, red cells, haemopoietic myeloid / lymphoid progenitors]. After 7 days high density culture in microflasks, [$10^5$ cells/ml, IMDM, FCS10%, Thrombopoietin 10ng/ml, Flt3-Ligand 50ng/ml,c-kit ligand 20ng/ml], CBE colonies formed adherent to the substrata, maintaining for 6 weeks, subcultured and continued minimum >13 weeks. B CBE Liver Tissue Engineering: CBE's were cultured with hepatic growth medium [IMDM, FCS10%, HGF 20ng/ml, bFGF 10ng/ml, EGF 10ng/ml, c-kit ligand 10ng/ml] in a NASA-derived Synthecon microgravity rotating bioreactor. Rotational and volume considerations produced a low shear stress environment with optimal gas exchange. **RESULTS:** CBE's were positive for TRA-1-60, TRA-1-81, SSEA-4, SSEA-3 and Oct-4, but not SSEA-1, indicating restriction to the human stem cell compartment. Tissue Bioreactor engineered CBE's

developed positivity for hepatic markers (week 4) Cytokeratin-18, Alphafetoprotein, Albumin. Cohesive tissue constructs developed. **CONCLUSION:** CBE's are a viable alternative for stem cell research and defined tissue engineering and appropriate for clinical translation protocols.

### Ubiquitin Dependent Proteolysis of Rapsyn and its Physiological Significance

K. Min, S. Nam, J. Lee; Biological Sciences, Seoul National University, Seoul, Republic of Korea

Rapsyn (Receptor-Associated Protein at the SYNapse) plays an important role in acetylcholine receptor (AChR) clustering, which is required for normal neuromuscular transmission. Rapsyn is co-transported, and probably pre-assembled, with the receptors before the functional receptors are transported to the plasma membrane. Both overexpression and knock-down of rapsyn result in the failure of AChR clustering *in vivo*. In a search for the regulatory mechanism of rapsyn abundance in *C. elegans*, we found that RPY-1, the rapsyn homolog, is ubiquitinated and degraded by proteolysis. RNA*i* analyses revealed UBC genes for rapsyn degradation. In addition, genes involved in neddylation were required for rapsyn degradation, suggesting that a cullin-containing E3 ligase complex is involved in this process. We identified the adaptor protein between the cullin protein and its substrate rapsyn. Knockdown of any gene involved in RPY-1 degradation caused higher stability of rapsyn even under the normal condition, suggesting that the cullin complex system functions for quality control of the components in a protein complex in the physiological conditions. We then identified a human homolog of the BTB-containing adaptor for rapsyn. We found that this human homolog interacts with and ubiquitinates rapsyn together with the cullin E3 ligase. We mapped the domains within rapsyn and the BTB-containing protein required for their interaction. Our data raises the possibility that genes involved in rapsyn degradation may be causal genes for the congential myasthenic syndrome in humans.

### Interdomain Interactions in the Tumor Suppressor Discs Large Regulate Binding to the Synaptic Protein GukHolder

Y. Qian, K. E. Prehoda; Department of Chemistry, Institute of Molecular Biology, Eugene, OR

Membrane-associated guanylate kinase (MAGUK) is a large family of scaffolding proteins found in many signal pathways at the cell membrane in multi-molecular organisms. Here we show that binding of the synaptic protein GukHolder (GukH) to Discs Large (Dlg), a member of MAGUK proteins, is actively regulated through complex interdomain interactions. GukH binds to a composite binding site on the SH3 and Guanylate Kinase-like (GK) domains of Dlg, but this binding site is obscured by an intramolecular interaction between the SH3 and GK domains. A protein interaction domain, PDZ, adjacent to the SH3 domain relieves this inhibition. The protein CRIPT, which links Dlg to the microtubule cytoskeleton, binds the PDZ domain and causes a conformational change in the PDZ-SH3-GK cassette that obscures the GukH binding site. The PDZ-SH3-GK module is a common feature of MAGUK scaffolds. Our results indicate that the complex multi-domain architecture of scaffolds can be used to actively regulate the proteins that they associate with.

### CRF and Urocortin Differentially Modulate GluRdelta2 Expression and Distribution in Parallel Fiber-Purkinje Cell Synapses

N. Gounko,[1] V. Rybakin,[2] D. Kalicharan,[1] Z. Siskova,[3] A. Gramsbergen,[4] J. J. L. van der Want[1]; [1]Cell Biology, University of Groningen, Groningen, The Netherlands, [2]Institute of Biochemistry I, University of Cologne, Cologne, Germany, [3]Membrane Cell Biology, University of Groningen, Groningen, The Netherlands, [4]Medical Physiology, University of Groningen, Groningen, The Netherlands

Stabilization and maturation of synapses is crucial for neuronal circuit formation. Early in development, an overabundance of synapses is formed, followed by selective maintenance or elimination of specific synapses and ultimately resulting in the formation of correct and durable connections. The ionotropic glutamate receptor GluRdelta2 is highly expressed in cerebellar Purkinje cells and plays a role in the differential distribution of parallel fiber and climbing fiber synapses on Purkinje cell dendritic spines. However, the mechanisms responsible for the distribution of the GluRdelta2s in the postsynaptic membrane are not well understood. Here, we analyze the effect of corticotropin-releasing factor (CRF) and urocortin (UCN), two closely related peptide regulators, on the GluRdelta2 expression in Purkinje cells and its distribution in Purkinje cell spines' postsynaptic membranes in *in vitro* culture. Using real time PCR, we establish that both CRF and UCN do indeed modulate the expression of GluRdelta2 gene, but only urocortin treatment results in an increased GluRdelta2 protein level, suggesting a posttranscriptional mechanism of its regulation. We further observed different immunogold patterns of GluRdelta2 distribution in the PSD. UCN treatment provides a linear distribution, whereas CRF treatment results in a clustered distribution of GluRdelta2 along the PSD, probably through the regulation of the submembrane cytoskeleton. We propose a model explaining these functional differences based on differential receptor preference and signaling cascade activation by CRF and UCN. We hypothesize that CRF and UCN may induce local dendritic instability, allowing activity-dependent morphological changes in Purkinje dendritic spines resulting in global effects on synaptic transmission and plasticity.

### Control of Neuronal Morphogenesis and the Delta/Notch Signalling Pathway by Shrub, a Coiled-Coil Protein Involved in Multivesicular Body Formation

N. T. Sweeney,[1] J. E. Brenman,[2] Y. N. Jan,[2] F. Gao[3]; [1]Gladstone Institute of Neurological Disease and Neuroscience Graduate Program, UCSF, San Francisco, CA, [2]Department of Physiology and Howard Hughes Medical Institute, UCSF, San Francisco, CA, [3]Gladstone Institute of Neurological Disease, Neuroscience Graduate Program and Dept. of Neurology, UCSF, San Francisco, CA

Dendritic branching is a complex process controlled by many signaling pathways, including Notch. Here we report the identification of mutations in the *shrub* gene that led to increased dendritic branching and enhanced signaling by the Notch pathway. Using multiple dendritic (MD) sensory neurons in *Drosophila* larvae and the MARCM technique, we found that neurons with *shrub* mutations showed ectopic dendritic and axonal branching, indicating a cell-autonomous function in neuronal morphogensis. *Shrub* encodes a novel coiled-coil protein homologous to yeast protein Snf7. Snf7 is involved in the formation of a subset of late endosomal compartments known as the multivesicular bodies. *Shrub* mutations caused

abnormal distribution of late endosomal markers. In addition, the expression levels of Notch intracellular domain (NICD) and Notch ligand Delta, as well as Notch-dependent transcription, were elevated in *shrb* mutant embryos. Genetic studies reveal a novel cell-autonomous function for Delta in promoting dendritic branching. These data support a model in which regulation of dendritic morphogenesis by *shrb* involves endosomal modulation of the Delta/Notch signaling pathway.

2082

**Association of PrPc with Syntaxin 1A and Hsp40**

K. Beck, J. E. A. Braun; Physiology and Biophysics, University of Calgary, Calgary, AB, Canada

Cellular prion proteins ($PrP^c$) are glycoproteins expressed on the cell surface of many cell types, but are predominantly found in the CNS, localized to pre- and post-synaptic membranes. The cellular function of $PrP^c$ at these sites remains largely unresolved. Here we sought to establish whether direct *in-vitro* protein-protein interactions could occur between $PrP^c$ and SNARE proteins (syntaxin 1A, VAMP and SNAP25), which mediate synaptic vesicle fusion at the pre-synaptic plasma membrane, and also the molecular co-chaperones CSP and Hsp40. Our results revealed novel interactions between $PrP^c$ and both syntaxin 1A-GST and Hsp40-GST at 4 and 37 $^oC$. Interactions between $PrP^c$ and Hsp40-GST were specific and concentration-dependent. Conversely, interactions between $PrP^c$ and immobilized syntaxin 1A were biphasic and were blocked in the presence of VAMP and SNAP25. Our findings suggest a role for $PrP^c$ in modulating the synaptic vesicle exocytotic machinery as well as proteins that are crucial for recovery from stress-induced protein damage.

**Long-Lasting Filopodial-like Protein Complexes Induced by Repeated Cocaine Administration in the Rat Nucleus Accumbens**

S. Toda, H. Shen, S. Cagle, P. W. Kalivas; Neurosciences, Medical Univ. South Carolina, Charleston, SC

Addiction to cocaine is associated with persistent changes in synaptic function, especially in medium spiny neurons of nucleus accumbens (NAc). Given that actin-based ultrastructual change of spine underlies cocaine-induced neuronal plasticity, just as the case of long-term potentiation or long-term depression, we investigated the effect of acute or repeated cocaine on actin cycling and actin-regulating proteins in the rat NAc using subcellular fractionation. Acute and chronic cocaine administration produced reversible and enduring, respectively, elevations in F-actin in the NAc. Acute cocaine administation induced F-actin accumulation in association with the increase of p-cofilin. Inhibition of p-cofilin by a cell-permeable TAT-cofilin peptide did not decrease the level of F-actin, however, it promoted the recruitment of ARP3 and PSD-95 in postsynaptic density (PSD), suggesting a transition to a lamellipodia-like structure by inhibiting LIMK1-cofilin cascade. Repeated cocaine administration followed by a 3-weeks withdrawal maintained the upregulated level of F-actin in parallel with continuous increase of Mena, p-VASP and p-cortactin at tyrosine 412, although the level of LIMK1 and p-cofilin was downregulated. Microinjection of latrunculin A in the NAc rapidly and reversibly disrupted F-actin as well as many PSD proteins in the repeated cocaine animals, but not in control animals. Taken together, it is concluded that repeated cocaine administration induces an enduring filopodial spine morphology containing mature PSD protein complex in the NAc and that this actin-based ultrastructure is maintained by enhanced actin turnover.

**Long Term Culture of Adult Rat Spinal Cord Cells in a Novel Serum-Free Medium and on a Synthetic Organosilane Substrate: A Morphological, Immunocytochemical and Electrophysiological Characterization**

M. Das, N. Bhargava, S. Patil, S. Seal, J. J. Hickman; University of Central Florida, Orlando, FL

In this work, we documented by morphological analysis, immunocytochemistry and electrophysiology, the development of a culture system that promotes the growth and long-term survival of dissociated adult rat spinal cord neurons and glial cells. This system is comprised of a patternable, non-biological, cell growth promoting organosilane substrate N-1[3-(trimethoxysilyl)propyl]-diethylenetriamine (DETA), coated on a glass surface and an empirically derived novel serum-free medium, supplemented with specific growth factors[1]. The culture consists of 60% neurons and 40% glia. Neurons were characterized by immunoreactivity for neurofilament150, neuron specific enolase, MAP-2, beta-tubulin, NeuN, ISLET-1, choline acetyltransferase(ChAT), Vesicular Glutamate Transporter 1(VGLUT1), Vesicular GABA Transporter(VGAT) and MO-1 antibodies. The glial cells were characterized by immunoreactivity for GFAP, O1, O4, myelin basic protein and OX-42 antibodies. Electrophysiology experiments indicated that 60% of the cells expressed voltage dependent inward and outward currents similar to the neurons and were able to generate single, double and multiple (repetitive firing) action potentials. 40% of the cells either showed inward, outward or very small inward and huge outward currents and these recordings are similar to the recording documented for the glial cells in the literature. The cultures were maintained for 8-10 weeks. This novel culture system will be a useful tool to study adult mammalian spinal cord cell patterning, electrophysiology, repair, myelination, degeneration and to screen different putative drug candidates for spinal cord repair and degenerative diseases of the spinal cord such as Multiple Sclerosis and Amyotrophic Lateral Sclerosis. **A Role for the C elegans L1CAM Homologue, LAD-1/SAX-7, in Tissue Attachment and Potential Synapse Function**

X. Wang, L. Chen; GCD, University of Minnesota, Minneapolis, MN

Cell adhesion molecules belonging to the L1 family (L1CAMs) are highly conserved proteins implicated in vertebrate and invertebrate nervous system development. We are carrying out a genetic analysis of the *C. elegans* L1CAM homologue, *lad-1*/*sax-7* to determine L1CAM functions and mechanisms. Genetic mutants with impaired *lad-1*/*sax-7* function exhibit pleiotropic phenotypes; these include abnormal axon trajectories, neuronal cell body distribution, and gonad morphology. These phenotypes are obvious in adult but not younger animals, suggesting they are a result of defective maintenance of tissue attachment. In addition to these phenotypes, *lad-1*/*sax-7* mutant animals also show variable embryonic lethality. Analysis of these embryos suggests that *lad-1*/*sax-7* plays a role in both embryonic morphogenesis and muscle function. Interestingly, animals that are genetically null for *lad-1*/*sax-7* exhibit uncoordinated movements as well as aldicarb and levamisole resistance, phenotypes that are not exhibited by *lad-1*/*sax-7* hypomorphs, suggesting that *lad-1/sax-7* may play a role in synaptic function. We will be reporting our results on our analysis of this potential synaptic function for *lad-1*/*sax-7*.

**_Sec5_ Genetics and its Localization and Function at the _Drosophila_ Neuromuscular Junction**

R. O. Teodoro, T. L. Schwarz; Neurology, Childrens Hospital, Harvard Medical School, Boston, MA

Many forms of membrane traffic contribute to the development and function of the nervous system. Moreover, neurons, like most eukaryotic cells, need to control the location of distinct forms of exocytosis in order to form and maintain specialized cellular domains. Localized exocytosis likely helps shape the branching of axons and dendrites and the growth of synaptic boutons. The exocyst is a protein complex that is essential for polarized secretion. In *Drosophila*, mutants in the exocyst protein Sec5 are defective in many trafficking assays, including neurite extension, but do not show any defects in secretion of neurotransmitter. Here, we show that Sec5 is enriched at the neuromuscular junction. Because bouton number is linked to muscle size, we rescued Sec5 expression selectively in either neurons or muscle. Expressing Sec5 in the nervous system does not prevent *sec5* mutants from dying as 1$^{st}$ instar larvae, but it appears to give rise to more elaborate neuromuscular junctions. Muscle rescue of Sec5 prolongs the lifespan of the mutants to the 2$^{nd}$ instar, but the morphology of the junctions is defective. Together, these results suggest that muscle size and bouton number can be uncoupled by selective restoration of Sec5 function. To identify genes that interact with the exocyst, we are conducting an enhancer/suppressor screen using a temperature sensitive (ts) allele of *sec5*. *Sec5$^{ts}$* has a complete eye at 18$^0$C, a partial eye at 21$^0$C, and no eye at 25$^0$C. Thus this genotype at 21$^0$C provides a suitable sensitized background for uncovering enhancers and suppressors of the eye phenotype. The identification of genes in the same genetic pathway as the exocyst will likely offer new insights into the mechanism through which the exocyst acts and how it regulates other pathways.

2087

**Differential Regulation of Peripheral Arborization and Central Afferent Bifurcation of Primary Sensory Neurons by Slit/Robo Signaling**

L. Ma, A. Plump, M. Tessier-Lavgine; Biological Sciences, Stanford University, Stanford, CA

To build functional neural networks, neurons like those in the dorsal root ganglion (DRG) develop unique branched structures for their peripheral projections in the skin and for their central projections in the spinal cord (SC). We report that the formation of these different structures is regulated by the Slit/Robo signaling pathway. First, the secreted molecule Slit2 was shown to stimulate branching formation of dissociated DRG neurons cultured in collagen gels. Using this assay, we demonstrate that this positive activity can be mimicked by activation of the Slit receptor Robos, using either specific antibodies or myristyolated cytoplasmic domains. Furthermore, in mice lacking both *Robo1* and *Robo2* or missing all three Slit genes, we found a reduction in ophthalmic branches of trigeminal sensory neurons, suggesting that Slit/Robo is required for proper peripheral arborization. Second, by studying the central projection of DRG neurons in the SC, we found that the same pathway is also required for proper bifurcation, another branching step important for sensory axons to make proper connections in the SC. In mice lacking either both *Slit1* and *Slit2* or both *Robo1* and *Robo2*, sensory axons penetrate the spinal cord prematurely and the dorsal root entry site is mislocalized. Interestingly, single cell analysis suggests that this defect is due to the loss of a negative control over neurite growth direction during or after bifurcation. This conclusion is supported by a preliminary finding that the growth cone of young DRG cells can be transiently collapsed by Slit proteins in vitro. Taken together, our study reveals that Slit/Robo signaling contributes to patterning different branching morphologies of sensory neurons and its action, whether positive or negative, depends on the location and the age of these cells.

2088

**LIM Kinase1 Controls Synapse Stability Downstream of the Type II BMP Receptor**

B. A. Eaton, G. W. Davis; Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA

The formation of neural circuitry during development involves exuberant synaptic growth followed by local remodeling events that result in the stabilization of some synaptic contacts and the elimination of others. The molecular mechanisms that specify which synapses will be retained and which will be eliminated remain largely unknown. Here we demonstrate that the BMP receptor *wishful-thinking* (*wit*) is not only required for synaptic growth, as previously demonstrated, but is also necessary for synapse stabilization at the Drosophila NMJ. Mutations that eliminate the Wit receptor or the BMP ligand *glass-bottom-boat* lead to synapse disassembly and presynaptic retraction. Remarkably, analysis of the *mad* and *medea* mutations demonstrates that Smad-mediated signaling, acting downstream of the Wit receptor, is required for synapse growth but is not necessary for synapse stabilization. We identify LIM Kinase (DLIMK1)-dependent signaling as a second, parallel pathway that confers the added synapse stabilizing activity of the Wit receptor. We show that DLIMK1 binds a region of the Wit receptor that is necessary for synaptic stability but is dispensable for Smad-mediated synaptic growth. A genetic analysis demonstrates that DLIMK1 is necessary, presynaptically, for synapse stabilization but is not necessary for normal synaptic growth or function. Furthermore, presynaptic expression of DLIMK1 in a *wit* or *mad* mutant significantly rescues synaptic stability, growth, and function. DLIMK1 localizes near synaptic microtubules and functions independent of ADF/cofilin, highlighting a novel requirement for DLIMK1 during synapse stabilization rather than actin-dependent axon outgrowth. These data support a model in which non-canonical signaling downstream of the BMP receptor to DLIMK1 is necessary for presynaptic stabilization in response to postsynaptic trophic support.

2089

**Neuronal Growth on a Chip: Integration of Multiple Guidance Cues**

N. Li, T. M. Keenan, C. Hsu, A. Folch; Bioengineering, University of Washington, Seattle, WA

During embryonic neural development, axon tips (“growth cones”) are guided through a dynamic three-dimensional (3-D) landscape by soluble chemotropic factors and by immobilized, growth-permissive or growth-inhibiting contact cues present in the extracellular matrix and on the surface of surrounding cells. It has been difficult to probe the search algorithms of growth cones in response to multiple guidance cues during 3-D navigation due to the limitations of traditional cell culture methods. Our goal is to use micro/nano-fabrication techniques to grow murine embryonic cortical neurons in a microfluidic chip and to present the axons with multiple competing growth options. As 3-D substrates that feature variations in permissiveness and microtopography, we used poly-D-lysine (PDL) coatings on microfabricated steps of polydimethylsiloxane (PDMS) and complementary features of Matrigel. We found that axons display a preference for PDL over Matrigel and for the straightest path within a distance consistent with the exploratory range of the growth cone. When these two preferences are in conflict, axons choose to grow straight into Matrigel; when the straight path is not permissive, the axon turns in the direction that minimizes the turning angle. Neurons can also be

challenged by multiple gradients of diffusive factors delivered using microfluidic devices. A high-throughput analysis tool was developed to automatically analyze growth dynamics of multiple neurons. Our results suggest that growth cones make navigation decisions by integrating biochemical and topographical cues. The microchip also provides a valuable tool for other basic cell biology studies such as cell polarity, cell migration and chemotaxis.

**Neuronal Cell Culture Matrix for Better Maintainence and Surival of Neuronal Cell Cultures in Tissue Culture**

J. Sharma, D. R. Aguirre, N. DiMassa, H. Eran, R. Perez; Molecular Biology, Celprogen, San Pedro, CA

At present we have studied and developed a novel neuronal cell extracellular matrix which allows the following neuronal cell cultures : hippocampal, cerebral cortex and dentate gyrus to grow and make connections with other neurons in cell culture. The current neuronal cell culture extracellular matrix increases the neuronal surival rates by 85% when compared to poly-lysine D and Laminin coated flasks. The neuronal cell extracellular matrix allows one to subclone individual neurons with their axonal and dendritic connections in tissue cell culture platform. The neuronal cell cultures in this matrix demonstrated 90% pure neuronal cell population with only 5% - 10% astrocyte population in culture prior to the first passage and after the first passage neuronal cell culture populations were maintained at 95% neurons with 2 - 5% astrocytes in cell culture. The neuronal cell population demonstrated the following markers up to 6 passages Neurofilament, and MAP-2. The neuronal cell cultures showed the presence of MBP a marker of Oligodendrocytes in cell culture and were selectively removed from the neuronal cell culture to obtain 90% neuronal cell density in culture in Celprogen's Neuronal Growth media. In conclusion the present study demonstrated that primary neuronal cells can be maintained in tissue culture for 6 passages with better surival rates and showed the presence of neuronal markers. At present with this model system we are in the process of measuring neuronal transmitters and the synaptic proteins to validate the formation of synaptic vessicles in tissue culture model. With the current neuronal extracellular matrix technology which includes Celprogen's neuronal growth media continously circulating 10 ml tissue culture vessel would enable greater succes in the research and development of neuronal transplants for spinal cord injuries.

2091

**An Investigation of the Function of the Stonin 2 Protein in Rat PC12 Cells**

A. A. Wall, L. Kelly; Genetics, University Of Melbourne, Parkville, Australia

The mammalian Stonin proteins are homologues of *Drosophila melanogaster* Stoned B adaptor protein, which is involved in synaptic vesicle recycling. Mammalian Stonin 2 protein contains an N-terminal proline-rich domain that interacts with the clathrin adaptor AP2, the stonin-homology domain and the C-terminal µ-homology domain that has sequence homology to the µ2 subunit of AP2. Stonin 2 has been shown to interact with synaptotagmin I (sytI) and is enriched in the hippocampus suggesting that Stonin 2 has maintained some functional similarity to its *Drosophila* counterpart. Two independent studies of Stonin 2 using independently generated anti-N-terminal antibodies, identified proteins of conflicting size on SDS-PAGE (80kDa (expected size) and 120kDa). We have raised anti-Stonin 2 C-terminal antibodies in sheep, and have characterised endogenous Stonin 2 protein expression in the rat PC12 cell line. RT-PCR has confirmed that stonin 2 is transcribed in PC12 cells. When blots were probed with affinity purified anti-Stonin 2 antibodies only protein species of ~65kDa were observed. When HEK-293T cells, which show no stonin-2 expression, were transfected with a tetra-cysteine tagged full-length Stonin 2 cDNA, the antibodies detected a full-length protein at 120kDa along with 80 kDa and 65kDa breakdown products. This indicates that 65kDa protein seen in PC12 cells is likely to be a proteolytic product of the full length Stonin 2. Immunocytochemistry shows co-localisation of stonin 2 with synaptotagmin I, and sucrose gradients and sub-cellular fractionations of PC12 cells showed that the 65kDa stonin 2 proteolytic products are associated with both synaptic and dense-core vesicle fractions. A stably transfected Stonin 2 PC12 cell-line that has been found to express <50% of the endogenous level of stonin 2 will be used for further functional analysis of the role of stonin 2 *in-vivo*.

2092

**NAC1 is a Potential Substrate Adaptor for Cullin3-based Ubiquitin Ligase (E3) Complex**

H. Shen,[1] N. Champtiaux,[1] L. Korutla,[2] S. Toda,[1] S. A. Mackler,[2] P. W. Kalivas[1]; [1]Dept. of Neuroscience, Medical University of South Carolina, Charleston, SC, [2]Dept. of Medicine and Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, PA

NAc1, which was up-regulated after chronic cocaine in nucleus accumbens selectively, is a nuclear BTB-POZ protein. Although it can repress reporter gene expression in an *in vitro* transcription assay, we found NAC1 interacted with cullin3 (CUL3) directly through its BTB domain using yeast two-hybrid and GST pulldown assay. Overexpression of AAV-NAC1 in rat primary neurons induced an ubiquitinated inclusion appearing in nucleus, which accumulated CUL-3 and 20S proteasome. Accumulation of the 20s proteasome was by virtue of NAC1 binding to mov34, a subunit of the 26s. The proteasome inhibitor MG132 or PKC activation induced NAC1 translocation to the cytoplasm with 20S proteasome, indicating NAC1 might direct the ubiquitination and degradation of specific cytoplasmic targets. These results reveal NAC1 is a potential substrate adaptor for cullin3-based ubiquitin ligase (E3) complex, which links E3 ligase to the proteasome and thereby accelerates protein degradation via ubiquitination pathway.

2093

**Rescue of the Alpha-syntrophin Knockout Phenotype in Skeletal Muscle by Beta 1- and Beta 2-syntrophins**

R. Sealock, N. R. Kramarcy; Cell & Molecular Physiology, University of North Carolina, Chapel Hill, NC

In α-Syn-/- skeletal muscle, deficiencies include neuronal nitric oxide synthase (nNOS) and aquaporin-4 (AP4) at the sarcolemma and acetylcholine receptor, acetylcholinesterase, and utrophin at the neuromuscular junction (NMJ). The NMJ also shows morphological derangements. These characteristics first appear at day 3 postnatal and progress in spite of the normal presence of β1-syntrophin in neonatal (sternomastoid, gastrocnemius) and adult muscle (gastrocnemius). β2-Syntrophin is also present at the adult NMJ. To test whether these α-syntrophin homologs are intrinsically incapable of compensating for the loss of α-syntrophin, we transgenically overexpressed the β-syntrophins in α-Syn-/- mice under the control of the human skeletal actin promoter. Mice transgenically overexpressing α-syntrophin (from Drs. M. E. Adams and S. C. Froehner; creatine kinase promoter) served as control for overexpression artifacts. We achieved high, uniform levels of expression of each β-syntrophin on the sarcolemma and at the NMJ (similar to the α-syntrophin overexpresser, 10-20-fold total overexpression). Both β-syntrophins restored nNOS,

AP4, AChR and utrophin to wild type or near wild type levels. Morphologically, the fingers of AChR which project beyond synaptic gutters in α-Syn-/- NMJs were rarely present, and the lectin VVA-B4, a marker of junctional folds, labels at wild-type levels. Electron microscopy also shows extensive fold structures, but they are disordered in the β-transgenics: quantitatively, the number of fold openings/micrometer of synaptic cleft was restored to only 52% of wild type by the β2 transgene and 56% by the β1 transgene (compared to 35% in ASyn-/- mice and 80% in α-syntrophin transgenics). We conclude that the β-syntrophins are quantitatively weak in their ability to compensate for α-syntrophin but at non-physiologically high concentrations, they achieve nearly complete compensation in most parameters. ### Vps33a Regulates Behavior and Cerebellar Purkinje Cell Number

S. Chintala,[1] E. K. Novak,[1] R. Gautam,[1] G. Torres,[2] S. Patel,[2] K. Busch,[2] B. A. Meeder,[1] J. M. Horowitz,[1,3] R. T. Swank[1]; [1]Molecular and Cellular Biology, Roswell Park Cancer Institute, Buffalo, NY, [2]New York College of Osteopathic Medicine of New York Institute of Technology, Old Westbury, NY, [3]Medaille College, Buffalo, NY

A mutation in Vps33a causes symptoms of Hermansky-Pudlak Syndrome (HPS) in the buff (*bf*) mouse coat color mutant. Vps33a is a member of the Sec1 family and Class C protein complex, which are important in vacuolar biogenesis and protein trafficking from the Golgi to the yeast vacuole. Buff mice and other murine animal models of HPS exhibit defects in intracellular vesicle trafficking, ultimately causing significant abnormalities of lysosome-related organelles such as melanosomes, platelet dense granules and lung lamellar bodies. Since Sec1 family members have been implicated in synaptic transmission, buff mutants were tested for neurological abnormalities. Application of standardized behavioral tests (SHIRPA protocols) demonstrated significant motor deficits in buff mutants, and their severity increased in older (1 year) mutants. These included grip strength, righting reflex and touch escape, and older mice showed severe gait abnormalities. Stick models of behaviour showed a characteristic curving behaviour unlike the translational motion of control mice. Enumeration of Purkinje cells with calbindin, a calcium binding protein, revealed fewer Purkinje cells in young (9 week) buff mice compared to control mice, and this reduction in cell number was more pronounced in old (14 month) mutants. The size of the cerebellum was decreased in mutant compared to control. Also, Glial Fibrillar Acidic Protein (GFAP), concentrated in astrocytes, was upregulated in buff brain. Thus, the buff mouse may be a useful model to investigate the role of vesicle trafficking in Purkinje cell development and maintenance. Likewise, these and related observations suggest that certain types of HPS patients may exhibit neurological abnormalities.

### Functional Study of the Stress Inducible Protein 1: A Cellular Prion Protein Partner

M. H. Lopes,[1] G. N. M. Hajj,[1] A. G. Muras,[1] G. L. Mancini,[1] R. M. S. Castro,[1] K. C. B. Ribeiro,[2] R. R. Brentani,[1] R. Linden,[3] V. R. Martins[1]; [1]Laboratory of Cellular and Molecular Biology, Ludwig Institute for Cancer Research, São Paulo, Brazil, [2]Estatística, Centro de Tratamento e Pesquisa - Hospital do Cancer, São Paulo, Brazil, [3]Instituto de Biofísica, Universidade Federal do Rio de Janeiro, São Paulo, Brazil

Investigation of cellular prion protein ($PrP^c$)-interacting partners is an important tool to understanding not only cellular signaling triggered by, but also the biological function(s) related to $PrP^c$. Accordingly, we have demonstrated that $PrP^c$ interacts with STI1 (Stress inducible protein 1), a co-chaperone protein that modulates Hsp70 and Hsp90 activities. Since, STI1 expression is unknown and $PrP^c$ protein expression outside the nervous system is not well documented, we evaluated the distribution of both proteins in mice embryos at different stages of development. STI1 and $PrP^c$ are abundantly co-expressed in most tissues analyzed, since embryonic-day 10. In addition, we examined the signaling pathways and functional consequences of the $PrP^c$ interaction with STI1 in hippocampal neurons. Both $PrP^c$ and STI1 are highly co-localized in the hippocampus *in situ* and dissociated neurons, indicating that they can interact *in vivo*. STI1 elicited neuritogenesis in wild-type neurons, but not in $PrP^c$-null cells. $PrP^c$-STI1 interaction induced phosphorylation/activation of the mitogen-activated protein (MAP) kinase, which was essential for STI1-promoted neuritogenesis. STI1 also prevented cell death via PKA activation. These results demonstrate that two parallel effects of the $PrP^c$-STI1 interaction, neuritogenesis and neuroprotection, are mediated by distinct signaling pathways. Supported by FAPESP.

### The YXXL Cytoplasmic Motif of HLA-DM Prevents Sorting into Exosomes

A. Brunet,[1] M. Gauvreau,[1] A. Shaw,[2] J. Thibodeau[1]; [1]Microbiology and Immunology, University of Montreal, Montreal, PQ, Canada, [2]Oncology, University of Alberta, Edmonton, AB, Canada

HLA-DM is a non-classical MHC class II molecule that modulates the loading of antigenic peptides on molecules such as HLA-DR. Peptide exchange occurs in class II-rich compartments of the endocytic pathway where DM accumulates due to its tyrosine-based targeting signal. These compartments include multivesicular bodies in which HLA-DR and -DM interact at the level of the internal membranes. Mature peptide-loaded HLA-DR molecules end-up at the cell surface but also accumulate in exosomal vesicles. These small structures are shed presumably through the fusion of multivesicular bodies with the plasma membrane and are obtained by high speed centrifugation of the culture medium. Despite their co-localization with HLA-DR in MHC II-rich compartments, the presence of HLA-DM in exosomes remains to be demonstrated. Here, we show by immunoblot that DM is present in exosomal fractions of the 721.45 B lymphoblastoid cell line. A similar conclusion was reached when looking at exosomes from HeLa cells transfected with CIITA. To gain insight into the intracellular mechanisms regulating exosome entry and cargo retention, HLA-DM was transfected into HeLa cells. Interestingly, in these conditions, DM was excluded from exosomes. However, it was found in exosomes when its YXXL sorting motif was inactivated by site-directed mutagenesis or following co-expression of HLA-DR. Altogether, these results demonstrate that sorting signals in the cytoplasmic domains of transmembrane proteins can regulate exosome entry and raise the intriguing possibility that protein-protein interactions can modulate the activity of such signals.

### Identifying Components of the Adaptor Protein 3 Complex Pathway

V. Anand, G. S. Payne; Biological Chemistry, David Geffen School of Medicine at UCLA, Los Angeles, CA

Eukaryotic organisms distribute specific cellular tasks to specialized membrane-bound organelles. In order to maintain specialization, the subset of proteins required for the organellar tasks must be correctly localized. The adaptor protein 3 complex (AP-3) mediates protein traffic from the Golgi complex to the lysosome in both yeast and mammals. Mutations in human AP-3 can cause the rare heritable genetic disease Hermansky-Pudlak syndrome, a disease characterized by albinism and prolonged bleeding times. In yeast, one AP-3-dependent cargo is alkaline phosphatase (ALP), a zymogen that requires AP-3 mediated transport for efficient maturation. As a systematic approach to identify genes involved in the AP-3 pathway, we have generated whole cell extracts of a *Saccharomyces cerevisiae* single gene deletion library and immunoblotted for the presence of a precursor form of ALP. Preliminary data have identified genes with previously demonstrated involvement in AP-3 mediated transport and those whose specific involvement remains to be determined. One set of genes identified were certain subunits of the v-type vacuolar $H^+$-ATPase. The presence of every subunit of the $H^+$-ATPase is required for its generation of an electro-chemical potential. Therefore the presence of an ALP processing defect in some but not all of the $H^+$-ATPase subunits indicates that its function in the AP-3 pathway is independent of its electro-chemical generating potential.

2098

**Novel Chemical Inhibitors of Membrane Traffic Identified by Chemical-genetic Synthetic Lethal Screening**

M. C. Duncan,[1] D. G. Ho,[2] M. E. Jung,[2] G. S. Payne[1]; [1]Biological Chemistry, UCLA-Medical School, Los Angeles, CA, [2]Chemistry and Biochemistry, UCLA-Medical School, Los Angeles, CA

Small molecule inhibitors have proven to be powerful tools in cell biology. Here we describe a simple, high throughput method for chemical inhibitor identification that we have used to identify novel inhibitors of clathrin dependant traffic. The technique is based on synthetic genetic lethality - severe growth defects caused by specific combinations of mutations - but in this case the combination consists of mutation and chemical inhibitor. The strategy involves a facile and rapid growth-based screen for chemicals that recapitulate known synthetic genetic growth defects when applied to a particular mutant strain. We applied this technique to identify specific inhibitors of clathrin adaptor AP-1-dependant traffic between the TGN and endosomes. We screened ~30,000 chemicals and obtained three inhibitors. These inhibitors, which share a piperazinyl-phenyl-ethanone backbone, cause effects that mimic phenotypes of deletions of clathrin adaptor AP-1 subunits. For example, the compounds alter trafficking of AP-1 dependant cargoes, but do not alter endocytic trafficking. Additionally, these compounds cause synthetic growth defects similar to deletions of AP-1 when combined with different mutations. Limited structure-activity relationship analysis has been performed to identify key characteristics of active compounds. These novel compounds should be useful for further studies of membrane traffic in yeast, and potentially in other systems. Our results establish the efficacy of chemical-genetic synthetic lethal screening, a procedure that may be generally applicable for identification of small molecule inhibitors in a wide variety of other biological processes.

2099

**Vacuolar Membrane Deterioration Leads to Aging**

F. Tang; Biology, University of Arkansas at Little Rock, Little Rock, AR

In *Saccharomyces cerevisiae*, vacuoles degrade damaged proteins and organelles. Malfunction of this vacuole-mediated degradation may accumulate damaged proteins and organelles and thus lead to cell aging. Indeed, autophagy, one vacuolar degradation pathway, is required for life span extension in *daf-2* mutant of *C. elegans*. In this study, we analyzed the roles of vacuoles in the life span extension of yeast. A well established life span-extension treatment is caloric restriction. When yeast cells were cultivated in caloric restricted (low glucose) media, the autophagic activity was up-regulated. Moreover, caloric restriction induced vacuole inheritance defect; more than 50% of cells trapped vacuoles in the mother cell (vacuole inheritance defect) in low glucose medium, whereas only less than 10% of cells show the defect in media with normal glucose concentration. These observations indicate that vacuole inheritance may shorten the life span of the mother cell. One method to measure the life span of yeast is to count the number of buds produced by a mother cell in her whole life. A comparison of the life span of vacuole inheritance mutants indicated that blocking vacuole inheritance (*vac17*Δ) extends life span while accelerating the vacuole inheritance (VAC17-ΔPEST) shortens the life span. The transport complex (Myo2p-Vac17p-Vac8p) for vacuole movement localizes on selected microdomains on the vacuole membrane. These microdomains are most likely ordered microdomains. Blocking the assembly of ordered microdomain by *erg6Δ* or *sur4Δ* cause vacuole inheritance defect and shorten life span, implying that both vacuole inheritance and life span extension require the ordered microdomain. We propose that vacuole inheritance causes a deficit of ordered microdomains. This deterioration decreases the autophagic activity and shortens the life span.

**Vta1 Stimulates the AAA-ATPAse Vps4**

I. F. Azmi,[1] B. Davies,[1] C. Dimaano,[2] P. Johanna,[1] M. Babst,[2] D. J. Katzmann[1]; [1]Biochemistry and Molecular Biology, Mayo Clinic College of medicine, Rochester, MN, [2]Department of Biology, University of Utah, Salt Lake City, UT

Down-regulation of activated receptors is crucial to prevent aberrant downstream signaling which can contribute to uncontrolled cellular proliferation. Internalized activated receptors enter multivesicular bodies (MVB) en route to degradation in the vacuole. Hence in eukaryotes, the MVB pathway plays an essential role in regulating cell surface protein composition and therefore is important for numerous cellular functions. Recent characterization of the class E Vps or Endosomal Sorting Complex Required for Transport (ESCRT) proteins has provided insights into the intricate mechanism governing MVB sorting and led to a working hypothesis for the role of these factors in the MVB sorting pathway. Currently, little is known about regulatory components of the MVB sorting machinery. The class E protein Vps4, an AAA-ATPase, acts late in the MVB sorting reaction to dissociate the ESCRT components and facilitate continued sorting. However, the regulation of Vps4 is not well defined to date. By utilizing biochemical and microscopic analysis in *Saccharomyces cerevisiae* we have characterized Vta1 as a positive modulator of Vps4 both *in vivo* and *in vitro*. Vta1 stimulates the ATPase activity of Vps4 through promoting or stabilizing Vps4 ologomerization. Furthermore we demonstrate that an evolutionarily conserved domain is necessary and partially sufficient for Vps4 binding and stimulation. We conclude that Vta1 homologs regulate Vps4-dependendant disassembly of ESCRT proteins through an evolutionarily conserved mechanism.

2101

### *env1* Allele of *VPS35* Suggests Additional Function for the Gene Product in *Saccharomyces cerevisiae*

C. Frost,[1] M. K. Takahashi,[2] E. Gharakhanian[3]; [1]Department of Chemistry and Biochemistry, California State University, Long Beach, Long Beach, CA, [2]Department of Biological Sciences, California State University, Long Beach, Long Beach, CA, [3]Biological Sciences, California State University, Long Beach, Long Beach, CA

Recognition, sorting, and localization of proteases to the degradative lysosome are vital for the operation of eukaryotic cells. We have utilized a novel mutant screen to isolate mutants defective in trafficking events at the endosome-to-lysosomal vacuole interface in the yeast *Saccharomyces cerevisiae* -- *env mutants. env1* was identified as an allele of *VPS35*. *env1* cells were compared to other *VPS35* allelic and deletion mutants for growth characteristics, Carboxypeptidase Y localization and processing, and vacuolar morphology. The *env1* mutant demonstrates pleiotrophic phenotypes that differ from those previously characterized for *vps35* mutants. e*nv1* also shows intragenic complementation with the *vps35-10* allele. Vps35p has been identified as a member of the protein complex involved in retrograde transport from the late endosome to TGN. Our results suggest an additional role for Vps35p at the late endosome-to-lysosome interface.

### Structure and Function of Nucleus-Vacuole Junctions in *Saccharomyces cerevisiae*

E. L. Kvam, D. S. Goldfarb; Biology, University of Rochester, Rochester, NY

Nonessential portions of the *Saccharomyces cerevisiae* nucleus are targeted to the vacuole and degraded by “piecemeal microautophagy of the nucleus” (PMN). During PMN, small teardrop-like nuclear blebs are engulfed by invaginations of the vacuole membrane, pinched into the vacuole lumen, and degraded by lumenal hydrolases. PMN occurs in the context of nucleus-vacuole (NV) junctions, which are Velcro-like patches formed through specific interactions between Vac8p on the vacuole membrane and Nvj1p in the outer nuclear membrane (perinuclear ER). PMN occurs at low levels in log phase cells, but is induced by nutrient limitation. Although several other ER-organelle membrane contact sites have been observed in eukaryotes, NV junctions are unique because the bridging apparatus that links the perinuclear ER to the vacuole has been identified. Nvj1p binds and sequesters several proteins, including Vac8p, Tsc13p, and Osh1p, to the outer nuclear envelope, thereby creating a unique subdomain in the perinuclear ER. Mutations that affect the activity of Tsc13p, which is required for the biosynthesis of very long chain fatty acids, reduce the size and volume of PMN structures. PMN is also affected by mutations in the *OSH* family of genes, which are thought to mediate non-vesicular lipid transport. These results suggest that the lipid composition of NV junctions regulates the formation of PMN structures. NV junctions may also have roles in cellular lipid homeostasis. We have mapped the three partner-binding domains of Nvj1p and determined that its unusual N-terminal domain is important for targeting to the perinuclear ER. These four domains represent the major regions of sequence conservation among *NVJ1* homologs in several divergent yeasts. NV junctions represent a unique model system for studying the biology of ER membrane contact sites and, as well, the molecular mechanism of selective microautophagy.

2103

### Coordination of Membrane Dynamics by Dynamin and SNARE Proteins

T. L. Baars, A. Mayer; Department of Biochemistry, University of Lausanne, Epalinges, Switzerland

Vesicular traffic involves membrane fission and fusion, two antagonistic processes which need to be carefully balanced to ensure transport between compartments while maintaining organelle identity. Whereas the molecular machinery mediating fission and fusion has been studied in detail only little is known about factors coordinating these membrane rearrangements. The vacuole of the budding yeast *Saccharomyces cerevisiae* has served as a model for studying membrane dynamics. Vacuoles undergo regulated cycles of membrane fission and fusion in the course of the cell cycle and in adaptation to changing environmental conditions. To gain insight into the coordination of vacuolar membrane remodelling we microscopically screened a set of yeast mutants for aberrant vacuolar morphology and disturbed response to osmotic stress. Our data reveal a role of the vacuolar-ATPase in stress-induced fragmentation and suggest that an acidification-defect-associated phenotype may be epistatic to vacuole fragmentation. Moreover the study shows the involvement of the yeast dynamin-like protein Vps1p and of SNARE proteins in maintenance of the equilibrium between membrane fission and fusion. We propose that an interplay between dynamin and SNARE proteins may represent a general concept for regulation of membrane dynamics.

2104

### A TGN Golgin Required for Mannose 6-Phosphate Receptor Recycling

J. V. Reddy, A. Schweizer Burguete, I. G. Ganley, S. R. Pfeffer; Department of Biochemistry, Stanford University School of Medicine, Stanford, CA

Mannose 6-phosphate receptors (MPRs) transport lysosomal enzymes from the trans-Golgi network (TGN) to endosomes. MPRs recycle back to the Golgi where they can participate in further rounds of transport. MPR recycling requires both the Rab9 GTPase and the cytosolic adaptor protein, TIP47. Rab9 positive transport vesicles have been observed to fuse directly with the TGN, yet nothing is known about how these transport vesicles dock with their target membrane. We show here that a member of the Golgin family of TGN localized proteins, GCC185, is a novel Rab9 effector. GCC185 binds Rab9 GTP in preference to Rab9 GDP and fails to bind Rab5. A tyrosine residue that is key for Arl1 binding to this family of TGN Golgins is not needed for Rab9 interaction. GCC185 is required for MPR recycling from endosomes to the TGN in living cells, as monitored visually by light microscopy and also biochemically, using an assay that monitors the tyrosine sulfation of a modified, cation-dependent MPR. A soluble fragment encoding the Rab9 binding site of GCC185 also inhibits MPR recycling in vitro. GCC185 does not rely on Rab9 for its TGN localization; depletion of GCC185 alters the Golgi ribbon slightly but does not interfere with Golgi function. Together, these data suggest that GCC185 is a key component involved in the tethering and docking of Rab9-bearing transport vesicles at the TGN.

2105

### CD1a Co-Localizes with MHC Class I in the Rab22a-Dependent Recycling Pathway

D. C. Barral, M. B. Brenner; Rheumatology, Immunology and Allergy, Brigham and Women's Hospital / Harvard Medical School, Boston, MA

CD1 proteins are major histocompatibility complex (MHC)-like antigen-presenting molecules that present lipid and glycolipid antigens to T cells.

The trafficking of the different CD1 molecules (a, b, c and d) has been shown to be clearly distinct. The intracellular localization of CD1 proteins is thought to intersect the compartments where the antigens traffic to and this could be the basis for the different existing trafficking pathways. After internalization, CD1b traffics deeply into the endocytic pathway and co-localizes almost exclusively with markers of late endosomes and lysosomes. On the contrary, CD1a does not traffic to late endocytic compartments and recycles back to the plasma membrane. In this study we sought to characterize the intracellular pathways followed by CD1a. By confocal microscopy we showed that CD1a co-localizes to a great extent with MHC class I (MHC I) in early/recycling endosomes of HeLa cells, identified by the presence of internalized transferrin ligand. Recently, MHC I was found to follow a Rab22a-dependent recycling pathway, which is used by cargo internalized independently of clathrin. Interestingly, CD1a co-localizes with the small GTPase Rab22a in the recycling tubular structures that contain cargo internalized independently of clathrin, such as MHC I. Moreover, CD1a, but not transferrin, accumulates with MHC I in the enlarged vesicles formed when cells are transfected with the Arf6 Q67L constitutively active mutant, suggesting that CD1a follows an Arf6-dependent endosomal recycling pathway. These findings shed light on the intracellular pathways followed by CD1a and suggest that CD1a is recycled with cargo that shows clathrin-independent internalization. Furthermore, these results link CD1a to the clathrin-independent internalization pathway, contrasting with the other CD1 isoforms, which are internalized in a clathrin-dependent process.

2106

### Rip11/Rab11 Interaction with Kinesin II Regulates the Sorting of Membrane Proteins in the Recycling Endosomes

G. Wilson,[1] K. Anderson,[1] E. Schonteich,[1] J. Burden,[2] C. Hopkins,[2] R. Prekeris[1]; [1]Cellular and Developmental Biology, UCHSC, Aurora, CO, [2]Imperial College, London, United Kingdom

Rip11 is a Rab11-interacting protein that belongs to a FIP protein family. We have previously shown (Peden et al., 2004; also see Burden et al. poster) that Rip11 is localized to recycling endosomes, where it regulates membrane protein sorting to a degradative pathway. In this study we identify kinesin II as a Rip11-binding protein that also plays an important role in protein sorting. Using yeast-two hybrid and a bead pull-down assays we have show that Rip11 and kinesin II interaction is independent of Rab11 binding and mapped the Rip11-binding region to a tail domain of Kif3B and/or Kif3A subunits of kinesin II. Furthermore, we used microtubule binding assays to show that Rip11 binds to microtubules by interacting with kinesin II, and that Rip11 binding to mirotubules can be blocked by 5 mM ATP or Kif3B tail domain. We have also shown that both Rip11 and kinesin II are enriched in purified recycling endosomes. Finally, we have used RNA interference analysis to show that both Rip11 and kinesin II are required for the sorting of CD63 and Lamp1 to the lysosomes while having little effect on transferrin receptor recycling.

2107

### Rab7 Regulation of EGFR Endocytic Trafficking

B. P. Ceresa; Cell Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK

The coordinated activation and degradation of the EGFR is a complex process that is regulated at many levels. Ligand binding to the EGFR triggers internalization of the ligand:receptor complex through a clathrin-mediated pathway. The complex is subsequently delivered to the early endosome, late endosome, and lysosome for degradation. Each step of endocytic trafficking is regulated by a unique set of proteins. Through the use of activating and inactivating mutants, we have identified the small molecular weight guanine nucleotide binding protein (G-protein) rab7 as regulator of EGFR trafficking between the late endosome and lysosome. Expression of the activating mutant rab7(Q67L), accelerates the rate of radiolabeled EGF degradation; expression of dominant negative rab7 [rab7(Q67L)] slows the rate of 125I-EGF and EGFR degradation. The change in rates of degradation are due to a defect in endocytic trafficking as rab7(N125I) expression inhibits the migration of the 125I-EGF from light to heavy endosome as determined by migration of Percoll gradients. These experiments reveal that rab7(N125I) causes an accumulation of 125I-EGF in an endosomal compartment of the same density of the late endosome. Therefore, we conclude that rab7 activity is necessary for efficient trafficking of the EGFR to the lysosome.

2108

### Regulation of E-cadherin Trafficking during Epithelial Cell Scattering

J. S. Tushir, F. Palacios, C. D'Souza-Schorey; Biological Sciences, University of Notre Dame, Notre Dame, IN

The constitutive endocytosis and recycling of E-cadherin constitutes a required step in maintaining the dynamics of the epithelial monolayer. Alterations in E-cadherin traffic or a decrease in the surface levels of the E-cadherin complex, results in decreased cell adhesion and in some instances in epithelial to mesenchymal transitions. We have shown that upon v-Src activation, a cell signal that initiates cell scattering during epithelial to mesenchymal transitions, E-cadherin is ubiquitinated and shuttled to the lysosome for degradation, instead of following its normal route of recycling back to the cell surface. Thus Src-regulated lysosomal targeting of E-cadherin constitutes an efficient mechanism to disassemble cell-cell contacts during cell scattering. We are interested in investigating the regulation of E-cadherin traffic to the lysosome. We have found that Src signaling does not result in the activation of metalloproteases; however interference with lysosomal function blocks E-cadherin degradation and epithelial cell scattering. The sorting of ubiquitin-tagged E-cadherin to the lysosome is mediated by Hrs (hepatocyte growth factor-regulated tyrosine kinase substrate), an endosomal scaffolding protein, as well the GTPases, Rab5 and Rab7. The interaction of Hrs via its UIM (ubiquitin interaction motif) domain, and its co-localization with ubiquitin-tagged E-cadherin is required for efficient lysosomal targeting of cadherin. However, E-cadherin degradation in lysosomes is independent of Src-induced phosphorylation of Hrs. These investigations demonstrate a pivotal role for endosomal membrane traffic during epithelial cell scattering and describe some key regulators of this process.

## Endothelial Cells (2109-2120)

2109

### Physiologic Cyclic Strain Inhibits the Proliferation of Vascular Endothelium

W. Durante, D. Ensenat, K. J. Peyton; Medicine, Baylor College of Medicine, Houston, TX

Vascular endothelial cells (ECs) are constantly exposed to cyclic strain that arises from the periodic change in vessel wall diameter as a result of pulsatile blood flow. Recent scientific studies indicate that cyclic strain regulates EC orientation, permeability, and apoptosis. In the present study,

we investigated whether cyclic strain also influences EC growth. Cultured human dermal microvascular ECs or bovine aortic ECs were plated onto collagen-coated Bioflex plates and subjected to a physiological level of cyclic strain (6% at 1 hertz) using the Flexercell 3000 Strain Unit. Treatment of human or bovine ECs with fetal bovine serum (5%) for 7 days stimulated a time-dependent increase in cell number that was markedly reduced by the application of cyclic strain. A significant decrease in the number of ECs was first noted after 3 days and this became more pronounced after 7 days of cyclic strain. The cyclic strain-mediated decrease in EC number was not due to cell detachment, necrosis, or apoptosis. Cyclic strain increased the fraction of cells in $G_2M$ and decreased the percentage of cells in the $G_0/G_1$ phase of the cell cycle. Cyclic strain had no effect on the expression of cyclin D1, cyclin E, cyclin A, and cyclin B1, or activation of retinoblastoma protein. In contrast, cyclic strain stimulated the expression of the cyclin-dependent kinase inhibitor, p21. In conclusion, the present study demonstrates that a physiologically relevant level of cyclic strain (6% at 1 hertz) inhibits the proliferation of ECs derived from different species and vessels. This antiproliferative effect is associated with the induction of p21 and the arrest of ECs in the $G_2M$ phase of the cell cycle. The ability of cyclic strain to inhibit EC growth provides an additional mechanism by which hemodynamic forces regulate EC function.

**Norepinephrine Evokes Changes in Aortic Endothelial Cell Morphology Through PKA-mediated Processes**

S. Dissing, S. Ditlev, K. Tritsaris; Department of Medical Physiology, University of Copenhagen, Copenhagen, Denmark

New stable blood vessels are formed through stimulation of endothelial cells by several growth factors such as VEGF, PDGF and FGF. However, other agonists as for instance catecholamines might also play an important role in mediating the formation of organized, functional vessels through cell activations as well as through apoptotic processes. We have studied possible interactions between the sympathetic nervous system and VEGF-mediated controll of angiogenesis using cultured pig aortic endothelial (PAE) cells that express the VEGFR-2 and we found that norepinephrine (NE) stimulation interacts with cellular signaling regulated by VEGF. NE leads, besides $Ca^{2+}$ signaling, activation of Src and formation of NO and cAMP, also to dephosphorylation of the anti-apoptotic signaling enzyme Akt (protein kinase B). The decrease in phosphorylation of Akt is mediated through cAMP, activation of protein kinase A and the Src tyrosin kinase. NE also affects the growth factor-induced tube formation since endothelial cells grown on matrigels in the presence of 10 µM NE appear as small, thin features. Cells display long protrusions often with an unstructured appearance lacking the ability to regulate tube formation. We used small interference RNA directed against PKA to reduce the expression of PKA specifically. This resulted in reduction of the PKA mRNA level by more than 80 % and the cellular amount of PKA by 70 % as evaluated using real time PCR and western blotting. The RNA interference dampened the NE effect on cell structure changes, consistent with PKA activity playing a role in regulation of cell morphology. In conclusion the interplay between sympathetic and growth factor stimulation seems to involve NE-mediated attenuation of Akt activity, resulting in changes of endothelial cell structure that might influence the formation of new blood vessels.

**Embryonic Stem Cell-Derived Endothelial Cells and In Vivo-Derived Endothelial Cells: A Comparison**

K. E. McCloskey,[1,2] D. Smith,[3] H. Song,[4] H. Jo,[4,3] R. Nerem[2]; [1]Bioengineering, UC Merced, Merced, CA, [2]Institute for Bioengineering and Bioscience, Georgia Institute of Technology, Atlanta, GA, [3]Cardiology, Emory University, Atlanta, GA, [4]Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA

Stem cell research has gained in popularity due to their potential to repopulate specific tissues that may be damaged. Many cell therapies involve in vitro stem cell differentiation, however; tissue-specific cells derived from stem cells in vitro have a very different history compared with cells derived in vivo. Stem cell therapies will only become clinically relevant if the stem cells differentiated in vitro function as their in vivo counterparts. Our laboratory has developed techniques for isolating a highly purified population of endothelial cells (>96% purity) from mouse embryonic stem (ES) cells. ES-derived endothelial cells (ECs) stained positive for EC markers Flk-1, Flt-1, vascular endothelial cadherin (VEcad), platelet-endothelial cell adhesion molecule-1 (PECAM-1), CD105, and CD34. Comparisons of in vitro-derived ECs with endothelial cells isolated from the mouse aorta (MAECs) indicate that both ES-derived ECs and MAECs are approximately the same size and have comparable proliferation rates. They also express similar amounts of endothelial nitric oxide synthase, VE-cadherin, PECAM1, Flk1, and Flt1, however, the EC-derived ECs incorporate lower levels of low density lipoprotein (LDL) and express less von Willebrand Factor than mature normal MAECs. Alternatively, ES-derived ECs exhibit greater angiogenic behavior both in collagen gels and on Matrigel than MAECs, a potential indicator that ES-derived ECs are not completely “mature” cells and, therefore, a potentially ideal cell source for vasculogenic therapies.

**FcγRIIB Mediates C-Reactive Protein Inhibition of Endothelial NO Synthase**

C. Mineo,[1] A. K. Gormley,[1] I. S. Yuhanna,[1] S. Osbourne-Lawrence,[1] L. L. Gibson,[1] L. Hahner,[1] R. V. Shohet,[2] S. Black,[3] J. E. Salmon,[4] D. Samols,[3] D. R. Karp,[2] G. D. Thomas,[2] P. W. Shaul[1]; [1]Pediatrics, University of Texas Southwestern Medical Center, Dallas, TX, [2]Internal Medicine, University of Texas Southwestern Medical Center, Dallas, TX, [3]Biochemistry, Case Western Reserve University, Cleveland, OH, [4]Medicine, Cornell University Weill Medical College, New York, NY

C-reactive protein (CRP) is an acute phase reactant which is positively correlated with cardiovascular disease risk and endothelial dysfunction. Whether CRP has direct actions on endothelium and the mechanisms underlying such actions are poorly understood. We have demonstrated in cultured endothelial cells that CRP prevents endothelial NO synthase (eNOS) activation by diverse agonists including vascular endothelial growth factor, insulin, high-density lipoprotein and acetylcholine (Ach). Diminished NO production through eNOS inhibition by CRP results in the promotion of monocyte adhesion to endothelial cells. CRP antagonism of eNOS occurs nongenomically and is due to blunted eNOS phosphorylation at Ser-1179. Treatment of endothelial cells with okadaic acid reverses CRP antagonism of eNOS, indicating a key role for the phosphatase,PP2A. Aggregated IgG, the known ligand for Fcγ receptors, causes parallel okadaic acid-sensitive loss of eNOS function, indicating a role for FcγRIIB in CRP- and aggregated IgG-mediated eNOS antagonism. We further showed that FcγRIIB is expressed in endothelium, and that CRP antagonism of eNOS requires FcγRIIB in heterologous expression studies in COS-7 cells. Moreover, in $Fc\gamma RIIB^{+/+}$ mice CRP blunts Ach-induced increase in carotid artery vascular conductance; in contrast, CRP enhances Ach responses in $Fc\gamma RIIB^{-/-}$ mice. These collective findings indicate that FcγRIIB mediates CRP inhibition of eNOS via PP2A, providing a mechanistic link between CRP and endothelial dysfunction.

**Visualization of Morphological Changes of Single Endothelial Cells in Response to Cyclic Stretch**

S. Iwayoshi,[1] K. Furukawa,[1] T. Ushida[2]; [1]Department of Mechanical Engineering, School of Engineering, University of Tokyo, Tokyo, Japan, [2]Center for Disease Biology and Integrative Medicine, School of Medicine, University of Tokyo, Tokyo, Japan

Endothelial cells (ECs) are known to change their shapes aligned perpendicular to the direction of cyclic stretch. However, the mechanisms are still not clear. In this study, we developed a new cell-stretching device which applies uniaxial strech to cells cultured on elastic silicone membrane. Since the membrane is equally stretched from both ends by rotation of oval cams, the center of the membrane remains stationary during the stretch motion, which allows continuous visualization of cyclically stretched/relaxed cells. By using this apparatus, morphological changes of single human vein endothelial ECs in response to cyclic stretch (1Hz, 10%, 2 hours) were visualized and analyzed. The data showed that there were two major patterns of morphological changes of ECs, depending on their initial shapes. While ECs with round shapes at initial state changed their shapes to become more elongated in a direction perpendicular to that of the stretch, cells oriented and elongated in the stretch direction at initial state changed their shapes to become rounder first and then to become elongated in the direction perpendicular to that of the stretch. Cytoskeletal visualization of human aortic ECs with GFP-tagged actin also showed contraction of stress fibers oriented in the stretch direction after 30 min cyclic stretch, which resulted in the orientation of the ECs in the direction perpendicular to that of the stretch. In addition, the cyclic-stretch-induced endothelial morphological change was blocked by Y-27632, a Rho-related kinase inhibitor, or blebbistatin, a myosin inhibitor. Taken together, cell retraction as well as elongation could play important roles in the stretch-induced endothelial morphological changes, and this retraction might be induced by stress fiber contraction via ROCK-mediated myosin phosphorylation.

**Three-Dimensional Visualization of Weibel-Palade Bodies by Electron Tomography**

K. M. Valentijn, K. A. Jansen, W. J. C. Geerts, J. Post, A. J. Verkleij, A. J. Koster; Molecular Cell Biology, University of Utrecht, Faculty of Biology, Utrecht, The Netherlands

Endothelial cells secrete via regulated exocytosis von Willebrand Factor (vWF), which mediates blood clotting in response to vascular injury. VWF is stored by endothelial cells in cigar-shaped organelles, the so-called Weibel-Palade Bodies (WPBs), of 0.1-0.3 by 1-4 μm in size. Electron microscopy studies have shown that the lumen of WPBs displays typical longitudinal striations that appear as tubular structures in cross sections. Interestingly, vWF self assembles into high molecular weight multimers and immunogold microscopy studies suggest that the striations represent vWF multimers. To this date, little is known on the structural characteristics of these tubular striations. Therefore we have initiated a high resolution microscopic study using electron tomography to gain further understanding of the morphology of this specialized organelle. Thick sections (250 nm) of chemically fixed and epon flat-embedded as well as high-pressure frozen and freeze-substituted human umbilical-vein endothelial cells were studied by electron tomography. We determined that the number of tubular striations ranged from 8 to 28 per WPB, and that they were 11.6 ± 1.9 nm (n=51) in diameter. These striations were equally spaced from each other by a distance of 33.6 ± 5.9 nm (n= 111). Longitudinally sectioned WPBs visualized by electron tomography allowed for the tracking of single tubular striations all the way through the WPBs. While most striations ran longitudinally and parallel to each other, a few started to curve towards the extremities of the WPBs. These data suggest that multimers of vWF are highly organized in WPBs via a yet to be identified scaffold. Currently our research focuses on improving our understanding on the organization of the tubules in WPBs with particular interest on how the tubule organization relates to the cigar shape of WPBs and whether the tubules interact with the limiting membrane of WPBs.

**Nitric Oxide Causes Relaxation of an Endothelial Cell Layer by a Adenylate Cyclase - Independent Mechanism**

B. M. Spataro, G. E. Plopper; Biology, Rensselaer Polytechnic Institute, Troy, NY

Using Electric Cell-substrate Impedance Sensing (ECIS) we have found that addition of 0.2 mM NOC-12, a donor of nitric oxide (NO), causes an increase in resistance in lung endothelial cells. Peaks in resistance occur approximately fifteen hours after the addition of NOC-12. Since "classical" NO-cGMP signaling occurs in minutes, and does not affect resistance in our cells, we assume that other signaling pathways are mediating this response. In testicular epithelial cells, nitric oxide activates production of cyclic AMP by adenylate cyclase and subsequent activation of Protein Kinase A (PKA). This cyclic AMP/PKA pathway regulates tight junction dynamics. We hypothesize that this signaling cascade may be involved in the changes in resistance observed in our cells. We found that elevation of cAMP with IBMX, a cAMP phosphodiesterase inhibitor, induced peaks in resistance that differed from those caused by NOC-12. Addition of a PKA inhibitor had no effect on the increase in resistance caused by NOC-12. These results suggest that NO-induced changes in endothelial resistance are independent of the cyclic AMP/PKA pathway in lung endothelial cells.

2116

**15d-$PGJ_2$ Suppressing MMP-2 Expression is Mediated via Nitric Oxide Induction by p38 Signaling Pathway in Endothelial Cells**

H. Chen; Cardiovascular Disease Division, Institute of Biomedical Sciences,Academia Sinica, Taipei, Taiwan Republic of China

15-Deoxy-$\Delta^{12,14}$-prostaglandin $J_2$ (15d-$PGJ_2$) derived from arachidonic acid has been suggested to exert anti-inflammatory effects. The intracellular accumulation of 15d-$PGJ_2$ found in the atherosclerotic lesion may play a role during atherogenesis. 15d-$PGJ_2$ has been elicited to increase expression of activating transcription factor 3 (ATF3), induce production of nitric oxide (NO), and inhibit cell migration in various types of cell. However, the detail mechanisms of the affective role of 15d-$PGJ_2$ in ECs are not clear yet. In the present study, ECs treated with 15d-$PGJ_2$ increased ATF3 protein level in a dose- and time-dependent manner. ECs treated with 15d-$PGJ_2$ increased NO production due to the activation of eNOS. The 15d-$PGJ_2$-induced production of NO and ATF3 were inhibited by pre-treating ECs with L-NAME, a NOS blocker. Likewise our previous study demonstrated that NO suppressed Matrix metalloproteinase-2 (MMP-2) via ATF3 induction. MMP-2 mRNA expression and its promoter activity were suppressed after ECs were treated with 15d-$PGJ_2$. In addition 15d-$PGJ_2$-treated ECs showed a suppressed secretion of MMP-2 as a result was revealed by zymographic assay. SB203580, a p38-pathway inhibitor, but not SP600125 and PD98059, JNK and ERK inhibitors, respectively, is involved in 15d-$PGJ_2$-induced expression of ATF3 in ECs. Consistently 15d-$PGJ_2$-induced expression of ATF3 was suppressed after ECs were transfected with a catalytically inactive mutant of p38. Moreover, 15d-$PGJ_2$-induced phosphorylation of eNOS and

production of NO were attenuated by pre-treating ECs with SB203580. Concordantly these results suggest that 15d-$PGJ_2$ activates p38 signaling pathway followed with eNOS activation and the increased NO production inhibits MMP-2 expression via an induction of ATF3. Thus 15d-$PGJ_2$ may play a negative role by inhibiting endothelial migration via the reduction of MMP-2 expression.

2117

**Calmodulin and Regulation of $Ca^{2+}$ Signaling and Barrier Functions of Brain Endothelial Cells**

Y. V. Kim, V. Siddharthan, K. S. Kim; Pediatrics Infectious Diseases, Johns Hopkins University, Baltimore, MD

Human brain endothelial microvascular cells (hBMEC) are major constituent of blood brain barrier (BBB). Many pathological conditions, such as stroke and inflammation, are associated with $Ca^{2+}$-dependent BBB disruption. Small ubiquitous protein calmodulin (CaM) is the key intracellular $Ca^{2+}$ sensor that transfers agonist-induced $Ca^{2+}$ changes to numerous $Ca^{2+}$/CaM-dependent proteins. However, the role of CaM in BBB regulation is not fully understood. In this study we investigated how CaM antagonists (trifluoperazine, W-7 and calmidazolium) affect $Ca^{2+}$ signaling, barrier functions of hBMECand spatial distribution of junctional proteins. Using single-cell, real-time fluorescent microscopy and continuous monitoring of transendothelial electrical resistance (TEER) we found that CaM antagonist induced dose- and time-dependent prolonged $Ca^{2+}{}_{in}$ increase due to $Ca^{2+}$ release from thapsigargin-sensitive $Ca^{2+}$ pool independently on extracellular $Ca^{2+}$. CaM antagonists did not block initial, phospholipase C-dependent, rapid $Ca^{2+}$ rise induced by G-protein coupled receptor agonists, such as thrombin, ATP or histamine. However, CaM antagonists significantly impaired subsequent opening of the store-operated $Ca^{2+}$ channels (SOCCs) according to the known capacitative calcium entry mechanism. Moreover, despite such prolonged $Ca^{2+}{}_{in}$ increase, CaM antagonists did not induce changes of TEER and permeability across the endothelial cell monolayer. The obtained data suggest that activation of CaM and SOCCs are essential steps in BBB dysfunctions and CaM antagonists may be useful as potential drugs during various neurological disorders.

**Early Dynamics of Tyrosine Phosphorylated Proteins in Cyclically Strained Endothelial Cells**

Y. Chiu,[1,2] K. Fujiwara[1]; [1]Cardiovascular Research Institute, University of Rochester, Rochester, NY, [2]Department of Biochemistry and Biophysics, University of Rochester, Rochester, NY

Cyclic strain, one of the mechanical forces associated with blood flow, has been recognized as an important modulator of vascular cell physiology. While many biochemical modifications and chronic cellular effects have been reported in cyclically stretched cells, the early molecular events involving protein phosphorylation, an essential element of signal transduction, remain to be investigated by proteomic approaches. The goal of this study is to identify phosphoproteins whose level of tyrosine phosphorylation is regulated in early phase of acute cyclic strain. Confluent bovine arterial endothelial cells cultured on an elastic silicon membrane were subjected to uni-axial cyclic stretch (25% in length, 0.5Hz) for up to 60 min. The stretched cells were lysed for biochemical analysis or fixed for morphological study. The general level of protein tyrosine phosphorylation was significantly enhanced and peaked at 5 min in response to stretch. In immunoblots using phosphotyrosine-specific antibodies (4G10), we consistently noted 17 bands whose tyrosine phosphorylation levels changed in a stretch-dependent manner. The 125kD and 42kD bands were identified as FAK and ERK2, respectively. These results are consistent with other reports showing that phosphorylation of FAK and ERK is early molecular event in cyclically stretched cells. More notably, several other proteins showed significant transient increase after the stretch onset, particularly those with molecular masses of approximately 130kD, 126kD, 110kD, 90kD, 72kD, and 68kD. Immunoprecipitation with 4G10 was used to purify these phosphoproteins for MS identification. Immunofluorescence labeling revealed peripheral accumulation of pY397-FAK and cell-cell junction recruitment of general phosphotyrosyl proteins within 10min of stretch, while PECAM-1 distribution had no detectable changes. These data demonstrate the early dynamics of mechano-responsive phosphoproteins and support the notion that cell-cell junction is an important site for mechanosignal transduction.

2119

**Molecular Interaction of Protein-Zero Related in Endothelial Cells**

K. Kusano, T. N. Thomas, K. Fujiwara; Cardiovascular Research Institute, University of Rochester Medical Center, Rochester, NY

Protein-zero related (PZR), an IgV-type immunoreceptor with two ITIMs, is expressed in various cells including vascular endothelial cells (Xu et al., ECR272 (2002)) and we have already cloned bovine PZR from bovine aortic endothelial cells (BAECs). PZR specifically binds to SHP-2, an SH2-domain containing tyrosine phosphatase, when the ITIMs are phosphorylated. In ECs, PECAM-1 and Gab1, two other proteins with two ITIMs, are also expressed and they have been shown to also bind to SHP-2 in a tyrosine phosphorylation-dependent manner. Using anti-SHP-2, we indeed co-immunoprecipitated PZR, PECAM-1, and Gab1 from the extract of BAECs treated with pervanadate and found that these three proteins were the major SHP-2 binding proteins in BAECs. These results suggested that SHP-2-dependent signaling is regulated not only by PECAM-1 and Gab1 but also by PZR in ECs. Because the PECAM-1/SHP-2 association is induced in ECs that are challenged with mechanical stimuli such as fluid shear stress and hyperosmotic shock (HOS), we wondered if PZR/SHP-2 interaction was also heightened by HOS. The SHP-2 interaction with PZR was indeed increased in HOS-stimulated BAECs. However, unlike for PECAM-1, the HOS-stimulated SHP-2 binding to PZR was strongly reduced in the presence of NAC, an anti-oxidant, suggesting that tyrosine phosphorylation of PZR and PECAM-1 is regulated differently in ECs. We also observed that PZR is localized to the cell-cell contact sites and intracellular granules in BAECs as well as REN cells (methothelioma cell line) by immunofluorescence analysis. These results also indicate that tyrosine phosphorylation of PZR is regulated differently and may participate in different signaling events.

2120

**Ellagic Acid Inhibits Il-1β-induced Cell Adhesion Molecule Expression in HUVECs**

Y. Yu,[1] Z. Wang,[1] W. Chang,[2] C. Wu[3]; [1]Nutrition, China Medical University, Taichung, Taiwan Republic of China, [2]Sports Medicine, China Medical University, Taichung, Taiwan Republic of China, [3]Biological Science &Technology, China Medical University, Taichung, Taiwan Republic of China

Expression of cell adhesion molecules by the endothelium and the attachment of monocytes to endothelium may play a major role in atherosclerosis. Ellagic acid is a phenolic compound presents in fruits and nuts including raspberries, strawberries, walnuts and grapes. In this

study, we investigated the antioxidative effects of ellagic acid and expression of vascular cell adhesion molecule induced by IL-1β in human umbilical vein endothelial cells (HUVECs). The result indicated that ellagic acid possess antioxidant property. Ellagic acid significantly reduced the binding of human monocytic cell to IL-1β treated HUVECs. The production of reactive oxygen species (ROS) by IL-1β was dose-dependently suppressed by ellagic acid. Supplementation with increasing doses of ellagic acid up to 50 μM was most effective for the inhibition of the expression of VCAM-1 and E-selectin. Furthermore, the inhibition of IL-1β induced monocyte adhesion by ellagic acid was manifested on the suppression of nuclear translocation of NFκB p65 and p50. In conclusion, ellagic acid inhibits IL-1β induced ROS production and the expression of VCAM-1 and E-selectin, resulting in decrease of monocytes adhesion. Thus ellagic acid has anti-inflammatory properties and may play an important role in the prevention of atherosclerosis.

### Progression into Cell Cycle and Neuroendocrine-like Morphological Changes are Induced in Lncap Cells in Response to Osteoblast-derived Factors

A. Beckett,[1] B. A. Masri,[2] H. Hare,[1] N. Mawji,[1] N. Blaszczyk,[1] M. D. Sadar[1]; [1]Genome Sciences Center, BC Cancer Agency, Vancouver, BC, Canada, [2]Orthopaedic Surgery, Vancouver General Hospital, Vancouver, BC, Canada

Osseous prostate cancer metastases constitute a major problem in the clinical management of prostate cancer. The skeleton is the most common site of metastasis for men with prostate cancer and these lesions are associated with poor prognosis. Metastasis to the bone can occur only if cancer cells are able to escape the periprostatic space, enter the circulation, adhere to and invade the bone endothelium and ultimately become established in their new microenvironment. A model was utilized whereby prostate cancer cells were cultured in media conditioned with the secretions from osteoblast-like cells obtained from explants of human trabecular bone. This model mimics the clinical scenario for the disease as indicated by increased expression of prostate-specific antigen and enhanced cellular proliferation of prostate cancer cells. Analysis of gene expression using Affymetrix GeneChips and subsequent validation via competitive reverse-transcription PCR identified a number of genes involved in the G2-M cell cycle transition phase that were up-regulated in prostate cancer cells exposed to osteoblast-derived factors. These genes included Cdc2, cyclin B1, cyclin B2, Cdc25C and Plk1. Concurrently, increased cell viability and an increased number of cells in G2-M and S phase of the cell cycle were measured. Neuroendocrine-like morphology, similar what is observed in the development of androgen-independence, developed in prostate cancer cells after treatment with osteoblast-derived factors. Inhibition of the advancement of prostate cancer cells by intervention through the cell cycle could provide a mechanism by which to prevent the establishment of prostate cancer cells in the bone microenvironment. This may be accomplished by targeting the G2-M phase transitional genes shown to be up-regulated in response to the osteoblast-derived factors effectively causing G2 phase cell cycle arrest.

2122

### Expression Profiling of Genes Correlated with Response to 5-Fluorouracil Chemotherapy in Colon Cancer

R. C. Pezo, R. H. Singer; Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

Using single cell expression profiling we are examining the transcription of genes involved in the sensitivity of colon cancer cells to 5-Fluorouracil (5-FU). Our goal is to develop a set of markers that would be predictive of response to 5-FU-based chemotherapy and to potentially identify novel genes involved in mediating sensitivity to 5-FU. Probes directly labeled with multiple fluorophores for Fluorescence in situ Hybridization (FISH) can simultaneously visualize multiple nascent messenger RNA transcripts. This yields a gene expression profile for each single cell. Application of this technique to clinical samples allows us to preserve tissue architecture while circumventing the issue of tissue heterogeneity. Gene expression profiles can then be applied to tissue in clinical trials and correlated with outcomes. Thus single cell expression profiling of tumors would allow us to identify important subpopulations of cells which may only represent a minor percentage of the sample but may have important phenotypes such as chemosensitivity or metastatic potential. This technique would provide data that would be valuable in correlating the transcriptional profile of cells with tumorigenesis, metastasis, and drug response. Using this information, chemotherapy treatments can be tailored to the individual patient.

2123

### Identification of Neutralizing Antibodies to a G Protein-Coupled Receptor (GPCR) Ligand, Human Gastrin, Using a Flow Cytometry-based Intracellular Calcium Flux Assay

P. Larsen,[1] A. Patel,[1] E. Pongo,[1] D. Bohmann,[1] J. Brink,[1] T. Neben,[1] M. Roell,[1] R. Hansen,[1] S. Grimes,[2] M. Handa[1]; [1]Preclinical Research, XOMA LLC, Berkeley, CA, [2]Aphton Corporation, Philadelphia, PA

Overexpression of the gastric hormone gastrin has been implicated in tumor progression in gastrointestinal cancers, making it a potential target for antibody therapeutics that neutralize its function. Gastrin binds to a G-Protein coupled receptor (GPCR), $CCK_2R$, and triggers intracellular calcium flux through a phospholipase C (PLC)-mediated signaling pathway. Therefore, in order to identify gastrin neutralizing antibodies, we developed a flow cytometry-based assay to measure gastrin-induced calcium flux in a $CCK_2R$ stably transfected cell line using the calcium sensitive fluorescent dyes Fluo-3 AM and Fura Red AM. Due to the rapid response of the target cell line to gastrin stimulation, the Cytek Time Zero system was used for on-line injection of stimulus. Using this assay, a panel of fully human phage display-derived gastrin specific antibody fragments was screened for gastrin neutralization and compared to top mouse hybridoma-derived monoclonal antibodies. Those showing greater than 70% neutralization were reformatted to whole IgG molecules. Reformatted antibodies were retested, and the top candidates analyzed to generate $IC_{50}$ values. The most potent antibody from the calcium flux assay also exhibited the highest affinity as measured by BIAcore®, suggesting a direct correlation between potency and affinity for this target. The top candidates were tested for neutralization of ERK1/2 phosphorylation and showed similar potency profiles as the calcium flux assay, further supporting the capacity of these antibodies to neutralize cell signaling mediated by gastrin. In summary, we have utilized a FACS-based intracellular calcium flux assay to select a potent neutralizing fully human antibody to gastrin derived from phage display technology which is competitive in function to a lead mouse monoclonal antibody derived from hybridomas.

2124

**The Ubiquitination Activity of BRCA1 in Association with BARD1 Regulates Centrosomal Function**

S. Sankaran, J. D. Parvin; Pathology, Brigham and Womens' Hospital, Boston, MA

The breast and ovarian cancer specific tumor suppressor, BRCA1, has multiple functions aimed at maintaining genomic stability in the cell by participating in a variety of cellular processes including transcription, DNA damage repair, and cell cycle progression. We show that BRCA1 and BARD1 localize to centrosomes throughout the cell cycle, and the E3 ubiquitin ligase activity of the heterodimer inhibits centrosome function. Centrosome function was tested in vivo and in vitro in assays that measure microtubule (MT) nucleation. A point mutant of BRCA1 that is specifically deficient in E3 ubiquitin ligase activity not only fails to inhibit centrosome mediated MT nucleation but leads to hyperactive centrosomes at higher concentrations indicating that the mutant had a dominant negative effect in vitro and in vivo. We mapped domains of BRCA1 and BARD1 required to regulate centrosome function. Although carboxy-terminal truncations of each BRCA1 and BARD1 could produce active E3 ubiquitin ligases, only heterodimers of the full length BRCA1 and BARD1 could regulate centrosome function. Results of the in vitro assay were consistent with in vivo findings. The regulation of centrosome function by BRCA1/BARD1 is the first described functional assay to be regulated by BRCA1-dependent ubiquitination. We conclude that the BRCA1-dependent E3 ubiquitin ligase maintains centrosomes in the quiescent state in breast cells, and loss of BRCA1 in the precancerous breast cell leads to centrosomal hypertrophy, a phenotype commonly observed in incipient breast cancer. Dysregulation of centrosomes would then be mutagenic and cause the aneuploidy of breast tumor cells.

2125

**Secreted Caveolin Promotes Tumor Formation of Human Prostate Cancer Cells in Mice**

R. Bartz,[1] J. Zhou,[2] J. Hsieh,[2] W. Li,[1] R. G. W. Anderson,[1] P. Liu[1]; [1]Cell Biology, UT Southwestern Medical Center at Dallas, Dallas, TX, [2]Urology, UT Southwestern Medical Center at Dallas, Dallas, TX

Caveolae are plasma-membrane domains that form omega-shaped invaginations in many cells. One of the structural components of these lipid domains is caveolin-1 (Cav-1). Cav-1 is also found in lipoprotein particles secreted by exocrine cells. Here, we present evidence that secreted Cav-1 has biological activity. LNCaP cells, a human prostate cancer cell line, do not express endogenous Cav-1. When they are transfected with Cav-1, however, they secrete Cav-1 in lipid particles. To investigate the biological function of this secreted particle, we injected 10 nude mice at six sites with Cav-$1^+$ LNCaP cells ($3x10^5$/site). Another 10 mice were similarly injected with Cav-$1^-$ LNCaP cells as a control. All of the animals injected with Cav-1 expressing LNCaP cells displayed a high incidence of solid tumor formation at the site of injection (2-3 tumors/animal in two trials) whereas no solid tumors were observed at sites of Cav-$1^-$ LNCaP cell injection 8 weeks after injection. To see if it was the Cav-1 secreted by expressing cells that influenced tumor formation, one side of each nude mouse (8 mice) was injected at 3 sites with Cav-$1^+$ LNCaP cells and the contralateral side at 3 sites with Cav-$1^-$ LNCaP cells. As expected, Cav-$1^+$LNCaP cells formed solid tumors at most injection sites (1.5/animal). Surprisingly, the non-expresising cells on the contralateral side also formed solid tumors (1/ animal), suggesting that the Cav-1 secreted by expressing cells was affecting tumor growth of non-expressing cells at a distance. Immunohistochemistry did not detect any Cav-$1^+$ LNCaP cells in the induced tumors. Similar observation were made using the PC3 cell prostate tumor cell, which normally expresses Cav-1. These results suggest that the secreted Cav-1 particle has autocrine and endocrine activity *in vivo.*

2126

**Single Antibody Determination of Phospho- and Non-phospho c-Myc in Small Samples with a New Blotless Nano Western System**

D. W. Voehringer,[1] X. Bi,[1] D. Deb-Basu,[2] A. Fan,[2] D. Felsher,[2] J. Ferrante,[1] C. Kirby,[1] R. O'Neill[1]; [1]Cell Biosciences, Palo Alto, CA, [2]Oncology, Stanford University, Stanford, CA

Overexpression of the c-Myc protein is an underlying cause of many cancers. Normal c-Myc protein levels are low and kept in check through short protein half-life. Previous reports have shown that in c-MYC conditional transgenic model systems, returning c-MYC to normal levels leads to sustained tumor regression. Hence, targeting the inactivation of c-Myc may be useful for the treatment of cancer. One possible therapeutic approach may be to target gene products that regulate c-Myc activation. Myc is known to be regulated by several post-transcriptional modifications, but to date there is no method to monitor these changes in a sensitive and quantitative manner. Here we measure, in a conditional c-Myc cell line stimulated to express c-Myc, protein phosphorylation state using the novel method of Blotless Nano Western. The system first physically separates the phospho- and non-phospho forms of c-Myc in a small capillary. After focusing, in-capillary protein immobilization and subsequent probing with an antibody directed against total c-Myc protein allows for high sensitivity detection of c-Myc protein. Phosphorylated and non-phosphorylated species were separated, and detected by the single antibody enabling the determination of the *level* of c-Myc activation in a single sample. We anticipate this will allow repeat sampling of fine needle aspirates from mouse tumors where current methods require multiple mice for a single conventional Western blot assay. Our approach will be useful in examining key signaling in pathways that control c-Myc status and more importantly be useful in the identification and screening of novel drugs that target c-Myc activation for the treatment of cancer.

2127

**Human Survivin Links the Relocation and Function of Aurora B Kinase to Central Spindle for Completion of Cytokinesis**

Y. Ke,[1] Y. Miao,[1] L. Zhao,[1] H. Deng,[1] F. Wang,[1] Z. Dou,[2] A. Shaw,[2] X. Yao[1]; [1]Chinese Academy of Science, Institute of Cellular Dynamics, Hefei, China, [2]Physiology, Morehouse School of Medicine, Atlanta, GA

During cell division, chromosome segregation is orchestrated by the interaction of spindle microtubules with the centromere. A dramatic reorganization of interpolar microtubules into a highly organized central spindle between the separating chromatids is required for the initiation and execution of cytokinesis. Central spindle organization requires mitotic kinesins and the chromosomal passenger of Aurora B kinase complex with INCENP and survivin. The current working model argues that INCENP targets Aurora B to its points of action while the precise role of survivin is not yet known. Here we show that human survivin governs Aurora B kinase activity and its relocation to the central spindle using mitotic kinesin MKLP2. We found that survivin interacts with MKLP2 C-terminal tail and disruption of MKLP2-survivin interaction prevents the relocation of Aurora B-INCENP protein complex to the central spindle and caused cytokinesis defects. This MKLP2-mediated, survivin-dependent relocation of the Aurora B protein complex was demonstrated by a set of rescue experiments in which exogenous expression of full-length but not motor-less or tail-less MKLP2 restores the Aurora B kinase complex trafficking and faithful cytokinesis. Surprisingly, survivin-deficiency resulted in minimized

Aurora B kinase activity and aberrant targeting of mitotic kinesin MKLP1. The importance of the Aurora B phospho-regulation was validated by correct targeting of ectopic expression of a phosphorylation-mimicking mutant of MKLP1 and faithful completion of cytokinesis. These results indicate that survivin represents a link between the relocation of Aurora B kinase activity to central spindle and completion of cytokinesis.

2128

**Identification and Characterization of Genes Conferring Resistance to Signal Transduction Inhibitors in Malignant Human Mammary Epithelial Cells**

S. Moonlee, P. A. Kenny, M. J. Bissell; Cancer Biology, Lawrence Berkeley National Laboratory, Berkeley, CA

We have demonstrated previously that the malignant phenotype of a human mammary tumor cell may be reverted in 3D cultures using inhibitors of β1-integrin, EGFR and PI3K. These pathways become reciprocally crossmodulated when cells are cultured in a 3D laminin-rich extracellular matrix assay but not in 2D. In order to screen for additional pathways involved in the restoration of the breast acinar structure, we have generated a retroviral cDNA library from malignant mammary epithelial cells and screened for genes conferring resistance to the phenotypic reversion induced by inhibitors of EGFR and PI3 Kinase. Transduction of HMT3522-T4-2 cells with this library allowed us to successfully isolate several reversion-resistant colonies. We rescued the cDNA inserts from these colonies and validated the resistance phenotype by re-expression in naïve T4-2 cells. We are currently focusing on five genes. These include genes that confer resistance against EGFR inhibition or against PI3-K inhibition. We are currently determining how these proteins interact with, and modify the activities of these signaling pathways, and also determining their contribution to normal mammary acinar morphogenesis.

2129

**Human c-Src Tyrosine-phosphorylates Protein Kinase G (PKG) and PKG Serine-phosphorylates Human c-Src, Enhancing Tyrosine Autophosphorylation: Potential Mechanism of Decreased Apoptotic Cell Death in Cancer Cells**

R. R. Fiscus, C. G. Choi, J. Tsim, L. H. Leung, C. Y. Wong; Dept. Physiol. (Fac. Med.) and Mol. Cell. Gerontol., Chinese University of Hong Kong, Shatin, NT, Hong Kong Special Administrative Region of China

Our laboratory has shown that nitric oxide, natriuretic peptides and cGMP analogs, via cGMP/PKG activation, enhance cell survival by inhibiting key steps of pro-apoptotic pathway in normal mammalian cells (e.g. pancreatic islets). In transformed mammalian cells (e.g. neuroblastoma and human ovarian cancer cells) the cGMP/PKG pathway appears already activated and contributes to anti-apoptotic/pro-survival effects. Because v-Src tyrosine-phosphorylates PKG and enhances its activity, we hypothesized that, in cancer cells, higher levels of c-Src tyrosine kinase may phosphorylate PKG, increasing PKG-mediated anti-apoptotic effects. The present study, using recombinant PKG-1α and human c-Src in vitro, shows that c-Src tyrosine-phosphorylates PKG-1α (Western blot, PY20 antibody). Autophosphorylation of c-Src was enhance by PKG-1α, suggesting PKG serine-phosphorylates c-Src, enhancing Src tyrosine kinase activity. Previously, protein kinase A (PKA) was shown to phosphorylate c-Src at serine-17 and enhance its tyrosine kinase activity. Sequence at serine-17 (R-R-R-S-) suggested that c-Src could be a good substrate for PKG. To test this, we used an antibody recognizing phosphorylation at serine/threonine with arginine at -3 position (characteristic of PKA/PKG phosphorylation sites). PKG, like the positive control PKA, phosphorylated human c-Src. The data indicate human c-Src tyrosine-phosphorylates PKG-1α and PKG-1α serine-phosphorylates human c-Src, enhancing autophosphorylation. Because Src tyrosine kinase activity is elevated in many cancer cells and PKG activation inhibits onset of apoptosis, our data suggest that c-Src and PKG may work in concert, one phosphorylating the other, to inhibit apoptosis, thus promoting cell survival. **Lack of Natural Tumor in the Ocular Lens Is Partially Derived from the Distinct Function of the RAF/MEK/ERK Signaling Pathway**

D. W. Li, J. Liu; The Hormel Institute, University of Minnesota, Austin, MN

The ocular lens is the only organ that does not develop spontaneous tumor. The molecular mechanism for this phenomenon remains unknown. Through examination of the signaling pathways mediating stress-induced apoptosis, here we presented evidence to show that different from most other tissues in which the extracellular signal-regulated kinases (ERKs) pathway is generally implicated in mediation of survival signals activated by different factors, the RAF/MEK/ERK signaling pathway alone plays a key role in stress-activated apoptosis of lens epithelial cells. Treatment of N/N1003A cells with calcimycin, a calcium mobilizer, activates the RAF/MEK/ERK pathway through RAS, which is indispensable for the induced apoptosis because inhibition of this pathway by either pharmacological drug or dominant negative mutants greatly attenuates the induced apoptosis. Calcimycin also activates p38 kinase and JNK2, which are not involved in calcium-induced apoptosis. Downstream of ERK activation, p53 is essential. Activation of RAF/MEK/ERK pathway by calcimycin leads to distinct up-regulation of p53. Moreover, over-expression of p53 enhances calcimycin-induced apoptosis while inhibition of p53 expression attenuates calcimycin-induced apoptosis. Up-regulation of p53 directly promotes Bax expression, which changes the integrity of mitochondria, leading to release of cytochrome C, activation of caspase-3 and eventually execution of apoptosis. Thus, our results that the RAF/MEK/ERK pathway mediates stress-induced apoptosis not only provide a novel signaling pathway for calcium-induced apoptosis but also give a partial explanation for the lack of spontaneous tumor in the lens. Upon DNA damages induced by various stress factors, activation of the RAF/MEK/ERK pathway, instead of promoting survival of the cells with genetic lesions, signals apoptosis of the damaged cells. In this way, the cells bearing the genetic damages are removed in a timely manner and thus tumor development is avoided.

**Isolation and Characterization of New MicroRNAs Expressed Early in Mouse Telencephalon, Exploring Their Roles in Mantainance of Neural Progenitors and Neurodevelomental Processes**

M. Zollo,[1] P. Carotenuto,[1] L. Garzia,[1] A. M. Bello,[1] N. Marino,[1] V. Aglio,[1] C. Roma,[1] V. Maffia,[1] G. Vitale,[1] J. Rubenstein,[2] A. Bulfone[3]; [1]CEINGE, Advanced Biotecnology S.C.RA.L, Naples, Italy, [2]Nina Ireland Laboratory of Developmental Neurobiology, Center for Neurobiology and Psychiatry Genetics, University of California at San Francisco, San Francisco, CA, [3]Stem Cell Research Istitute, Istituto Scientifico San Raffaele, Milan, Italy

Available data on genome sequence, expressed regions of the genome and gene expression in specific tissues is revolutionizing biological research.

A series of critical steps, ordered in a spatial and temporal time in the development of human brain, are occurring in an organized manner in order to give rise to a properly formed normal forebrain. Disorders associated to alteration on these steps are still orphan of gene identification. We aim within this functional genomic project approach to identify and characterize new genes involved in the developing mouse telencephalon and translate their functions to human so as to identify their homologues and associate them to neurodevelopmentaldisorders. We present here the full characterization of 832 transcripts preferentially expressed at E14.5 mouse telencephalon. Of this collection, 323 (39%) correspond to novel rare transcripts, which include 48 (14%) new microRNAs. These latest class corresponds to an unique collection of microRNAs precursors preferentially expressed at E.14.5 telencephalon and with a potential control function versus target genes related to cellular proliferation, migration and neural specification and differentiation. Within this collection one microRNA, 24.E3, was found highly expressed in Neural Stem Cells and thus controlling level of expression of several target genes involved in trascriptional factor activation connected to neurogenenis including cell cycle and proliferation, nuclear/cytoplam transport and a cancer associated gene. Preliminary data related to other microRNAs identified will be presented, thus representing a valuable resource for the identification of novel genes and targets involved in neurodevelopmental processes. **The D806N Mutation in EphA3 Identified in Human Colorectal Cancer Causes Loss of Tumor Suppressive Functions**

E. Johnson, B. Wang; Medicine, Pharmacology, Case Western Reserve University, Cleveland, OH

Overexpression and mutation of several Eph kinases has been reported in a variety of human tumors. However, the role of Eph kinase overexpression and mutations in tumor etiology and progression remain to be elucidated. Using site directed mutagenesis and a retroviral expression system we set out to investigate the functional consequences of S792P and D806N mutations previously reported in human colorectal cancer. Wild type (WT) and mutant EphA3 were tagged with FLAG epitope in between the signal peptide and the mature sequence to enable ready detection and anti-FLAG antibody clustering of the receptors. Stimulation with either ephrinA5-Fc or M2 anti-FLAG antibody resulted in increased tyrosine phosphorylation of WT- and S792P-EphA3 in 293E cells. In contrast, similarly stimulated D806N-EphA3 failed to become phosphorylated suggesting that D806N, but not S792P mutation, caused a loss of EphA3 catalytic activity. Indeed, D806N mutant was found to be kinase-inactive in an in vitro kinase assay. These observations led us to focus on D806N mutation in colorectal cancer cells. Among colorectal cancer cell lines screened, DLD1 was chosen because of low expression of endogenous EphA kinases. Similar to our report with EphA2 kinase, ligation of WT-EphA3 on DLD1 cells decreased integrin-dependent adhesion to fibronectin and retarded wound healing. The inhibitory effects were diminished by D806N mutation. Moreover, while the overexpression of WT-EphA3 slowed DLD1 cell proliferation in three-dimensional MatriGel and planar clonal growth assays, D806N failed to suppress cell proliferation. Thus the expression and subsequent activation of EphA3 are capable of suppressing several cell behaviors associated with malignant transformation. More importantly, the acquisition of the D806N mutation abrogates the normal functions of EphA3. The loss of function mutation in human colorectal cancer may contribute to the malignant progression.

**Impairment of TGFβ-Increased Stat3 Activity during Acqusition of Drug Resistance**

N. Shih,[1] S. Tseng,[1] K. Chen,[2] B. Ho,[3] Y. Lin[4]; [1]Cancer Reseach Division, National Health Research Institutes, Taipei City, Taiwan Republic of China, [2]Graduate Institute of Life Sciences, National Defense Medical Center, Taipei City, Taiwan Republic of China, [3]Graduate Institute of Medical Science, Taipei Medical University, Taipei City, Taiwan Republic of China, [4]Department of Medicine, Fu-Jen Catholic University, Taipei City, Taiwan Republic of China

Acquired drug resistance of tumor cells has been reported to associate with insensitivity to cytotoxic cytokines. However, the molecular mechanism(s) for this cross-resistance is still obscure. We examined possible signaling alterations associated with adriamycin resistance and TGFβ insensitivity. A lung adenocarcinoma cell line, NCI-H23, resistant to adriamycin (H23ADR) is much more refractory to TGFβ-mediated growth suppression than parental cells (H23P). Upon ligand stimulation, receptor-mediated Smad2 activation and Smad-dependent transcriptional activation of a report gene could be observed in both cell lines. However, in contrast to Mv1Lu cells, the activation magnitude was not sufficient to induce growth arrest and cell death in H23P cells, indicating that TGFβ-induced growth suppression in the cells is Smad-independent event and purely attributed to increase in cell doubling time from 28.8 to 118.7 hours. Comparing activation profile of Samd2-independent signaling molecules, we first demonstrate that Stat3-mediated pathway is affected during acquisition of adriamycin resistance. TGFβ1 augmented endogenous Stat3 activity in H23P cells, but barely affected that in H23ADR cells. Consistently, MCF7 parent and its adriamycin-resistant partner also showed a similar result. Experiments using constitutively active or dominant-negative Stat3 further confirm that TGFβ-increased Stat3 activity plays a negative regulator to growth of H23 cells. Additionally, the study using H23 cells resistant to taxol, cisplatin, or 5-flurourodine demonstrates that failure response to TGFβ-augmented Stat3 activity is unique to cells acquired adriamycin resistance; whereas, intriguingly, acquired taxol resistance of H23 cell further downregulates endogenous Stat3 activity and is correlated with its cell growth. The data suggests that Stat3-mediated pathway is the major altered target during anticancer drug resistance and accounted for cells insensitive to TGFβ. Thus, the role of Stat3 in cross-resistance to adriamycin and TGFβ may provide an alternative way to monitor tumor malignancy.

**SEPT6: Genomics, Transcripts, Expression Profile and Evidence of Deregulated Expression in Lymphoma**

C. B. Todd,[1] M. Dattani,[2] H. Grabsch,[2] S. S. McDade,[1] K. J. Hillan,[3] P. A. Hall,[1] H. Russell[1]; [1]Center of Cancer Research and Cell Biology, Queen's University Belfast, Belfast, United Kingdom, [2]Academic Unit of Pathology, University of Leeds, Leeds, United Kingdom, [3]Genentech Inc, South San Francisco, CA

An increasing body of data indicate that members of the septin gene family are implicated in human neoplasia. For example SEPT9 lies at a locus that shows allelic imbalance in ovarian and breast cancer, is a target for retroviral insertional mutagenesis and is over-expressed in diverse human tumours and is a translocation partner for MLL in human leukaemia. SEPT6 has also been implicated in leukaemia as a fusion partner of MLL. We therefore investigated the genomic architecture, transcript profile, mRNA and protein expression of SEPT6. The 12 exons of SEPT6 span 77.6 kbase on Xq24 and undergo complex splicing events. We defined these splicing events and report 7 distinct transcripts that encode 5 distinct

polypeptides. Of note are 3 discrete transcripts encoding the same 427 amino acid polypeptide: a phenomenon also seen with SEPT9. We used a quantitative RT-PCR strategy to define the expression of these transcripts in cell lines and in fetal and adult tissues and show tissue specific patterns of expression. We took advantage of Affymetrix probe sets from sequences in exon 11a (212415_at), 11b (212413 _at, 212414 _at and 214298_x_at) and exon 12 (213666_at) and define SEPT6 mRNA expression in normal, diseased and neoplastic human tissues (n=10360). The RT-PCR data validated the expression array and SEPT6 is expressed predominantly in lymphoid and CNS tissues. These data are further substantiated by the use of anti-SEPT6 sera we generated that show that SEPT6 expression is high in these cell types. SEPT6 protein is associated with the microtubule network and we have also identified a novel nuclear form of SEPT6 and show this to be mediated by a bipartite NLS in the C terminus of SEPT6. Finally we show that SEPT6 is consistently over-expressed in lymphoid neoplasms (n=106).

**The Endolysosmal Membrane Protein Endolyn Is Up-regulated in Cancer Cells via Elevated Ap-1 Activities**

G. Zhou,[1] Y. Zhang,[2] J. Tang,[1] D. Mole,[3] S. M. Watt,[2] C. F. Campbell[1]; [1]Centre for Cancer Research and Cell Biology, Queen's Univesity of Belfast, Belast, United Kingdom, [2]Stem Cell Research Laboratory, Oxford Centre, National Blood Service, Oxford, United Kingdom, [3]Department of Surgery, Queen's Univesity of Belfast, Belast, United Kingdom

The endolysosmal membrane protein endolyn (CD164) regulates proliferation, differentiation, and migration of stem and progenitor cells but little is known about its role and transcription regulation in relation to the cancers. This study aimed to compare the expression pattern of endolyn in normal and malignant tissues and explore the underlying regulatory mechanisms. Using immunohistochemical staining, various cancerous and the corresponding normal tissue samples, collected from over a hundred patients and spotted on multiple tissue microarrays, were assessed for their endolyn expression. It was found that endolyn expression was up-regulated in almost all investigated cancer tissues (with immunostaining scores at least 3-4), compared with only basal levels in normal tissues from the same patients (scored at 0-2). Several other endolysosome related proteins, including lysosome associated membrane protein I (LAMP I), lysosome integrated membrane protein I (LIMP-II), Munc-8, and cathepsin D, were also shown to be up-regulated in cancers but generally to less extents. The up-regulation of endolyn occurs mainly at the transcription level as indicated with comparing endolyn mRNA levels in cancer and the adjacent normal tissues. A 225 bp-DNA sequence upstream the coding region of the human endolyn gene was predicted to contain a number of potential binding sites for transcription factors relevant to carcinogenesis. This region was further experimentally proved a promoter region, driving the expression of reporter sequence in several cancer cell lines. Furthermore, it was shown that the transcription complex AP-1 particularly contributes to the up-regulation of endolyn gene in cancer cells. These results suggest that endolyn deregulation, and consequently the altered endolysosomal function, may play important roles in the multiple molecular networks related to cancer development and progression.

**Signaling Pathways for Troglitazone Activation of ERK1/2: Coupling to PPRE-driven Gene Expression and Ammoniagenesis in MCF-7 cells**

E. Friday,[1] R. Oliver,[2] T. Welbourne,[2] F. Turturro[1]; [1]Medicine-Feist-Weiller Cancer Center, Louisiana State University Health Sciences Center, Shreveport, LA, [2]Molecular and Cellular Physiology, Louisiana State University Health Sciences Center, Shreveport, LA

We previously demonstrated that TRO induces a profound cellular acidosis in MCF-7 cells by inhibiting NHE-mediated acid extrusion. This inhibition was associated with marked GW9962 insensitive reduction in cellular proliferation (Clin Cancer Res 10:7022, 2004). The present study was designed to elucidate the signaling pathway(s) involved and the relationship to PPRE-driven gene expression and acidosis as reflected in cellular acidification and pH-sensitive ammoniagenesis from glutamine. Acute studies were performed on cells grown on glass chambers and intracellular pH assayed by BCECF fluorescence. Exchanger activity was monitored and expressed as $\Delta pH/\Delta t$. The levels of total- and phospho-ERK1/2 were measured by western blot analysis. Functional PPARγ activity was assessed by transient transfection with a PPARγ response element (PPRE) luciferase construct. Ammonium concentration in the media (measured by the microdiffusion method) was used as an index of chronic acidosis. Acutely, TRO (25uM) activated ERK 1/2 by 3.1 fold ($p<0.02$) within 4 minutes and was blocked by pretreatment with PD98059 and U0126. TRO also induces a severe cellular acidification ($p<0.01$). This acidification was abrogated by PD98059+U0126 pretreatment. Pretreatment with an EGFR kinase inhibitor (PD153035) prevented TRO-induced ERK 1/2 activation. This would indicate that TRO acts at either EGFR or upstream to activate ERK1/2. Chronically, TRO induced PPRE-driven luciferase expression 1.3 fold ($p<0.05$) and this effect was eliminated by PD98059+U0126 pretreatment. TRO enhanced ammoniagenesis 1.7 fold ($p<0.05$) and this effect was also eliminated by pretreatment with PD98059 + U0126. Our results are consistent with cellular acidosis and PPRE-driven gene expression largely controlled via ERK1/2 activation induced in turn by TRO acting near, or, at EGFR in MCF-7 cells.

**Docosahexaenoic Acid Alters the Size and Distribution of Lipid Rafts**

R. S. Chapkin,[1] N. Wang,[2] J. R. Lupton,[3] I. A. Prior[4]; [1]Center for Environmental and Rural Health, Texas A&M University, College Station, TX, [2]Statistics, Texas A&M University, College Station, TX, [3]Department of Nutrition and Food Science, Texas A&M University, College Station, TX, [4]The Physiological Laboratory, University of Liverpool, Liverpool, United Kingdom

We recently generated nutritional data suggesting that chemoprotective dietary n-3 polyunsaturated fatty acids (n-3 PUFA) are capable of displacing acylated proteins from microdomains in vivo (FASEB J 18:1040, 2004). A primary source of very long chain n-3 PUFA in the diet is derived from fish enriched with docosahexaenoic acid (DHA, 22:6n-3). In this study, we sought to determine the effect of DHA on the size and distribution of lipid rafts in vivo. Using immunogold electron microscopy of plasma membrane sheets coupled with spatial point analysis, morphologically featureless microdomains were visualized in HeLa cells. Cells were transfected with GFP-truncated H-ras (GFP-tH is located exclusively to inner leaflet rafts) and subsequently incubated with DHA and control fatty acids, linoleic acid (LA, 18:2n-6) or oleic acid (18:1n-9) for 48 h. Univariate K-function analysis of GFP-tH (5 nm gold) revealed that the interparticle distance was significantly reduced ($p<0.05$) by DHA treatment compared to control fatty acids. These findings suggest that the plasma membrane organization of inner leaflets is fundamentally altered by DHA-enrichment. We speculate that our findings may help define a new paradigm to better understand the complexity of n-3 PUFA modulation of signaling networks. Supported in part by NIH grants CA59034, CA74552 and P30ES09106.

**Functional Coupling of Endoplasmic Reticulum Signaling to the Induction of Dormancy and Drug Resistance in Human Squamous Carcinoma Cells**

A. C. Ranganathan, L. Zhang, A. Adam, J. Aguirre-Ghiso; School of Public Health, Department of Biomedical Sciences, University at Albany, Rensselaer, NY

Minimal residual disease, a stage in cancer progression where tumor cells after disseminating from the primary tumor enter into a protracted state of dormancy, has significant clinical relevance. However, the mechanisms that regulate tumor cell dormancy and its subsequent resistance to chemotherapy are understudied due to the lack of proper model systems. We have established a model of tumor dormancy in human squamous carcinoma (Hep3), where prolonged passaging of these cells *in vitro* results in a non-clonal acquisition of a dormant phenotype characterized by a spontaneous induction of p38 signaling. Here we show that constitutively activated p38 signaling pathway in dormant cells is linked to the upregulation of BiP/Grp78 expression and increased PERK phosphorylation and GADD153 promoter activation, all characteristic of an endoplasmic reticulum (ER) stress response. Further, we found that the active ER stress rather than inducing apoptosis selectively protects dormant cells from chemotherapy-induced apoptosis independent of proliferation and of P-glycoprotein mediated multidrug resistance and also favors the induction of dormancy *in vivo.* Pharmacologic or genetic inhibition of p38 activity resulted in a reversion of these changes and restored drug sensitivity and tumorigenicity. RNA interference and dominant negative expression analyses revealed that both BiP and PERK promote the survival of dormant cells and that BiP upregulation prevents Bax activation, and cytochrome-C release. Moreover, inhibition of the PERK induced eIF2α phosphorylation by the expression of GADD34, a regulatory subunit of eIF2α phosphatase PP1 resulted in the interruption of dormancy *in vivo*. We therefore propose that high p38 activation coupled to ER stress signaling confers novel survival advantage to the disseminated metastatic cells by activating the dormancy program and protecting them from stress insults such as chemotherapy.

2139

**Complete Inhibition of P-glycoprotein by Simultaneous Treatment with Modulators and the UIC2 Monoclonal Antibody**

Z. Bacsó; Biophysics and Cell Biology, University of Debrecen MHSC, Debrecen, Hungary

P-glycoprotein (Pgp) is one of the active efflux pumps that extrude a large variety of chemotherapeutic drugs from the cells, causing multidrug resistance. The conformation sensitive UIC2 mAb potentially inhibits Pgp mediated substrate transport. However in most cases this inhibition is partial, since UIC2 binds only to 10-40 % of all Pgps present in the cell membrane. The rest of the Pgp molecules assume the conformation recognized by this antibody only in the presence of certain substrates or modulators (e.g. vinblastine, cyclosporine A). Here, we have developed a simple procedure involving the combined application of modulators and UIC2 mAb, followed by removal of the modulator, achieving near 100% inhibition of pump activity by the antibody. The accumulation of various Pgp substrates, including calcein-AM, daunorubicine (DNR) and $^{99m}$Tc-hexakis-2-methoxybutylisonitrille ($^{99m}$Tc-MIBI) was completely restored by the above procedure. Remarkably, the inhibitory binding of the antibody is brought about by 10 times lower cyclosporine A (CsA) concentration than the effective concentration of CsA, when it is applied alone. We could also demonstrate this inhibition in the presence of whole mouse blood, hence *in vivo* application of this antibody appeared to be feasible. This possibility was confirmed by the dramatic increase of DNR accumulation in xenotransplanted $Pgp^+$ tumours in response to a combined treatment with UIC2 and CsA, both administered at doses barely effective when applied alone. These observations raise the possibility of a novel, specific and effective way of blocking Pgp function *in vivo*, by the combined application of modulators and a humanized form of this antibody.

**Genetic Polymorphisms of the CYP1B1 Gene and Environmental Chemical Exposure in Breast Cancer Susceptibility**

J. C. Deacon, R. Goth-Goldstein, M. L. Russell; Lawrence Berkeley National Laboratory, Berkeley, CA

Polycyclic Aromatic Hydrocarbons (PAHs) are common lipophilic organic chemicals metabolized in the body through the Cytochrome P-450 1B1 (CYP1B1) enzyme pathway, where CYP1B1 metabolizes PAHs into electrophilic intermediates that can form adducts with DNA. *CYP1B1* can be strongly expressed in mammary tissue where PAH-DNA adducts can cause mutation and cancer. Single Nucleotide Polymorphisms (SNPs) are versions of genes differing by one base-pair and can differ from each other in function. Difference in catalytic function between SNPs of *CYP1B1* may extend the electrophilic presence, thus effecting cancer susceptibility. An ongoing epidemiologic study in Brazil compares *CYP1B1* genotype, *CYP1B1* expression levels, and PAH-DNA adduct levels in normal breast tissue of breast cancer patients and controls, and estimates participant PAH exposure by questionnaire. The genotyping of participants for two *CYP1B1* SNPs has produced a partial data set and is herein discussed. DNA was isolated from mammary tissues of participants and genotyped for two SNPs by Polymerase Chain Reaction and Restriction Fragment Length Polymorphism (PCR /RFLP). PCR was used to amplify a segment of the gene and RFLP involved use of enzymes to digest SNPs for visualization by electrophoresis. 25 genotyped samples show 22 samples with SNP M1 (88%) and 8 samples with SNP M2 (33%). These M1 and M2 frequencies are higher than shown in other groups. These data represent only 25% of the study's total participants. Once all data is collected, a case v. control comparison may show correlation between these parameters and breast cancer incidence. Contributors to this study are Maira Caleffi, Ana Paula Wernz C. Muller, and Chris A. Erdmann.

**Structure/Function Analysis of ErbB2's Ability to Disrupt Epithelial Apical-Basal Cell Polarity**

A. V. Lucs,[1,2] S. K. Muthuswamy[1]; [1]Cold Spring Harbor Laboratory, Cold Spring Harbor, NY, [2]SUNY Stony Brook, Stony Brook, NY

ErbB2/Her2/Neu is a receptor tyrosine kinase that is overexpressed in 25-30% of breast cancers and correlates with poor clinical prognosis in node-positive patients. Since ErbB2 has no known peptide ligand, we have previously developed a small molecule dimerization strategy to inducibly activate ErbB2. Using this system, we have shown that ErbB2 has the ability to transform polarized epithelial cells by promoting proliferation and disrupting the apical-basal polarity. To gain insight into the mechanism by which ErbB2 transforms polarized epithelia, we are investigating the role played by specific autophosphorylation sites in ErbB2. MDCK cells expressing mutants of ErbB2 that either lack one autophosphorylation site or possess only one autophosphorylation site are being generated and analyzed. Funding supported by DOD Breast Cancer Research Program DAMD17-03-1-0196.

**LIMD1 is a Novel Regulator of Bone Homeostasis**

H. Luderer, S. Bai, E. Morgan, K. Weilbaecher, G. Longmore; Washington University in St. Louis, St. Louis, MO

Bone remodeling is regulated by the coordinated activity of two cell types, osteoclasts (OC) and osteoblasts (OB). Osteoclasts are highly migratory cells that adhere to bone causing localized bone resorption. Osteoblasts balance this destructive activity by creating new bone. Osteoblasts also contribute to OC development by secreting factors (RANKL/OPG) inducing/inhibiting OC differentiation. Therefore, these highly specialized cell types exist in a delicate equilibrium that, when disrupted, results in pathologic consequences such as osteoporosis, arthritis, and tumor metastasis to bone. Recently, the cytosolic LIM protein Ajuba was found to contribute to IL-1-induced NF-kB and AP-1 activation by influencing the assembly/activity of an atypical protein kinase C (aPKC)/ p62-sequestosome/ TRAF6 complex (Feng and Longmore, MCB, 2005). Ajuba's closest relative, LIMD1, also interacts with the aPKC/p62/TRAF6 complex, contributing to RANKL (IL-1 related)-induced OC differentiation by affecting AP-1 activation. When LIMD1-/- mice were challenged with intra-arterial tumor injections they were protected from development of bone metastasis. Similarly, in a model of serum-induced inflammatory arthritis LIMD1 -/- mice developed fewer destructive bone lesions than wild type (wt) mice. Dysfunction of OC, OB, or both could explain these results. While LIMD1-/- mice indeed exhibit an OC defect, we found, surprisingly, that they also have a defect in OB development and function. Osteoblasts isolated from LIMD1-/- mice display increased mineralization, but support reduced OC differentiation, compared to wt controls. RT-PCR analysis of gene expression profiles during OB differentiation revealed that LIMD1-/- OB secrete less RANKL and more OPG. These data suggest an important role for the Ajuba/Zyxin family of LIM proteins in maintaining bone homeostasis under stress conditions. Understanding the mechanisms involved in maintaining the equilibrium between OC and OB will undoubtedly provide novel therapeutic targets for the potential treatment of arthritis, cancer, and other diseases of the bone.

**CHIP Ubiquitinates Parkinson's Disease-associated L166P Mutant DJ-1 in a Chaperone-independent Manner**

J. A. Olzmann, J. W. Pridgeon, L. Li, L. S. Chin; Pharmacology, Emory University, Atlanta, GA

Mutations in the ubiquitously expressed dimeric protein DJ-1 have recently been implicated in an autosomal recessive early-onset form of Parkinson's disease (PD). Our recent work demonstrates that the PD-associated L166P mutation disrupts DJ-1 protein folding, resulting in a spontaneously unfolded protein that is catalytically inactive and is incapable of dimerization. Furthermore, we find that the L166P mutant protein is rapidly polyubiquitinated and targeted for degradation by the proteasome. The molecular mechanism by which the L166P mutant protein is specifically recognized and earmarked for ubiquitination and subsequent degradation is currently unknown. Here we report that L166P mutant, but not wild-type DJ-1, specifically interacts with the U-box type E3 ubiquitin-protein ligase CHIP (carboxyl terminus of the Hsc70-interacting protein). CHIP has been shown to cooperate with the molecular chaperone Hsp70 in the recognition and ubiquitination of several misfolded proteins. Interestingly, our data indicate that, unlike the known CHIP substrates, L166P mutant DJ-1 does not interact with Hsp70. By using an *in vitro* reconstituted ubiquitination assay with recombinant proteins, we show that CHIP facilitates the ubiquitination of L166P mutant DJ-1 in the absence of chaperones. Ubiquitinated L166P mutant proteins migrate as a high molecular weight smear, indicating that CHIP mediates the polyubiquitination of the mutant DJ-1. Our findings suggest that, in addition to the well-known chaperone-dependent E3 ligase activity, CHIP can also directly ubiquitinate some substrates in a chaperone-independent manner. Further characterization of the molecular events that control the selective ubiquitination and degradation of misfolded or damaged proteins should enhance our understanding of the pathogenesis of PD and related neurodegenerative disorders. Supported by NIH Grant AG021489 and NS047199.

**Neuroprotective Function of the Mitochondrial Protease HtrA2/Omi**

K. Klupsch,[1] H. Plun-Favreau,[1] M. Martins,[2] S. Brandner,[3] J. Downward[1]; [1]Cancer Research UK, London Research Institute, London, United Kingdom, [2]MRC Toxicology Unit, Leicester, United Kingdom, [3]Institute of Neurology, London, United Kingdom

The mitochondrial serine protease HtrA2 (also known as Omi) is released from the intermembrane space during apoptosis. Once in the cytosol, HtrA2 has been implicated in enhancing cell death. However, HtrA2 knock out mice show no evidence of reduced rates of cell death. On the contrary, these animals suffer loss of a population of neurons in the striatum resulting in a parkinsonian syndrome. This phenotype suggests that it is the protease function of this protein in the mitochondria, and not its pro-apoptotic action in the cytosol, that is critical. Recently, two HtrA2 point mutations have been identified in Parkinson's disease (PD) patients. These mutations seem to result in partial loss of proteolytic activity, possibly contributing to the etiology of PD in these patients. Mammalian HtrA2 may therefore function in vivo in a manner similar to its bacterial homologues DegS and DegP, which are involved in protection against cell stress. DegS senses unfolded proteins in the bacterial periplasm, activating a proteolytic cascade that results in the transcriptional upregulation of stress response genes. Because of this homology, we decided to test the response of wild type and HtrA2 knock out cells to mitochondrial stress stimuli. Our approach involved transcriptional profiling of mouse embryonic fibroblasts (MEFs) derived from wild type and HtrA2 knock out mice. Mitochondrial stress was triggered with rotenone, a complex I inhibitor of the respiratory chain known to induce a parkinsonian phenotype in mice. Using this approach, we have identified several genes that are differentially regulated in mouse cells. We conclude that mitochondrial HtrA2 might function in a manner similar to its bacterial homologues by protecting the mitochondria under stress conditions. The compromise of this function might result in increased neuronal cell death and contribute to neurodegenerative diseases like Parkinson's disease.

**Role of Parkin's Conformation in Interaction with UbcH7**

V. A. Hristova,[1] R. J. Rylett,[2] G. S. Shaw[1]; [1]Biochemistry, University of Western Ontario, London, ON, Canada, [2]Cell Biology, Robarts Research Institute, London, ON, Canada

Autosomal Recessive Juvenile Parkinson's (ARJP) is a neurodegenerative disorder that affects dopaminergic neurons of the substantia nigra. Neurodegeneration is correlated with a variety of truncation and point mutations in the 465 amino acid protein known as parkin. It has been

suggested that parkin functions as a ubiquitin ligase (E3), and in so doing can interact with ubiquitin conjugating enzymes (E2) such as UbcH7 and UbcH8. The present study focuses on the *in situ* and *in vitro* nature of parkin interactions with UbcH7 to obtain a better understanding of the role that this may have in neurodegenerative processes. Parkin expression and purification was achieved in both HEK 293 (human embryonic kidney) and SH-SY5Y (human neuroblastoma) cells, as was heterologously and endogenously expressed UbcH7. A wide range of experimental approaches were used in this study, including GST-pull down assays, immunoprecipitation (IP), and fluorescence resonance energy transfer (FRET) to monitor interaction of parkin with UbcH7. Current studies are focused on the conformational changes induced in parkin by metal ions, EDTA, and interaction with proteins such as UbcH7 by applying methods like circular dichroism. Purified parkin required for these studies has been obtained from bacterial-lysates containing the parkin-GST fusion protein. Conditions that optimize bacterial growth and parkin expression, as well as the development of a series of chromatography steps that yield pure protein, have been identified. Changes in the secondary structure of parkin's RING domains in the presence of EDTA may reveal key conformations responsible for interaction with UbcH7 and other E2 proteins.

**Molecular Characterization of Pathogenic Amino Acid Substitutions within the PARK8 Gene, *LRRK2***

J. P. Taylor, J. Dachsel, S. Lincoln, I. F. Mata, J. Kachergus, J. Johnson, M. J. Farrer; Neuroscience, Mayo Foundation, Jacksonville, FL

Parkinson's disease is one of the most common neurological diseases affecting 1.8% population over 65. Genetics plays a significant role in parkinsonism as well as other forms of neurodegeneration. Pathogenic mutations in six genes are implicated in monogenic Parkinson's disease although their functional roles in the pathways of this disorder are unknown. We recently identified seven pathogenic mutations in LRRK2 (leucine rich repeat kinase 2) that maps to chromosome 12q12 (PARK8). Patients with LRRK2 mutations exhibit clinical features similar to the classic Parkinson's disease phenotype, but intriguingly their pathology is heterogeneous and may include Lewy bodies and tau inclusions, classical hallmarks of many neurodegenerative disorders. Lrrk2 is a predicted novel protein kinase. It is highly conserved among vertebrates. In addition to the MAPKKK domain Lrrk2 has predicted leucine rich repeat, Rab-like GTPase and WD40 functional domains. Here we present initial functional characterization of the Lrrk2 protein using cell biology techniques. We showed, using homology modeling to predict the structure of the Lrrk2 domains, that deleterious mutations are located within critical conserved regions of the predicted kinase and GTPase domains. We have used epitope tagged wildtype and mutant expression constructs to demonstrate that Lrrk2 subcellular localization is not altered by pathogenic mutations in BE(M17) neuroblastoma cell lines and investigated the putative kinase activity of Lrrk2 using immunoprecipitation kinase assays. We present here that Lrrk2 is capable of kinase activity but that targets in the MAPKKK pathway such as MKK 4 and 7 are not substrates for Lrrk2. Data will be presented to demonstrate the effect of pathogenic amino substitutions on Lrrk2 kinase activity. Modulation of kinase activity in LRRK2 associated Parkinson's disease represents a powerful target for future drug development; agents that promise symptomatic benefit by halting disease progression.

**Investigating Potential Bacterial Sources of Dopaminergic Neuron Toxicity in *C elegans***

S. B. Memon, J. Armagost, T. Hodges, J. B. Olson, G. A. Caldwell, K. A. Caldwell; Biological Sciences, The University of Alabama, Tuscaloosa, AL

Parkinson's disease (PD) involves the progressive loss of dopamine (DA) neurons from the *substantia nigra pars compacta*. Genetic forms of PD account for only 5-10% of known cases and environmental factors appear pivotal to sporadic causality. Evidence from both environmental and genetic forms of PD indicates that overloading the ubiquitin-proteasome system is a causative risk factor for PD. Furthermore, when proteasome inhibitors were injected directly into the brains of rats, PD-like symptoms resulted (McNaught et al., 2004; *Ann Neurol.* 56:149-162). Many proteasome inhibitors were originally isolated from bacterial strains within the order Actinomycetales. There is a high rate of sporadic PD among patients from rural backgrounds, where well water and farming potentially represent sources of increased exposure to Actinomycetes. To determine if exposure to Actinomycetes could cause dopaminergic neurodegeneration, we exposed the soil nematode, *C. elegans*, expressing a GFP reporter in dopaminergic neurons (*dat-1*::GFP), to four species of *Streptomyces* (*S. lividans, S. venezuelae, S. griseus*, and *S. coelicolor*). Interestingly, when *dat-1*::GFP worms were grown on *S. lividans* and *S. venezuelae*, they displayed dopminergic neurodegeneration that increased over time, wherein at 4 days exposure 52% and 59% of dopaminergic neurons were abnormal, respectively, compared to 19% of worms grown on *E. coli* OP50. Neurodegeneration was found to be specific to dopaminergic neurons following exposure to *S. lividans* and *S. venezuelae*. Currently, we are testing enriched media to determine whether neurodegeneration will be enhanced. Additionally, we are analyzing worms exposed to these *Streptomyces* strains for more generalized stress responses and are attempting to purify the factors responsible for dopamineric neurodegeneration. Future studies will include examining a combination of environmental and genetic stressors, wherein we will assay *C. elegans* with genetic backgrounds linked to PD following exposure to Streptomycetes and other Actinomycetes.

2148

**Hypothesis-based RNAi Screening in *C elegans* to Identify Genes Associated with Parkinson's Disease**

K. A. Caldwell, S. Hamamichi, M. L. Norris, G. A. Caldwell; Biological Sciences, The University of Alabama, Tuscaloosa, AL

Parkinson's Disease (PD) is the second most common neurodegenerative disorder. Recent progress in understanding familial forms of PD has identified several gene products that, when mutated, may result in protein mishandling and oxidative stress. For example, mutated or overexpressed alpha-synuclein forms aggregates, and ultimately results in a formation of the characteristic protein inclusion bodies called Lewy bodies, the clinical hallmark of PD. We have exploited the advantages of the transparent nematode, *C. elegans*, to systematically screen for factors that affect alpha-synuclein misfolding in vivo. We have employed RNAi feeding methodology using bacteria producing dsRNA targeting specific genes to screen for genetic factors influencing the misfolding of a human alpha-synuclein::GFP fusion as worm age. Candidate genes implicated in the function of the ubiquitin-proteasome system (UPS), ER-associated degradation (ERAD) pathway, unfolded protein response (UPR), and autophagy were screened. Furthermore, using the mature bioinformatics available for *C. elegans*, candidate genes indentified from microarray co-expression (Stanford Topology Map) and protein interaction (interactome) data for worm homologs of PD-associated proteins, such as DJ-1, Nurr1, PINK1, UCHL-1, parkin, and LRRK2 were also tested. From over 900 total targets, we identified 17 positive genes that result in increased alpha-synuclein misfolding. As a secondary test for putative relationships to PD, we have thus far shown that 2 of these alpha-synuclein effectors can protect *C.*

*elegans* dopaminergic neurons from oxidative damage and neurodegeneration when their corresponding cDNAs are overexpressed in transgenic nematodes. Further analysis is underway to determine if these proteins also exhibit protection against alpha-synuclein dependent degeneration of dopaminergic neurons. In all, this strategy provides a paradigm for the investigation of cellular factors that influence protein misfolding and management of intracellular stress associated with human movement disorders.

**Budding Yeast Model for α-Synuclein: Increased Toxicity Linked to Ubiquitin-Proteasome Pathway Dysfunction, Oxidative Stress, and E46K Mutant**

T. Vaidya, K. Brandis, N. Sharma, S. Herrera, T. Saylawala, M. Vahedi, S. Vahedi; Lake Forest College, Lake Forest, IL

Parkinson's disease (PD) is a common neurodegenerative disorder that results from the selective loss of midbrain dopaminergic neurons. Misfolding and aggregation of the protein α-synuclein, oxidative damage, and proteasomal impairment are all hypotheses for the molecular cause of this selective neurotoxicity. Here, we describe a *Saccharomyces cerevisiae* model to evaluate the misfolding, aggregation, and toxicity-inducing ability of wild-type α-synuclein and three mutants (A30P, A53T, and A30P/A53T) and we compare regulation of these properties by dysfunctional proteasomes and oxidative stress. We found prominent localization of wild-type and A53T α-synuclein near the plasma membrane, supporting known *in vitro* lipid-binding ability. In contrast, the A30P was mostly cytoplasmic, while A30P/A53T displayed both types of fluorescence. Surprisingly, these forms of α-synuclein were not toxic to several yeast strains tested. In contrast, the new familial mutant E46K was strongly toxic to several strains, and displayed both plasma membrane localization and cytoplasmic aggregates. When yeast strains mutant for the proteasomal barrel (*doa3-1*) were evaluated, delayed α-synuclein synthesis and membrane association was observed; while strains mutant for the proteasomal cap (*sen3-1*) exhibited increased accumulation and aggregation of α-synuclein. Both *sen3*-1and *doa3-1* mutants exhibited synthetic lethality with α-synuclein. When yeasts were challenged with an oxidant (hydrogen peroxide), α-synuclein was extremely lethal to cells that lacked manganese superoxide dismutase Mn-SOD (*sod2Δ*), but not to cells that lacked copper, zinc superoxide dismutase Cu,Zn-SOD (*sod1Δ*). Despite the toxicity, *sod2Δ* cells never displayed intracellular aggregates of α-synuclein. We suggest that the toxic α-synuclein species in yeast are smaller than the visible aggregates and toxicity may involve α-synuclein membrane association. Thus, yeasts have emerged effective organisms for characterizing factors and mechanisms that regulate α-synuclein toxicity. (Supported by NSF-MRI, NSF-CCLI & NIH R15)

**Fission Yeast Model for α-Synuclein: Concentration-Dependent Aggregation Without Plasma Membrane Localization or Toxicity**

K. A. Brandis, I. Holmes, S. England, L. Kukreja; Biology, Lake Forest College, Lake Forest, IL

Despite fission yeast's history of modeling salient cellular processes, it has not yet been used to model human neurodegeneration-linked protein misfolding. Since α-Synuclein misfolding and aggregation are linked to Parkinson's disease, here, we report a fission yeast (*Schizosaccharomyces pombe*) model that evaluated α-synuclein misfolding, aggregation, and toxicity and compared these properties with those recently characterized in budding yeast (*Saccharomyces cerevisiae*). Wild-type α-synuclein and three mutants (A30P, A53T, and A30P/A53T) were expressed with thiamine-repressible promoters (using vectors of increasing promoter strength pNMT81, pNMT41, pNMT1) to test directly in living cells the nucleation polymerization hypothesis for α-synuclein misfolding and aggregation. In support of the hypothesis, wild-type and A53T α-synuclein formed prominent intracellular cytoplasmic inclusions within fission yeast cells in a concentration- and time-dependent manner, whereas, A30P and A30P/A53T remained diffuse throughout the cytoplasm. A53T α-synuclein formed aggregates faster than wild-type α-synuclein and at a lower α-synuclein concentration. Unexpectedly, unlike in budding yeast, wild-type and A53T α-synuclein did not target to the plasma membrane in fission yeast, not even at low α-synuclein concentrations or as a precursor step to forming aggregates. Despite α-synuclein's extensive aggregation, it was surprisingly non-toxic to fission yeast; future genetic dissection may yield molecular insight into this protection against toxicity. We speculate that α-synuclein toxicity may be linked to its membrane binding capacity. To conclude, *S. pombe* and *S. cerevisiae* model similar yet distinct aspects of α-synuclein biology, and both organisms shed insight into α-synuclein's role in PD pathogenesis. (Supported by NSF-MRI, NSF-CCLI & NIH R15)

**Characterization of a Novel Interaction between Parkin and Ataxin-3**

T. E. Thorarinsdottir,[1] T. Fantaneanu,[1] L. Fallon,[1] G. A. Rouleau,[2] E. A. Fon[1]; [1]Centre for Neuronal Survival, Montreal Neurological Institute, Montreal, PQ, Canada, [2]Centre for Research in Neuroscience, McGill University Health Centre Research Institute, Montreal, PQ, Canada

Parkinson´s Disease (PD) is a neurodegenerative disease that involves the death of dopamine neurons and leads to devastating motor and functional impairments. One of the genes identified to cause a familial form of PD is *parkin*. *Parkin* encodes for parkin, an E3 ubiquitin ligase, and loss of parkin activity can lead to the accumulation of toxic proteins and result in the death of susceptible neurons. It is important to identify proteins that can alter parkin activity in order to develop new therapeutic targets for PD. We have identified Ataxin-3 (Atx3) as a novel parkin interacting protein, which may modulate parkin's activity. Mutations in Atx3 have long been known to result in another neurodegenerative disease, Machado-Joseph disease (MJD). MJD is the most common dominantly inherited ataxia worldwide and occasionally presents with features of parkinsonism. Using *in vitro* pulldowns and co-immunoprecipitation, we have shown that parkin and Atx3 interact in a bimodal fashion, with the N-terminal Ubiquitin like domain (UBL) of parkin interacting with Atx3 Ubiquitin interacting motifs (UIMs), as well as the C-terminal in-between-RING region of parkin interacting with the N-terminal Josephin domain of Atx3. Further, we have confirmed previous reports of Atx3 harboring deubiquitinating activity within its Josephin domain and shown that Atx3 is specifically able to deubiquitinate *in vitro* auto-ubiquitinated parkin. These results indicate a role for Atx3 in modulating parkin's E3 ligase activity and we have identified a specific substrate of Atx3 deubiquitinating activity. Further characterization of this interaction will provide important clues about the pathogenesis of the two diseases and could potentially lead to innovative new therapeutic targets.

2152

**Functional Redundancy Between Parkin and HHAri: Implications for Neurodegenerative Disorders**

S. S. Parelkar,[1] C. Kim,[1] J. Cadena,[1] Z. Wang,[1] R. Sugal,[1] B. Pazik,[2] L. M. Schwartz[1,2,3]; [1]Molecular and Cellular Biology Program, University of

Massachusetts, Amherst, MA, [2]Pioneer Valley Life Sciences Institute, Springfield, MA, [3]Department of Biology, University of Massachusetts, Amherst, MA

Some patients with Autosomal Recessive Juvenile Parkinson's disease (ARJP) carry loss of function mutations in the gene encoding the ubiquitin E3 ligase Parkin. In contrast to Parkinson's disease, surviving dopaminergic neurons in ARJP do not form Lewy bodies, abnormal cytoplasmic inclusions rich in misfolded proteins. Given the global loss of Parkin in ARJP it is not clear why phenotypic consequences are largely restricted to dopaminergic neurons. One hypothesis is that another protein with redundant Parkin functions can substitute for Parkin in most cells. Candidates for such a redundant protein should meet a number of basic criteria. First, it should be a ubiquitin E3 ligase and bind to the same E2 conjugases as Parkin. Second, it should bind to many of the same cellular substrates as Parkin. Third, it should be able to facilitate the formation of aggresomes/Lewy bodies with the same properties as Parkin-induced aggresomes. Lastly, it should be widely expressed in the nervous system but significantly reduced in dopaminergic neurons. Using biochemical, cell culture and *in vivo* assays, we have found that the Human Homolog of Drosophila Ariadne-1 (HHAri) meets all of these criteria. Also, HHARI is a component of Lewy bodies in Parkinson's disease. These data suggest that redundancy in Parkin functions may partially account for the lineage-restricted defects observed in ARJP.

2153

**Analysis of Parkin and Tau Double Mutant Mice: Parkin as a Possible Modifier of the Risk of Tauopathy**

R. Guerrero,[1] P. Navarro,[1] E. Gallego,[1] J. Avila,[2] J. G. de Yebenes,[1] M. P. Sanchez[1]; [1]Neurology, Fundacion Jimenez Diaz-Capio, Madrid, Spain, [2]CSIC/UAM, Centro de Biologia Molecular "Severo Ochoa", Madrid, Spain

*Park-2* gene mutations are frequently found in autosomal recessive-juvenile parkinsonism (AR-JP). In other familial parkinsonisms, mutations in the *tau* gene have been reported. However, heterozygous *Park-2* mutations and haplotypes and polymorphisms of both genes constitute risk factors to develop tauopathies in the normal population. Thus, a defective interaction between parkin and tau could cause neurodegenerative diseases. In mouse models, *Park-2* gene deletion or tau mutations produce mild phenotypic alterations. However, the combination of both mutations may trigger the appearance of tau pathology. To study this possibility we generated a double mutant mouse deficient for *Park-2* expression and overexpressing a human mutant *tau* transgene. We analyzed the development and behavior of these mutants, and the macro- and microscopic aspects of young brains. We also analyzed the levels of tau expression and phosphorylation in brain sections and in protein extracts of young mutant mice. Mice develop normally and do not show any clinical deficit. We did not observed evident neuronal loss throughout the brain. However, the subcellular distribution of human tau is different. Moreover, we observed accumulation of endogenous hyperphosphorylated tau in neurons of cortex and hippocampus, regions also showing reactive astrocytosis. Levels of PHF-1 phosphorylated tau are increased in protein extracts from these regions while a tendency for an increase in GFAP expression was observed in hippocampus. Thus, the combination of *Park-2* deletion with tau transgene expression in young Park$^{-}$/Tau tg mouse brains aggravates the effects produced by each isolated mutation alone. Our results suggest that parkin, apart from being involved in AR-JP, may also be a modifier of the risk of tauopathy. Moreover, it is possible that patients with sporadic tauopathies have a combination of risk factors related with parkin and tau.

2154

**Regulation of Parkinson's Disease Protein α-Synuclein Ubiquitination by Siah-1 E3 ligase**

J. T. Lee,[1] T. C. Wheeler,[2] L. Chin,[1,2] L. Li[1,2]; [1]Department of Pharmacology, Center for Neurodegenerative Diseases, Emory University School of Medicine, Atlanta, GA, [2]Department of Pharmacology, School of Medicine, University of North Carolina, Chapel Hill, NC

Parkinson's disease (PD) is a movement disorder characterized by the degeneration of dopaminergic neurons in the substantia nigra. Dysregulation of the ubiquitin-proteasome pathway has been implicated as an important mechanism for PD pathogenesis. Lewy bodies, a pathological hallmark of PD, contain aggregated α-synuclein and ubiquitin. Point mutations (A53T, A30P, or E46K) and gene triplication of α-synuclein have been linked to early-onset autosomal dominant familial PD. Although ubiquitinated α-synuclein species have been found in Lewy bodies of PD patients, the molecular events that regulate α-synuclein ubiquitination remain poorly characterized. Here, we report that α-synuclein interacts with mammalian *seven in absentia homologue*-1 (Siah-1), a RING finger type of E3 ubiquitin-protein ligase. *In vitro* binding assays and coimmunoprecipitation studies demonstrate that α-synuclein and Siah-1 associate both *in vitro* and *in vivo.* Immunofluorescence confocal microscopic analyses reveal that α-synuclein colocalizes with Siah-1 and E2 ubiquitin-conjugating enzyme UbcH8 in mammalian cells. By using an in *vivo* ubiquitination assay, we show that Siah-1 facilitates the ubiquitination of α-synuclein, suggesting that α-synuclein is a substrate of Siah-1 E3 ligase. Interestingly, Siah-1-mediated ubiquitination does not appear to target α-synuclein for degradation by the proteasome. Further investigation of the functional consequences of Siah-1-mediated ubiquitination may provide insight into the molecular mechanisms by which ubiquitination regulates neurotransmission and neurodegeneration. Supported by NIH Grant AG021489 and NS047199.

**Nardilysin Enhances α-Secretase Activity for Amyloid Precursor Protein**

Y. Hiraoka, K. Yoshida, E. Nishi; Molecular Pathology Unit, Horizontal Medical Research Organization, Graduate School of Medicine, Kyoto University, Kyoto, Japan

Alzheimer's disease (AD) is associated with excessive deposition of amyloid-β (Aβ) peptide in the brain. The putative α-secretase cleaves the amyloid precursor protein (APP) and produces soluble fragment (sAPPα) and carboxyl-terminal fragment (C83). The cleavage occurs within the Aβ sequence, so that an enhancement of α-secretase may prevent the progression of AD. Three members of ADAMs (a disintegrin and metalloprotease), ADAM9, ADAM10 and ADAM17/ tumor necrosis factor-α converting enzyme (TACE), are the main candidates for α-secretases. Recently, we have demonstrated that nardilysin (N-arginine dibasic convertase; NRDc) enhances ectodomain shedding of heparin-binding epidermal growth factor-like growth factor (HB-EGF) through activation of TACE (manuscript in submission). In this study, we examined the effect of NRDc on α-secretase activity for APP. APP were transiently transfected into COS7 cells with NRDc or/and TACE. After 24 h of transfection, the amount of sAPPα in the conditioned medium and C83 in the cell lysates were detected by ELISA and immunoblot analysis, respectively. NRDc expression in concert with TACE dramatically increased both sAPPα and C83, compared to a sole expression of TACE. Peptide cleavage assay *in vitro* also showed that recombinant NRDc enhanced TACE-induced cleavage of the peptide substrate corresponding to α-secretase cleavage site. These results indicated that NRDc enhances α-secretase activity for APP via activating TACE. Moreover, co-expression

experiment showed that NRDc enhances α-secretase activity for APP induced by other ADAMs, such as ADAM9, ADAM10 or ADAM12. The result suggests that NRDc is an activator for wide range of ADAMs and regulates α-secretase activity. Together, our findings identify NRDc as a potent activator of α-secretases for APP, and may lead to a novel strategy for the treatment of AD.

2156

**Role of Lysosomal pH in the Degradation of Fibrillar Forms Alzheimer's Amyloid β Peptide in Microglial Cells**

A. Majumdar, N. Asamoah, D. Cruz, F. R. Maxfield; Biochemistry, Weill Medical College of Cornell University, New York, NY

Microglia are phagocytic cells that play a major role in the clearance of fibrillar forms Alzheimer's amyloid β peptide (fAβ). Microglia internalizes fAβ and delivers it to late endosomes and lysosomes, but degradation of the fAβ is slow and incomplete. To investigate the reason for this inability to degrade fAβ we monitored the degradation of fAβ by microglia and macrophages using quantitative fluorescent microscopy. We also looked into the role of lysosomal pH in controlling this fAβ degradation. **Methods:** fAβ was labeled with Cy3 dye. Microglia and Macrophage cells were pulsed with Cy3 fAβ and were chased for different time periods. After the chase periods the loss in Cy3 intensity in the cells were monitored to evaluate the extent of fAβ degradation. Microglia cells were also treated with various proinflammatory reagents and the Cy3 fAβ degradation was monitored after these treatments. For lysosomal pH measurement the cells were loaded with Fluorescein, Rhodamine double labeled dextran and pH was determined by calculating the ratio of Rhodamine to Flourescein fluorescence. **Results:** Cy3 fAβ degradation experiments show that in contrast to the microglia, macrophages can degrade fAβ efficiently and completely. Although primary culture of microglia does not degrade fAβ but when activated by proinflammatory reagents microglia start to degrade fAβ. Lysosomal pH measurements in microglia and macrophages show that microglia has alkaline lysosomes compared to the macrophages and the proinflammatory reagents which make the microglia degrade fAβ also makes the microglial lysosomes more acidic. **Conclusion:** Unlike microglia macrophages can degrade fAβ efficiently. The alkaline pH of the lysosomes of the microglia can be an important factor for this inefficiency. When activated by proinflammatory reagents lysosomes of microglia becomes acidic thus making them capable of degrading fAβ.

2157

**Tau Dependent Microtubule Depolymerization Induced by β-amyloid**

M. E. King,[1] C. G. Glabe,[2] G. S. Bloom[1]; [1]Biology, University of Virginia, Charlottesville, VA, [2]Molecular Biology and Biochemistry, University of California at Irvine, Irvine, CA

Aberrantly folded proteins that polymerize into insoluble filaments form the two histopathological hallmarks of Alzheimer's disease (AD): extracellular plaques of ß-amyloid (Aß) peptides and intracellular neurofibrillary tangles made from the microtubule associated protein, tau. A growing body of evidence suggests that AD progression involves amyloid pathology leading downstream to tau pathology, but details of this putative mechanistic connection have remained obscure. We have modeled the potential link between amyloid and tau pathologies by co-expressing YFP-tubulin and CFP-tau in CV-1 cells, exposing the cells to various forms of Aß, and monitoring cellular responses by time-lapse fluorescence microscopy. Aß was prepared in vitro to form oligomers that are recognized by a conformation-specific antibody that detects early AD histopathology in vivo. At concentrations as low as 500 nM, oligomeric and pre-oligomeric Aß42 caused microtubules to depolymerize within one hour in tau expressing cells, but had no effects on cells that did not express tau. Similarly Aß40 also caused tau-dependent microtubule disassembly, but only at 3-5 fold higher concentrations. In contrast, fibrillar Aß42 and Aß40 did not cause microtubule disassembly in tau-expressing cells, even at much higher concentrations. Microtubules were insensitive to Aß in cells expressing fluorescent forms of the tau-related proteins, MAP2c or MAP4. These collective results suggest that oligomeric and pre-oligomeric Aß, rather than fibrillar Aß deposits, are the most toxic ß-amyloid species in AD, that oligomeric and pre-oligomeric Aß compromise neuronal health by tau-dependent disruption of microtubules, and that neurons are specifically targeted in AD because they are the only brain cell type that accumulates high levels of tau.

2158

**Herpes Virus and Amyloid Precursor Protein: Co-option of Cellular Transport Machinery for Viral Egress, a Multi-disciplinary Analysis**

E. L. Bearer,[1,2] R. E. Jacobs,[3] M. P. Conley,[1,2] P. Ferland,[1] M. Jang,[1,2] I. Burgos,[1,2] J. W. Au[1,2]; [1]Pathology and Laboratory Medicine, Brown University Medical School, Providence, RI, [2]Marine Biological Laboratory, Woods Hole, MA, [3]California Institute of Technology, Pasadena, CA

Herpes simplex virus (HSV) is a neurotropic virus that must travel both into and away from the neuronal cell body to reach the mucosal epithelium where it disseminates. We have reconstituted HSV transport in both anterograde and retrograde directions in the giant axon of the squid. We found that the virus interacts with cellular amyloid precursor protein (APP) with high affinity, with an average of 3,000 copies of APP associated with isolated viral particles displaying anterograde transport capability. By conjugating the cytoplasmic domain of APP to 100- nm fluorescent beads we have identified a "zipcode" for the synapse, a 15 amino acid peptide that is sufficient to interact with the axoplasmic transport system and deliver beads to the presynaptic terminal. APP-conjugated beads interact with high affinity to kinesin heavy chain in rat brain extracts ($K_D$ ~ 5 nM). The sequence of the APP peptide is highly conserved throughout phylogeny, with 13/15 identities between squid and human. Using deconvolution microscopy for quantitative intensity analysis of fluorescence images, we now show that HSV infection up-regulates APP expression. Nascent viral particles co-localize with APP in infected cells, with initial associations in the Golgi region but others apparently occurring throughout the egress pathway. We are now exploring micro-MRI to image viral trajectories in the living brains of mouse models through development of novel MR contrast agents and high resolution detection schemes. These results suggest that APP is a cargo motor receptor for HSV egress, and that HSV infection may be a risk factor for Alzheimer's disease. Supported by NINDS, NIGMS, The Moore Foundation, and the Dart Foundation.

**Alzheimer's Dementia is Due to Faulty, Endoplasmic Reticulum (ER), Posttranslational, Protein Processing**

J. L. Holtzman,[1] R. R. Erickson,[1] L. M. Dunning,[1] D. A. Olson,[2] S. J. Cohen,[3] A. T. Davis,[4] W. G. Wood,[1] R. A. Kratrzke[5]; [1]Pharmacology, University of Minnesota, Minneapolis, MN, [2]Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN, [3]Anesthesia, University of Minnesota, Minneapolis, MN, [4]Research, Veterans Administration Medical Center, Minneapolis, MN, [5]Medicine, University of Minnesota, Minneapolis, MN

**Background:** The β-amyloids (abetas) (MW ≥ 4.7 kDa) are the major components of the plaque observed in the brains of Alzheimer's patients.

The conundrum is that although they are produced in everyone during normal, ER, posttranslational processing of the amyloid precursor protein (APP), deposits are only seen in the brains of the elderly. Since in plaque the abetas are present as the free peptides, this observation would suggest that normally they are bound to carrier proteins. **Methods:** We analyzed by immunoblot with multiple antibodies the abetas in cerebrospinal fluid from normal humans. **Results:** In SDS-reducing gels all the detectable abetas have a Mr = 62 kDa and are bound to ERp57. The complex was stable when treated with neat formic or TFA acids. On the other hand, when these acids have been used to solubilize plaque, only the naked abetas have been reported. The complex was hydrolyzed by base (pH 9.0). In native gels the abetas chaperone complex had a Mr = 130 kDa and contained both ERp57 and calreticulin. **Conclusions:** Our data indicate that abetas deposits result from faulty, ER, posttranslational processing of APP with the failure to form a complex with the chaperones. This may be due to decreased levels of the chaperones. Alternatively, since ERp57/calreticulin only bind N-glycosylated proteins, there may also be decreased N-glycosylation with aging, as has been reported from other laboratories. Since the initiation, consolidation and retrieval of memory are dependent upon the continued synthesis of synaptic, membrane proteins, if their processing is similarly affected, it could explain the failure to form new synapses leading to the dementia characteristic of Alzheimer's disease.

**Neuroendocrine Innate Immunity as an Early Marker of Alzheimer's Disease: Results from a 18-Month Follow-up Study**

P. Prolo,[1] F. Chiappelli,[1] A. Angeli,[2] P. Perotti,[2] M. Pautasso,[3] M. Sartori,[2] A. Dovio,[2] T. Fraccalini,[4] L. Saba,[2] S. Mussino,[2] F. Fantò,[4] M. Rosso,[5] C. Mocellini,[5] E. Grasso[5]; [1]Dentistry, UCLA, Los Angeles, CA, [2]Internal Medicine, University of Turin, A.S.O. S. Luigi Gonzaga, Orbassano, Italy, [3]Flow Cytometry, University of Turin, A.S.O. S. Luigi Gonzaga, Orbassano, Italy, [4]Geriatrics, University of Turin, A.S.O. S. Luigi Gonzaga, Orbassano, Italy, [5]Neurology, A.S.O. S. Croce & Carle, Cuneo, Italy

We designed a longitudinal study to address NK cell activity as a prognostic factor in Alzheimer's disease (AD). We followed 18 subjects (61-84 years old) with mild AD under treatment with Donezepil (10 mg/daily), and 10 healthy control subjects (59-84 years old). Change in time for MiniMental State Examination (MMSE) was analyzed in parallel to immunophenotypic parameters of T cells, and response of NK activity to physiological modulation. Psychoimmune measures were obtained at entry and at six months intervals for 18 months. NK activity was assessed untreated and after modulation by cortisol at $10^{-6}$M. We tested augmentation of NK cytotoxicity by interleukin (IL)-2 (100 IU/ml). Neither the percent of NK cells nor baseline NK cell activity were different in AD compared to controls at entry. Response to modulation by cortisol was significantly greater in AD. Change in circulating CD3+Dr+ population with time in AD was inversely correlated with the change in time in the response of NK cytotoxic activity to cortisol. Based on change in MMSE score at entry and at 18 months, AD subjects were assigned to a "fast progression" ($\Delta > 2$ points) or to a "slow progression" group ($\Delta \leq 2$ points). Change in response of NK cytotoxic activity to cortisol, and the association of this parameter with circulating activated T cells in time was greater in Fast Progression, compared to Slow Progression AD. Our findings reveal an increased sensitivity to cortisol in AD, which can be detected at the level of the cellular compartment of the immune system. Results suggest that changes in the response of NK cells to negative (e.g., cortisol) or positive modifiers (e.g., IL-2) follow progression of AD, and might be an adequate early marker of AD.

***In Vitro* Activity of the γ-secretase Complex is Dependent on the Nature of Lipid Environment**

S. Zhou, H. Zhou, P. J. Walian, B. K. Jap; Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA

γ-secretase was first recognized through its role in the production of Aβ peptides that are pathogenic in Alzheimer's disease (AD). γ-Secretase is a membrane protein complex with unusual aspartyl protease activity that cleaves a variety of type I transmembrane proteins, such as APP, CD44, DCC, ErbB4, E-cadherin, LRP, N-cadherin, Nectin-1, and Notch, within their transmembranous regions; therefore, in addition to its role in AD, γ-secretase has been found to participate in many other important biological functions, such as cell fate decision, cell-cell connections and intracellular signaling. Purification and characterization of active γ-secretase complex, and the availability of in vitro activity assays are crucial steps toward elucidating its molecular mechanism. We have initiated investigations into how different factors, such as detergent removal and lipids used, modulate the in vitro activity of γ-secretase complex. In our experiment the in vitro activity of γ-secretase is evaluated based on the cleavage of a synthetic fluorogenic peptide substrate containing a C-terminal fragment of APP. To complement the activity assay, we have also been examining the formation of proteoliposomes under different reconstitution conditions by electron microscopy. We have found that in vitro activity of γ-secretase complex directly correlates with the degree of proteoliposome reconstitution. Taken together, these observations indicate that the γ-secretase complex requires an appropriate lipid bilayer environment for its activity in vitro. This work was supported by the National Institutes of Health.

**Biochemical Characterization of Ubiquilin: Dimerization and Interaction with Presenilin-2**

D. L. Ford, M. J. Monteiro; Biochemistry, University of Maryland, Baltimore, Baltimore, MD

Mutations in presenilin (PS1 and PS2) genes are associated with early-onset Alzheimer's disease. The presenilin proteins have been implicated in various cellular processes, including early embryo development, proteolytic cleavage of amyloid precursor protein, protein trafficking, cell cycle control, neuronal differentiation and apoptosis. Previously we reported that presenilins interact with ubiquilin, a highly conserved protein containing ubiquitin-like (UBL) and ubiquitin-associated (UBA) domains. In addition to presenilins, ubiquilin interacts with several other proteins, and this interaction appears to regulate stability and degradation of its binding partners. We have investigated the mechanism of interaction of ubiquilin with presenilin-2. Overexpression of ubiquilin-1 leads to an increase in PS protein levels. Since ubiquitin (UB) binds substrates through isopeptide lysine linkages, and UBA domains of proteins are known to bind ubiquitin chains, we investigated whether mutation of lysine residues in PS2 would alter interaction with ubiquilin. A yeast 2-hybrid system and beta-galactosidase assay were utilized, using PS2-loop and -COOH terminal regions as bait and ubiquilin as prey. Results indicate that ubiquilin interaction with PS2 is not fully dependent on ubiquitination of PS2 polypeptides. Interestingly, we found that mutation of residues within the carboxy-terminus of PS2 affects interaction with ubiquilin. Some of these residues are predicted to be critical for presenilin function and stability. We also demonstrate that ubiquilin is capable of self-interaction, which may serve a regulatory role in ubiquilin's interaction with presenilins and other proteins. This interaction does not appear to require ubiquilin's UBA and UBL domains; rather it is dependent upon the central region of ubiquilin. We further show that ubiquilin forms dimers, and have

obtained preliminary evidence suggesting the monomer is likely to be the active form that is involved in binding other proteins.

2163

**Effect of Cortistatin on Tau Phosphorylation**

A. Rubio,[1] M. Perez,[1] L. Lecea,[2] J. Avila[1]; [1]Centro de Biologia Molecular Severo Ochoa, Madrid, Spain, [2]Molecular Biology, The Scripps Research Institute, La Jolla, CA

The principal cytoskeletal components in a neuron are the microtubules, formed by tubulin and microtubule-associated proteins (MAPs). These MAPs stabilize microtubules and may determine the complex morphology of a neuron. Tau is a MAP capable of forming aberrant fibrillar polymers when it is hyperphosphorylated in pathological situations such as Alzheimer´s disease (AD). AD is a senile dementia characterised by short memory acquisition and consolidation deficits. These deficits have been correlated with the development of the disease: first, entorhinal cortex and hippocampus (where probably occurs memory acquisition) are affected and, afterwards, a progressive degeneration is found in cortical neurons (where probably occurs memory consolidation). Moreover, the recently described neuropeptide cortistatin, whose expression is restricted to gamma amino butyric acid (GABA)-containing cells in the cerebral cortex and hippocampus, may be involved in the modulation of memory, probably by regulating the transition of information (through the sleep) from the hippocampus to the cortex. The purpose of this work is to indicate the effect of cortistatin on tau phosphorylation at specific sites, recognized by 12E8 and tau1 antibodies. It has been proposed that phosphorylation at these two sites could affect the interaction of tau with microtubules. Treatments with cortistatin of primary cortical cultures, from mice, reveal a slight decrease in tau1 immunoreactivity and a progressive increase in tau phosphorylation at the site recognized by 12E8. We also characterized tau phosphorylation in a mouse that do not express the cortistatin peptide (CST -/-). Our data suggest that tau1 immunoreactivity is higher in CST -/- mice than in control mice. In contrast, tau phosphorylation at the site recognized by 12E8 is lower in CST -/- mice. In conclusion, cortistatin seems to increase tau phosphorylation at 12E8 and tau1 sites suggesting that tau release from microtubules is facilitated.

2164

**Induction of Abnormal Phosphorylation of Tau Requires Sequential or Simultaneous Action of GSK3beta and CDK5**

M. Hashiguchi; Department of Physiology, Tokyo Medical University, Tokyo, Japan

One of the pathological hallmarks of Alzheimer's disease (AD) patient is abnormally phosphorylated tau protein. AT100, an AD-specific tau antibody, recognizes a particular set of phosphorylated residues of the pathological tau. These phosphorylation cannot be achieved by a single tau kinase, but multiple tau kinases are obviously required. Two powerful tau kinases, GSK3beta and CDK5, are found to co-exist in tau phosphorylation protein complex in brain. It seems that the two kinases phosphorylate tau simultaneously. We conducted in-vitro kinase assay using recombinant tau, p35-CDK5 and GSK3beta. Phosphorylation status of tau was analyzed by two-dimensional phosphopeptide mapping. Two peptides, Ser202/T205 and Ser396/Ser404, were phosphorylated by either GSK3beta or CDK5, while other peptides, as revealed by spots on the 2D-map, were independently phosphorylated. Simultaneous application of p35-CDK5 and GSK3beta gave seven major spots. The same spots were shown by the sequential application of p35-CDK5 and then GSK3beta. However, sequential application in the reverse order gave only six spots, and one is missing. These results suggest that the tau in the brain phosphorylation complex is sequentially processed by closely located two kinases.

**Evidence for Amyloid Induced Transport Defects Initiated by Mechanical Blockage within Neuronal Processes**

S. B. Shah,[1] L. S. B. Goldstein[1,2]; [1]Cellular and Molecular Medicine, University of California, San Diego, La Jolla, CA, [2]Howard Hughes Medical Institute at UCSD, La Jolla, CA

Dystrophic neurites surrounding amyloid plaques are a hallmark of late-stage Alzheimer’s. At earlier stages of disease progression, animal models display organelle-filled swellings along their neurites, suggesting constriction of typical neuronal motor-driven transport pathways. These models also reveal increases in the degradation-resistant beta-amyloid (Aβ) 1-42, observed in several stages of fibrillization near plaques and swellings. We tested the hypothesis that Aβ is responsible for the development and/or exacerbation of these transport defects, and that transport defects result from an early event of mechanical blockage. We induced swellings in mouse neuroblastoma and hippocampal neurites via internalization of artificial obstructions (fluorescent beads of varying diameter: 20nm-500nm) or Aβ in varying fibrillization states (i.e., with different geometries). Percentages of neurites exhibiting swellings were quantified at various time points (1-16 hours) after cell exposure to the impediments. Electron microscopy confirmed bead internalization. Bead diameter and the percentage of neurites exhibiting swelling showed a positive correlation, particularly at later time points. Neurites exposed to fibrillar Aβ displayed a similar swelling phenotype in a dose- and time-dependent manner, while peptide Aβ induced cell necrosis. Quenching of FITC-Aβ fluorescence confirmed Aβ internalization. Real-time imaging of neurites exposed to beads >200nm allowed insight into swelling formation dynamics. Within one hour of exposure to non-fluorescing beads, several neurites displayed swellings consistent with our observations in fixed cells. Partial neurite retraction was followed by dramatic shifts in the cytoskeleton, resulting in decreased neurite diameter adjacent to the swellings, and sometimes, motion of swellings themselves. Probability of swelling induction was enhanced by reactive oxygen species generated following fluorescing bead excitation, but was not enhanced in the presence of the oxygen depleting agent Oxyrase. Kinematic analysis of organelles tagged with APP-YFP confirmed transport impairment as swellings developed. Support: NIH, HHMI.

**Metalloendoprotease Cleavage Triggers the Final Stage of Gelsolin Amyloidogenesis**

L. J. Page, J. Suk, M. E. Huff, J. W. Kelly, W. E. Balch; Department of Cell Biology-MB6, The Scripps Research Institute, La Jolla, CA

Amyloid diseases like Alzheimer’s and Familial amyloidosis of Finnish type (FAF) stem from endoproteolytic cleavage of a precursor protein to generate amyloidogenic peptides that accumulate as amyloid deposits in a tissue specific manner. FAF patients deposit both 8 and 5 kDa peptides derived from mutant (D187Y/N) plasma gelsolin in the extracellular matrix (ECM). The first of two aberrant sequential proteolytic events is executed by furin to yield a 68 kDa (C68) secreted fragment. We now identify the metalloprotease MT1-MMP, an integral membrane protein active in the ECM, as a protease that processes C68 to the amyloidogenic peptides. We propose a pathway in which aberrant cleavage in the

secretory pathway followed by proteolytic processing within the distinct chemical environment of the ECM regulates the locale and extent of amyloid deposition and defines the distinctive disease pathology of FAF.

### In Situ Small Particulate Assemblies of AA Protein in Experimental Murine AA Amyloid

S. Inoue; Anatomy and Cell Biology, McGill University, Montreal, PQ, Canada

Concerning the toxicity of amyloid proteins, soluble small oligomers of beta amyloid protein were reported to be toxic. In this study, experimental murine AA amyloid tissue was examined ultrastructurally and with immunolabeling in an effort to identify in situ small multimers of AA protein. Pieces of mouse spleen with experimental AA amyloid were fixed in a solution containing 96% ethanol, 1% glacial acetic acid and 3% water, and thin sections were stained with uranyl-lead. AA protein was partially present in a previously unreported form, that is, 6-9 nm wide particulate structures. Each particle was made up of the close parallel association of approximately 6 “helical rods” (tight helices of 1 nm wide filaments) each 5 nm long and 2-3 nm wide. Slight loosening of helices caused variations in the particle size, but when all helices in a particle were thinnest (2 nm wide), particles were flat hexagonal prisms 5 nm high and 7 nm wide made up of the close parallel packing of 6 helical rods with a tiny central pore filled with dark stain. The particles were scattered in the extracellular space, and were also closely associated with the membrane of degrading reticular cells. Their role in amyloid formation is not clear. Amyloid proteins are known to be capable of forming ion-permeable channels in lipid bilayer membranes, and murine SAA2.2 was shown to form 8 nm wide hexagons (hexamers) with a putative central pore. There is a certain similarity between particles in this study and these hexamers. A possibility is that these newly found AA protein particles are related to the formation of toxic membrane channels.

### SNARE Protein Regulates *Salmonella* Intracellular Survival

S. Dai, D. Zhou; Biological Sciences, Purdue University, West Lafayette, IN

After entering host cells, *Salmonella enterica* Typhimurium resides within membrane-bound vacuoles where it survives and replicates. *Salmonella*-containing vacuoles (SCVs) have been shown to undergo a series of maturation steps including sequentially acquisition of early and late endocytic pathway markers. *Salmonella* is able to avoid direct fusion with lysosome. To understand the underline mechanism of how *Salmonella* achieve this, we examined roles of syntaxin 7, syntaxin 8, and VAMP7 in *Salmonella* invasion and intracellular replication. Immunofluorescent staining showed increased localization of syntaxin 7 and VAMP7 on SCVs and Sifs from 6h to 24h P.I., while syntaxin 8 only localized on early SCV (2h P.I.) in both HeLa and RAW264.7 cells. The exogenously expressed wild-type or dominant negative form of Syntaxin 7 and syntaxin 8 had no significant effect on *Salmonella* replication in HeLa cells. In contrast, wild-type VAMP7 decreased *Salmonella* intracellular replication and dominant negative VAMP7 increased it. However, wild type or dominant negative VAMP7 had no obvious effect on the intracellular survival of SPI2 mutant in HeLa cells. Our study suggests that VAMP7 is involved in intracellular bacterial survival and might be a target of *Salmonella* SPI2 effector proteins.

2169

### A Single Domain Mediates both SPI-1 Type III Secretion and Translocation of *Salmonella* SopA

W. M. Higashide, D. Zhou; Biological Sciences, Purdue University, West Lafayette, IN

*Salmonella enterica* serovar Typhimurium encodes two type three secretion systems (TTSSs) within the *Salmonella* pathogenicity island 1 (SPI-1) and island 2 (SPI-2). These type III protein secretion and translocation systems function to inject a panel of bacterial effector proteins into host cells to promote bacterial entry and subsequent survival inside the host cells. Effector proteins contain secretion and translocation signals that are often located at their N-termini. We have determined that the N-terminal 45 amino acid residues of *Salmonella* SopA are necessary and sufficient for directing its secretion and translocation through the SPI-1 TTSS. Interestingly, $SopA_{1-45}$, but not $SopA_{1-44}$, is also able to bind to its chaperone InvB, implying that the SPI-1 type III secretion and translocation of SopA requires its chaperone. Our data demonstrates that the secretion and translocation signals of *Salmonella* SopA can not be separated and may even be the same domain. We speculate that the SPI-1 type III secretion and translocation of SopA may be coupled.

2170

### *S pombe* as a Model System for the Investigation of *Yersinia* Outer Membrane Proteins (Yops)

D. J. Wiley, K. Schesser; Microbiology and Immunology, University of Miami Miller School of Medicine, Miami, FL

The pathogenic yersiniae (*Y. pseudotuberculosis*, *Y. pestis* and *Y. enterocolitica*) utilize a type three secretion system to inject effector proteins, known as *Yersinia* outer membrane proteins (Yops), into host cells to evade host immune responses. These Yops are believed to contribute to yersiniae’s virulence by directly modulating host factors. However, the identification of specific host factors and the biological significance of their modulation have been hampered by the lack of a good discovery model system. Here, we identify fission yeast, *Schizosaccharomyces pombe*, as an ideal model system to investigate the functions and molecular targets of the Yops. Fission yeast have a highly defined pattern of growth and a cytoskeleton that is easily visualized and quantified by microscopy, which is especially relevant for Yops since most have been shown to affect the cytoskeleton. We have used *S. pombe* to study the function of the kinase domain of *Yersinia* protein kinase A (YpkA). In mice the kinase domain of YpkA is important for virulence, however, in model systems with YpkA being expressed at high levels the kinase domain appears to be dispensable. Our results show that the kinase domain of YpkA contributes to the disruption of the actin cytoskeleton in *S. pombe* and demonstrates the importance of expression level and duration when analyzing virulence activities. Moreover, we believe that *S. pombe* is well-suited for biochemical and genetic studies, including mutagenesis and suppression screens, which lend themselves to the application of identifying the pathways for each Yop’s role in *Yersinia’s* virulence.

2171

### Lipid Membrane Rafts Mediate *Pseudomonas aeruginosa* Internalization in Corneal Epithelium Following CTL Wear *in vivo* and *in vitro*

H. D. Cavanagh, N. Yamamoto, D. M. Robertson, W. M. Petroll; Ophthalmology, UT Southwestern Medical Center, Dallas, TX

**PURPOSE:** Corneal epithelium (CE) responds inversely to hypoxia induced by contact lens wear (CTLW) with increased binding and internalization of *Pseudomonas aeruginosa* (PA). The purpose of this study was to determine if membrane lipid rafts (MLR) play a role in this process *in vivo, in vitro* and following CTLW. **METHODS:** MLR formation was evaluated *in vivo* in rabbit CE with or without CTLW; immortalized human CE cells (hTERT) were used *in vitro*. MLR were detected by FITC-labeled β-subunit cholera toxin known to bind MLR component GM1 with multiphoton confocal microscopy. Three pathogenic PA strains were tested; internalization was assessed by gentamicin survival assay and confirmed by pretreatment of h-TERT cells with three cholesterol metabolism inhibitors. Cytotoxic effects of inhibitors were excluded by live-dead assays. Specific interaction of PA and MLR was confirmed by FACS analysis. **RESULTS:** Normal rabbit CE does not exhibit MLR *in vivo*; these are induced by PMMA CTLW, but not by PA exposure alone to all three test strains. PA exposure after PMMA CTLW showed binding to MLR-forming cells *in vivo* followed by MLR aggregation and internalization for all strains. A similar sequence of MLR formation and PA internalization was seen in hTERT cells. Internalization of all strains was blocked in a concentration dependent manner by cholesterol metabolism inhibitors ($P < 0.01$); cytotoxic effects were excluded by live-dead assays over concentrations studied. FACS analysis showed exposure of two PA test strains to cell lysate significantly increased fluorescence intensity, demonstrating binding of MLR-GM1 to PA. **CONCLUSIONS:** These findings demonstrate for the first time that CTLW-mediated PA internalization involves MLR platforms. These findings offer a unique new strategy for prevention of CTL-related PA infection by blocking MLR formation.

2172

**Differential Requirement for Syk and PI 3-Kinase in the Opsonin-Independent Engulfment of Pathogenic *Neisseria* by Neutrophil-Restricted CEACAM3**

H. Sarantis, S. E. McCaw, S. D. Gray-Owen; Department of Molecular and Medical Genetics, University of Toronto, Toronto, ON, Canada

While pathogenic *Neisseria* species (*Neisseria gonorrhoeae*, *Neisseria meningitidis)* attach to epithelia and other human tissues via carcinoembryonic antigen-related cellular adhesion molecules (CEACAMs), neisserial binding by the neutrophil-restricted CEACAM3 allows potent opsonin-independent bacterial engulfment and subsequent killing. Upon CEACAM3 engagement by gonococci, the receptor's cytoplasmic immunoreceptor tyrosine-based activation motif (ITAM) is phosphorylated by Src-family kinases, allowing phosphatidylinositol 3-kinase (PI3K) activation, F-actin assembly, and bacterial engulfment. In this study we sought to determine if the tyrosine kinase Syk was involved in the initiation of these signaling events. Because Syk is restricted to hematopoietic cells, we used a recombinant Syk-EGFP chimera to pursue studies in a transfected HeLa cell model. We have observed that Syk-EGFP associates with CEACAM3 and is phosphorylated during gonococcal infection of HeLa-CEACAM3 as well as human neutrophils. Furthermore, using genetic mutants of CEACAM3, we have shown that CEACAM3-Syk association is ITAM-dependent. Contrary to FcR (Fc receptor)-mediated phagocytosis, Syk-EGFP did not increase gonococcal uptake by HeLa-CEACAM3, and the Syk inhibitor piceatannol did not alter gonococcal uptake in human neutrophils. We have, however, observed that HeLa-CEACAM3 internalization of larger particles (5.6 μm anti-CEACAM IgG-coated beads) absolutely requires both Syk-EGFP and PI3K. This suggests the role of Syk in CEACAM3-mediated uptake involves membrane trafficking to sites of phagocytosis to allow sufficient pseudopod extension for phagosomal closure. Because gonococci are relatively small in size (~1 μm), encolusure of the bacteria-containing phagosome can occur in the absence of Syk, whereas engulfment of bacterial aggregates requires significant pseudopod extension. The close parallels that continue to be unravelled for CEACAM3- and Fc receptor-mediated engulfment depict a highly specialized, opsonin-independent means to capture and destroy CEACAM-binding pathogens, suggesting a highly evolved paradigm of specific innate immunity.

2173

**Analysis of the Penicillium marneffei Secretome: the Proteomics of an Opportunistic Pathogen**

G. R. Walker,[1] S. Pizzino,[1] K. Segna,[2] T. Kim,[1] C. Cooper[1]; [1]Biological Sciences, Youngstown State University, Youngstown, OH, [2]Biological Sciences, Christopher Newport University, Newport News, VA

Penicillium marneffei is an opportunistic fungal pathogen that exhibits a pronounced dimorphism. This fungus can exist as either a multicellular mould form or a single celled yeast form. The latter entity is the cause of penicilliosis in immune-compromised individuals. Opportunistic organisms secrete a variety of proteins (secretome) that are necessary for maintaining their structure as well as modifying their extracellular environment enabling them to survive in the host. Our laboratories have been applying proteomics to the problem of fungal dimorphism . Electrophoretic analysis of the P. marneffei secretome shows differential expression of proteins between the two growth forms. Past studies have shown that catalase activity, potential component of the secretory repertiore, is much higher in the yeast form, possibly enabling the organism to combat the superoxide attack of macrophages and may be part of the secretory repretoire of the cell. This study shows that there is a major yeast specific secretory protein with a molecular weight similar to that for catalase. Based on its mobility in two-dimensional electrophoretic gels, the protein has a molecular weight of approximately 65 kDal and a pI of approxiamately 4.0-4.5. Pre-fractionation by liquid isoelectric focusing supports the basic characteristics of this major yeast secretory protein. Further analysis of this is being carried out using mass spectroscopy. The identification of phase specific protein in the secretome will give us a better understanding of the mechanism of fungal dimorphism as it relates to pathogenesis.

2174

**Internalization of Group A Streptococcus into Primary Oropharyngeal Keratinocytes Involves Clathrin and Cholesterol**

A. P. Hakansson,[1,2] M. R. Wessels[1,2]; [1]Division of Infectious Diseases, Children's Hospital Boston, Boston, MA, [2]Harvard Medical School, Boston, MA

Group A streptococci (GAS) can be internalized by epithelial cells in vitro. We have previously shown that expression of streptolysin O (SLO) helps the bacteria avoid ingestion by epithelial cells. SLO-negative GAS are internalized in 50-fold higher numbers than SLO-producing bacteria, are quickly seen inside vesicles stained for lysosomal markers including synaptotagmin VII (SytVII), and are rapidly killed through a pH-dependent mechanism. Internalized SLO-positive GAS avoid trafficking to lysosomes and are killed in a slower fashion by a mechanism independent of pH. These results prompted a more complete investigation of the mechanism(s) used for internalization of GAS and how SLO modulate this process. A possible direct internalization of SLO-negative bacteria into lysosomes made us investigate the involvement of clathrin as synaptotagmins have been shown to contain clathrin-dependent internalization motifs. We also investigated the role of cholesterol as SLO is a

cholesterol-dependent toxin that may modulate internalization by interacting with cholesterol-rich membrane domains. Inhibition of clathrin-mediated uptake by monodansylcadaverin or chlorpromazine effectively reduced the internalization of both SLO-positive and negative GAS by 80-90%. In contrast, depleting cholesterol from the membrane with methyl-β-cyclodextrin or adding the sterol-binding molecule nystatin only inhibited the internalization of SLO-negative GAS (90%) without affecting internalization of SLO-positive GAS. These results suggested that SLO interferes with cholesterol-dependent internalization in a fashion similar to drugs that deplete or bind cholesterol. This hypothesis was supported by the finding that addition of SLO to cell monolayers caused a 70% reduction of internalization of SLO-negative GAS. Together, the findings suggest that GAS can be taken up through two different pathways, both of which require functional clathrin. One of these pathways also depends on the presence of cholesterol in the membrane and is inhibited by SLO.

2175

**Degenerative Effect of PepA from *Helicobacter pylori* on Gastric Epithelium Cell**

S. Yun,[1] S. Lee,[2] C. Uhm,[2] S. Hwang[1]; [1]Department of Bioscience, School of Life Science and Biotechnnology, Korea University, Seoul, Republic of Korea, [2]Department of Anatomy, College of Medicine, Korea University, Seoul, Republic of Korea

Aminopeptidase a/i (PepA) from *Helicobacter pylori* is first purified, cloned and expressed in *E.coli.* The cloned enzyme has the same enzymatic properties as the wild-type enzyme. PepA is 54.965kDa, homohexamer and it has amidolytic activity against PSP(L-phenylalanyl-3-thia-phenylalanine); the release of thiophenol upon enzymatic hydrolysis of PSP(L-phenylalanyl-3-thia-phenylalanine) is spectrophotometrically detected with the aid of 5,5'-dithiobis[2-nitrobenzoic acid] (DTNB). The enzyme is activated by $Mg^{2+}$, $Mn^{2+}$ ,or $Ni^{2+}$ and inhibited by ion chelators. AGS gastric epithelial cells are treated with PepA to investigate cellular changes by electron microscopy. We observed ultrastructural and morphological changes on gastric epithelium cells. The results suggest the potential use of PepA as a drug target to develop novel anti-H. pylori agents.

2176

**Recognition and Ubiquitination of *Salmonella* Type III Effector SopA by an Ubiquitin E3 Ligase, HsRMA1**

Y. Zhang, W. Higashide, S. Dai, D. Sherman, D. Zhou; Biological Sciences, Purdue University, West Lafayette, IN

*Salmonella* translocate bacterial effectors into host cells to confer bacterial entry and survival. It is not known how the host cells cope with the influx of these effectors. We report here that the *Salmonella* effector, SopA, interacts with host HsRMA1, an ubiquitin E3 ligase with a previously unknown function. SopA is ubiquitinated and degraded by the HsRMA1-mediated ubiquitination pathway. A *sopA* mutant escapes out of the *Salmonella*-containing vacuoles less frequently to the cytosol than wild type *Salmonella* in HeLa cells in a HsRMA1-dependent manner. Our data suggest that efficient bacterial escape into the cytosol of epithelial cells requires HsRMA1-mediated SopA ubiquitination and contributes to *Salmonella*-induced enteropathogenicity.

2177

**Apoptosis Triggered by Rv1818c, a PE Family Gene from *Mycobacterium tuberculosis* is Regulated by Mitochondrial Intermediates in T cells**

B. N. Kithiganahalli; Microbiology and Cell Biology, Indian Institute of Science, Bangalore, India

Ectopic expression of the *Mycobacterium tuberculosis* PE-family gene *Rv1818c,* triggers apoptosis in the mammalian Jurkat T cell line, which is blocked by the anti-apoptotic protein Bcl-2. Although complete overlap is not observed, a considerable proportion of cellular pools of ectopically expressed Rv1818c localizes to mitochondria. However, recombinant Rv1818c does not trigger release of cytochrome c from isolated mitochondria. Apoptosis induced by Rv1818c is blocked by the broad-spectrum caspase inhibitory peptide ZVAD-FMK. Unexpectedly, Rv1818cinduced apoptosis is not blocked in a Jurkat sub-clone deficient for caspase-8 (JI 9.2) or in cells where caspase-9 function is inhibited or expression of caspase-9 reduced by small interfering RNA (siRNA), arguing against a central role for these caspases in Rv1818c-induced apoptotic signaling. Depleting cellular pools of the mitochondrial protein Smac/DIABLO substantially reduces apoptosis consistent with mitochondrial involvement in this death pathway. We present evidence that Rv1818c-induced apoptosis is blocked by the co-transfection of an endogenous inhibitor of caspase activation XIAP (X-linked Inhibitor of Apoptosis Protein) in T cells. Taken together, these data suggest that Rv1818c-induced apoptotic signaling is likely regulated in part by the Smac-dependent activation of caspases in cells.

2178

**Autophagy Controls *Salmonella* Infection in Response to Injury to the *Salmonella*-Containing Vacuole**

C. L. Birmingham,[1,2] A. C. Smith,[1,2] M. A. Bakowski,[1,2] N. Mizushima,[3] T. Yoshimori,[4] J. H. Brumell[2,1]; [1]Medical Genetics and Microbiology, University of Toronto, Toronto, ON, Canada, [2]Infection, Immunity, Injury and Repair, Hospital for Sick Children, Toronto, ON, Canada, [3]Bioregulation and Metabolism, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan, [4]Cell Genetics, National Institute of Genetics, Mishima, Japan

*Salmonella enterica* serovar Typhimurium is a facultative intracellular pathogen that causes disease in a variety of hosts. *S.* Typhimurium invades the cells of its host and typically occupies a membrane-bound compartment called the *Salmonella*-containing vacuole (SCV). The bacteria modify the fate of the SCV using two independent type III secretion systems (TTSSs). Autophagy is a host cell cytosolic degradation pathway recently shown to interact with intracellular pathogens in a variety of ways. Here we investigated the involvement of autophagy in *S.* Typhimurium infection. We show that a subset of intracellular *S.* Typhimurium are recognized by the autophagy system at 1 h post infection. Confocal analysis showed that the autophagic marker LC3 associated with bacteria in the cytosol as well as with bacteria in SCVs. This association was dependent upon bacterial protein synthesis and the *Salmonella* pathogenicity island (SPI)-1 TTSS. Autophagy-deficient ($atg5^{-/-}$) cells showed higher numbers of *S.* Typhimurium in the cytosol and were more permissive for intracellular replication than normal cells. However, autophagy did not recognize Δ*sifA* bacteria that had escaped from the SCV at late times in infection (8-10 h). We propose a model in which the host autophagy system recognizes cytosolic bacteria and SCVs damaged by the SPI-1 TTSS to retain intracellular *S.* Typhimurium within vacuoles early after infection.

2179

**Endotoxin and Lipotechoic Acid Inhibit Plasma Gelsolin Severing Activity**

R. Bucki, P. A. Janmey; Institute for Medicine and Engineering, University Of Pennsylvania, Philadelphia, PA

Endotoxin and Lipotechoic Acid Inhibit Plasma Gelsolin Severing Activity R. Bucki and P. A. Janmey University of Pennsylvania, Institute for Medicine and Engineering, 1010 Vagelos Research Laboratories 3340 Smith Walk Philadelphia, PA, 19104 USA. Gelsolin is the first recognized member of an extensive protein family found in eukaryotic organisms ranging from amebas to humansthat severs actin filaments in a reaction that is regulated by Ca2+ and inositol lipids. Although originally identified as a cellular cytoplasmic protein implicated in the regulation of cellular actin remodeling, gelsolin also exists as an abundant secreted isoform of nearly identical structure and a product of the same gene. The function of this protein, designated plasma gelsolin, which circulates in humans at an average concentration of 250 mg/L, is mostly unknown. Cytoplasmic gGelsolin binds with high affinity and selectivity to polyphosphoinositides and to lysophosphatidic acid (LPA), which strongly inhibits gelsolin's actin filament severing function. In this study we have used spectrofluorometric techniques to evaluated the interaction of two highly acidic bacterial lipids, endotoxin (LPS) and lipotechoiclipoteichoic acid (LTA) binding towith a rhodamine B-labeled peptide PBP10 (RhB-QRLFQVKGRR), a $PIP_2$-binding site of gelsolin. Additionally, we have evaluated the effect of LPS and LTA on gelsolin's F-actin severing activity by measuring pyrene-F-actin depolymerization rates. We found that LPS and LTA bind to PBP10 peptide. When added to gelsolin LPS and LTAand strongly inhibit gelsolin's actin severing activity. These findings indicated that bacterial compounds could affect the F-actin buffering system of blood, and suggest gelsolin involvement in LPS and LTA traffic regulation.

**Role of the Molecular Chaperone Hsp90 in Folding and Processing of the Poliovirus Capsid Precursor Protein P1**

R. Geller,[1] M. Vignuzzi-Fabbri,[2] R. Andino,[2] J. Frydman[1]; [1]Biological Sciences, Stanford University, Stanford, CA, [2]Microbiology & Immunology, University of California San Francisco, San Francisco, CA

Viruses depend on the host cellular machinery for successful propagation. In particular, the folding and assembly of elaborate oligomeric viral structures such as the capsid may require assistance of the cellular folding machinery. Here we use Poliovirus as a model system to examine the role of molecular chaperones during infection. We find that the essential molecular chaperone Hsp90 is required for succesful poliovirus replication. Accordingly, treatment of tissue culture cells with the Hsp90 inhibitor Geldanamycin significantly inhibits the replication cycle of Poliovirus as well as that of the closely related Rhinovirus, the most frequent agent of the common cold. The Hsp90 chaperone system appears specifically required for folding and/or processing the capsid precursor protein P1, but not for other steps in the viral life cycle, including entry into the cell, uncoating of the capsid and viral RNA translation or replication. Strikingly, despite the rapid mutation rate of Poliovirus, we were unable to obtain viruses resistant to the Hsp90 inhibitor, indicating that the chaperone requirement cannot be easily circumvented. Our findings highlight the potential of chaperone inhibitors as antiviral agents.

**Dynamic Gag Complex-Actin Interactions during Equine Infectious Anemia Virus Assembly and Budding**

C. Chen,[1] J. Jin,[1] K. M. Weixel,[2] M. Rubin,[3] J. K. Craigo,[1] D. B. Stolz,[3] S. C. Watkins,[3] O. A. Weisz,[2] R. C. Montelaro[1]; [1]Department of Molecular Genetics and Biochemistry, University of Pittsburgh School of Medicine, Pittsburgh, PA, [2]Department of Medicine, Renal-Electrolyte Division, University of Pittsburgh School of Medicine, Pittsburgh, PA, [3]Department of Cell Biology and Physiology, University of Pittsburgh School of Medicine, Pittsburgh, PA

Retrovirus assembly and budding is a highly concerted process mediated by specific interactions between viral Gag polyproteins and host cofactors. Gag proteins recruit various components that regulate the endocytic pathway, including the formation of endosomes and multivesicular bodies for viral assembly and budding. Our previous studies have demonstrated a role for the association between Gag protein and the actin cytoskeleton in virion production of equine infectious anemia virus (EIAV), a lentivirus related to HIV-1. Here we further examined the Gag interaction with the actin cytoskeleton and its role in retrovirus assembly and budding, using high resolution imaging techniques including confocal microscopy, immuno-scanning EM, and bimolecular fluorescence complementation (BiFC) and biochemical analyses. Our confocal microscopy and immuno-scanning EM data demonstrated proximate location of EIAV Gag polyproteins with filamentous actins and BiFC analyses further confirmed the intimate interactions (2-6 nm) between actin and EIAV Gag polyprotein. Rapid migration (up to 0.2 μm/s) of Gag-actin complexes in the cytoplasm was also observed in living cells. Characterization of the viral determinants for actin interaction revealed an involvement of capsid and nucleocapsid -mediated Gag polyprotein multimerization prior to actin association and a positive correlation between actin interaction and virion production. These data indicate that oligomeric Gag proteins specifically recruit and adapt the actin filament network for trafficking and assembly of retroviral particles.

**Epitope Mapping of Anti-Dengue Virus Nonstructural Protein 1 Antibodies that Cross-React to Endothelial Cell Surface**

Y. Lin, H. Cheng, S. Wan, C. Lin; Department of Microbiology and Immunology, National Cheng Kung University Medical College, Tainan, Taiwan Republic of China

The onset of vascular leakage and hemorrhagic diathesis is one of the life-threatening complications that occur in dengue patients. The host-virus interactions that induce autoimmune responses may have implications in dengue hemorrhagic fever and dengue shock syndrome (DHF/DSS), yet the mechanisms remain unclear. Our previous studies showed a mechanism of molecular mimicry in which antibodies (Abs) directed against dengue virus (DV) nonstructural protein 1 (NS1) cross-reacted with endothelial cells and induced these cells to undergo apoptosis and immune activation. Some endothelial cell surface molecules recognized by anti-DV NS1 have been identified by 2D gel electrophoresis followed by Western blotting and mass spectrometry analysis. After alignment to database of NCBI and SwissPort, these proteins were identified as beta chain of H+-transporter/ATP synthase, protein disulfide isomerase-related protein, vimentin intermediate filament, heat shock protein 60, and protein disulfide isomerase. Furthermore, phage-displayed peptide library and peptide array of DV NS1 were used to determine the possible cross-reactive epitopes. Both data showed a conserved a.a. 315-324 peptide in C terminal region of DV NS1, called C20-10, as a cross-reactive epitope corresponding to bioinformatic prediction of EMBOSS Antigenic program. Synthetic oligopeptides of C20, a cysteine-rich region of a.a. 311-330

peptide as a speculated candidate was previously shown. This study demonstrated that C20-10 was also specifically bound by anti-DV NS1 and anti-target proteins. In contrast to normal controls and DF patients, higher titers of antibodies against C20 and C20-10 were detected in DHF patient sera. Taken together, these results suggested that anti-C20-10 may play an important role in the autoimmunity of DHF/DSS pathogenesis. In future, three-dimensional structure of DV NS1 determined by synchrontron radiation protein crystallography or NMR will be assessed for entire epitope mapping.

2183

**Tat Downregulation Protects Chronically HIV-Infected Jurkat Cells From Fas-Mediated Apoptosis**

A. J. Calderon, J. A. Lavergne; Microbiology, University of Puerto Rico - School of Medicine, San Juan, PR

AIDS is characterized by the progressive loss of both HIV-infected and uninfected $CD4^+$ T lymphocytes through apoptosis. However, the exact mechanisms and putative viral gene products involved in the regulation of apoptosis and cell cycle are not clearly defined. There is still much controversy regarding the fact that expression of HIV Tat and Vpr may induce apoptosis in some types of cells, yet may induce apoptosis resistance in others. To further evaluate the role of HIV Tat in apoptosis regulation in an *in vitro* model of chronic HIV-infection using Jurkat cells (J1.1 clone), we blocked the expression of Tat and Vpr by RNA interference (RNAi). We designed several intracellular expression vectors to create stable gene knockdown of either Tat or Vpr, and then characterized the apoptosis development and cell cycle progression in cells chronically infected with HIV. We found that RNAi against one Tat mRNA region (anti-Tat-1 vector) reduced the expression of both Tat and Vpr expression at the RNA level by almost 37%, and reduced Tat-expressing cells by 32%. In addition, viral replication in anti-Tat-1-treated cells stimulated by TNF-α, was reduced by 40%, supporting the role of Tat in HIV-1 replication. Anti-Tat-1-treated cells were found to be more resistant to nuclear apoptosis than mock-transfected J1.1 cells after stimulation with anti-Fas. These results suggest that Tat may have a role in enhancing Fas-mediated apoptosis during HIV-infection. These observations correlate with previous findings from Bartz and Emerman (1999), which found that a Tat-expressing cell line had increased expression and activity of caspase 8, an initiator of the Fas apoptosis pathway. We suggest that targeting HIV-1 Tat may be an effective means of reducing both viral replication and the progressive loss of $CD4^+$ T cells due to apoptosis in $HIV^+$ individuals.

***Boehmeria Nivea* Root Extract Suppresses Supernatant Hepatitis B Virus Surface Antigen and Viral DNA in Human Hep3B Hepatoma Cells**

K. Huang; Biotechnology, National Tsing-Hua University, Hsinchu, Taiwan Republic of China

**Abstract** In Taiwan, there has been a history of using the herb *Boehmeria nivea* for medical purposes such as hepatoprotection. The aim of this report is to study the effects of *B. nivea* root extract on HBV replication in Hep3B cell model system. HBsAg and HBV DNA were measured by enzyme-linked immunosorbant assay (ELISA) and PCR, respectively. Expressivity of viral gene *preS1* was determined by reverse transcriptase-PCR (RT-PCR), and cytotoxicity, by methyl tetrazolium (MTT) assay. In addition, Lamivudine (3TC) was used as positive control for drug efficacy assays. In Hep3B cells treated with *B. nivea* extract, secretion of HBsAg into the medium was significantly suppressed and no viral DNA could be detected; however, this effect was reversible. Similar to 3TC, *B. nivea* extract was not cytotoxic towards Hep3B, CCD966SK or mouse primary liver cells; it did not affect HBV genome stability and viral gene expression. *B. nivea* extract exhibited anti-HBV activities by potently inhibiting secretions of HBsAg and levels of supernatant HBV DNA, but it conferred no cytotoxicity. According to these results, we deduce that the anti-HBV effects manifested by *B. nivea* extract were probably derived from blockage in viral nucleocapsid assembly, or reduced stability of nucleocapsids that contain pregenomic RNA.

**The Molecular Cell Biology of the Immunomodulatory E3-19K Protein from Adenovirus**

M. Bouvier, H. Liu, J. Fu; School of Pharmacy, University of Connecticut, Storrs, CT

E3-19K is a type I membrane glycoprotein expressed by adenoviruses (Ads) for the purpose of modulating host antiviral immune responses. E3-19K associates with class I MHC molecules in the endoplasmic reticulum (ER) and blocks their transport to the cell surface thereby inhibiting presentation of virally-derived antigenic peptides to T cells. To date, little is known about molecular aspects of the mechanism by which E3-19K targets class I MHC molecules for retention in the ER. Towards this goal, we have developed an expression system for the ER-lumenal domain of the Ad type 2 E3-19K protein in baculovirus-infected insect cells. We have characterized the physicochemical properties of recombinant, soluble E3-19K using a variety of biophysical techniques. Results showed that the protein is monomeric in solution, thermally stable, and possesses a well-defined three-dimensional structure. In vitro reconstitution studies showed that recombinant, soluble E3-19K associates with recombinant, soluble peptide-deficient as well as peptide-filled HLA-A*1101 molecules. The complexes formed with high-affinity and in a 1:1 stoichiometry. These results demonstrate that interaction between E3-19K and class I MHC molecules occurs in the absence of any other host or Ad proteins. Our results provide the first example of a viral immunomodulatory protein that interacts with conformationally distinct forms of class I MHC molecules. Our studies also showed that peptide-deficient HLA-A*1101 molecules sequestered by E3-19K are capable of maturing into peptide-filled molecules, suggesting a role for E3-19K in maturation of class I molecules in Ad-infected cells. Together, our results suggest that Ads have evolved to exploit the early and late stages of the class I antigen presentation pathway to evade the immune system. These studies advance our understanding of the molecular cell biology underlying Ad pathogenesis. Research funded by NIH/NIAID (AI055717).

**Interactions between HIV-1 and HIV-2 Gag Polyproteins *in vivo***

V. P. Boyko; HIV Drug Resistance Program, National Cancer Institute, Frederick, MD

HIV-1 and HIV-2 use the same receptor and co-receptors, thereby targeting the same cell populations in coinfected individuals. To identify potential interaction between these two human pathogens, we examined whether HIV-1 and HIV-2 Gag proteins can coassemble and functionally complement each other. We designed HIV-1- and HIV-2-based vectors with mutations in either the nucleocapsid (NC) domain or the PTAP motif of Gag; all of these mutants have severely reduced virus titers. Flow cytometry analysis revealed that coexpression of the homologous NC and

PTAP mutants allowed the coassembly and complementation of the two mutant proteins resulting in recovery of virus infectivity. Coexpression of the HIV-1 and HIV-2 gag mutants could also generate infectious viruses; furthermore, the heterologous complementation could be at similar level of efficiency as the homologous complementation. We then directly demonstrated that HIV-1 and HIV-2 Gag can interact and coassemble, using the Bimolecular Fluorescence Complementation assay (BiFC). In this assay, yellow fluorescence protein (YFP) was divided into an N- and a C-terminal portion (ny and cy) and fused to target proteins. If the target proteins interacted and brought ny and cy together, then YFP emission could be detected. We detected strong YFP emission signal not only with the homologous pairs of HIV Gag fusion proteins but also upon coexpression of heterologous pairs of Gag fusion proteins. Taken together, our results indicate that HIV-1 and HIV-2 Gag polyproteins can coassemble and complement each other during virus replication. To our knowledge, this is the first demonstration that the authentic Gag of two distinct retroviruses can coassemble and complement each other's function. These studies have important implications for the efficacy of anti-AIDS drug treatments and the evolution of primate lentiviruses.

### Substrates for Cyclin dependent Kinases in the Promotion of Cell Cycle Transitions

T. Hunt; Cancer Research UK, Clare Hall Laboratories, Herts, United Kingdom

The key to cell cycle control is the idea of transitions between the phases of the cycle: G1 to S-phase, G2 to M-phase, the metaphase to anaphase transition and the return from mitosis to interphase. Entry to S-phase requires cyclin dependent kinase (Cdk) activity, normally provided by cyclin E-Cdk2 in the cells of higher eukaryotes, while entry into mitosis requires the combined activity of cyclins A and B together with Cdk1. We can now express active forms of all these kinases in bacteria, which allows us to investigate their substrate specificity, to explore the question of how many proteins must be phosphorylated in order to promote these transitions. And also to ask why it is, for example, that although cyclin E-Cdk2 can accelerate entry into mitosis under some circumstances, it appears to be unable to promote entry into mitosis by itself. It turns out that enumerating substrates for protein kinases is a considerable challenge, and I will report on progress in my laboratory.

### Contributions Made by Cdc25 Protein Phosphatases to Cell Cycle- and Checkpoint-Control in Embryonic and Adult Cell Cycles

H. Piwnica-Worms; Department of Cell Biology and Physiology, Howard Hughes Medical Institute and Washington University School of Medicine, St. Louis, MO

The Cdc25 phosphatases positively regulate cell division by dephosphorylating and activating cyclin dependent protein kinases (Cdks). In addition, Cdc25 proteins are targets of negative regulation by the DNA damage and replication checkpoints. In humans and rodents, there are three family members - Cdc25A, -B, and -C, encoded by three genes. Murine forms of *Cdc25* exhibit distinct patterns of expression throughout development and in adult tissues. In addition, Cdc25 family members can be distinguished based on their intracellular localization, their abundance and/or activity throughout the cell cycle, the Cdks that they target for activation and whether they are overexpressed in human cancers. Furthermore, the Cdc25A- and Cdc25C-regulatory pathways are inhibited by UCN-01, a protein kinase inhibitor currently in clinical trials for cancer treatment. We are interested in defining the contributions made by individual members of the Cdc25 family to cell cycle- and checkpoint-control in mammals and in determining whether Cdc25-regulatory pathways are valid targets for the development of anti-cancer agents. With this goal in mind, targeting gene strategies were employed to disrupt *Cdc25* family members in mice. The consequences of disrupting *Cdc25A*, *Cdc25B* and *Cdc25C*, either singly or in combination, will be discussed.

### Mitotic Spindle Morphogenesis: An Interphase Connection

Y. Zheng; Department of Embryology, The Carnegie Institution of Washington, Baltimore, MD

Accurate execution of mitosis is essential for equal chromosome segregation and for the maintenance of genome stability. Proper partitioning of other cellular structures and signaling molecules into daughter cells during mitosis is also important for cell fate determination and stem cell maintenance. Although cell cycle research in the past has shed light on the regulation of mitosis, our studies have revealed significant regulatory and morphological complexities of mitosis. More importantly, we have shown that the regulation of mitosis involves cellular machineries that were previously thought to have functions only in interphase. I will describe two new pathways that coordinate with the cell cycle machinery to regulate mitotic spindle morphogenesis and chromosome segregation. I will also discuss how the new pathways may influence the fate of the cell in the next cell cycle.

## Yeast Genomics in the Classroom: Using the Yeast Deletion Collection to Study Environmental Toxins and Food Additives (2190)

### Yeast Genomics in the Classroom: Using the Yeast Deletion Collection to Study Environmental Toxins and Food Additives

A. C. Ballew, M. Cyert, T. Stearns; Biological Sciences, Stanford University, Stanford University, CA

The goal of the HHMI sponsored Pre-Grad Program at Stanford University is to prepare students to pursue advanced degrees in graduate school by providing coursework that both teaches the fundamentals of modern experimental science, and informs students of the exciting career opportunities. At the heart of the Pre-Grad Program is a lecture/lab course that trains undergraduate students to solve biological problems using modern tools of genetics and genomics. The goal of the class is to understand the effects of environmental toxins or food additives on *Saccharomyces cerevisiae*. To foster a more inquiry-driven learning environment, the course is focused on compounds whose effects on eukaryotic cells are not well understood. Students in the course work together to perform a genome wide screen using the yeast deletion collection and identify mutants that are hypersensitive to several compounds. Genomics and database tools are used to analyze the gene lists and students design a project to follow up on findings from one of the screens. Students are required to submit a written research proposal and give regular presentations of their data to the class. At the end of the course the findings from the projects are presented at a departmental poster session and students submit a final paper describing their results. The writing assignments and presentations teach students valuable skills about communicating science. Students reported feeling more engaged in the course because these compounds are relevant to them and because they were doing original research. Results from at least two student projects have developed into undergraduate thesis projects. We conclude this course is a good model for engaging students in original research in a classroom setting.

## Cytoskeletal Dynamics in Living Cells (2191-2196)

2191

### Endothelial Cell Migration in 3D collagen matrices replicates *in vivo* morphodynamics

R. S. Fischer; Department of Cell Biology, Scripps Research Institute, La Jolla, CA

Previous work has demonstrated that substrate compliance and topology can have dramatic effects on cell morphology, indicative of alterations in spatial adhesion cues and/or actomyosin functions. Meanwhile, a large database of information on cell protrusion and the underlying actin dynamics has been generated in cells cultured in two dimensions. To translate this knowledge into more physiological conditions, we have investigated the protrusion morphodynamics and actin turnover in endothelial cells in both traditional two dimensional culture conditions and three dimensional collagen gels, and compared these protrusive structures to those found in branching vasculature *in vivo*. In all three systems, endothelial cells protrude with similar cyclic frequencies and rates, but use remarkably different cellular structures to do so. In three dimensional collagen gels, large flat lamellipodial structures are replaced by long, brachiated pseudopods, which contain relatively stable cortical actin surrounding microtubules. The tips of these pseudopods exhibit dynamic growth cone-like protrusions and filopodia. In some individual cells, both long pseudopods and flat lamellipodia-like structures can be seen, indicating that changes in gene expression are not required for the switch from lamellar to pseudopod morphology. We further demonstrate by FRAP analyses that actin turnover in these protrusion structures displays two recovery rates which occur in spatially distinct zones. In posterior regions of the pseudopod tips, recovery rates consist of both fast, isotropic diffusional components and a slower component likely derived from filament turnover. At the very tip of pseudopod extensions, new fluorescence accumulation occurs with a single, rapid rate indicative of diffusion-limited accumulation. These data indicate that although the morphology of protrusive structures in three dimensions is dramatically different from traditional two-dimensional cell structures, similar underlying mechanisms govern the morphodynamics in both cases.

### Spatio-temporal Coordination between Protrusion, Actin Network Assembly, Network Flow and Adhesion in Migrating Epithelial Cells

M. Machacek, K. Hu, C. Waterman-Storer, G. Danuser; Cell Biology, TSRI, La Jolla, CA

Protrusion of the leading edge initiates cell migration. The current understanding is that a densely branched network of actin filaments mediates the protrusion process. In epithelial cells two networks with different dynamical and molecular properties have been identified; the lamellipodium which is a 1-2μm wide band adjacent to the leading edge and the lamella which spans from the leading edge towards the cell body. The role and particularly the interaction of these two networks during protrusion are unclear. To address these questions we use quantitative Fluorescent Speckle Microscopy to measure network flow velocities, network assembly and disassembly rates and adhesion molecule accumulation as well as cell edge tracking to measure protrusion and retraction velocities with submicron resolution. The heterogeneous characteristics of the leading edge motion allowed us to observe simultaneously many states of the protrusion machinery. By statistical accumulation of the state variations we were able to identify the timing and causality between actin assembly, flow and edge movement. We found two distinct mechanisms of how protrusion and retraction are controlled by actin dynamics of the lamellipodium. The mechanisms differ in the temporal relation between protrusion, assembly, network flow and adhesion strength modulation but in both myosin II was not involved. The lamella was found to be kinematically decoupled from the lamellipodium and not directly related to protrusion. However, we measured that lamellipodium assembly was delayed by 10-20s relative to protrusion and therefore could not trigger protrusion events. We speculate that the lamella initiates protrusion and subsequently mediates lamellipodium formation which completes the protrusion cycle. This demonstrates that the two networks are mechanically and, as shown in a previous study (Ponti *etal.* Science) molecularly distinct structures, yet their dynamics are closely coordinated in mediating protrusion.

2193

### Novel Roles of Actin Binding Proteins in *Listeria monocytogenes* Actin-Based Motility Revealed Within a Cellular Context

R. Buencamino, R. D. Vale; Graduate Group in Biophysics, Cellular and Molecular Pharmacology and HHMI, University of California, San Francisco, San Francisco, CA

*Listeria monocytogenes* is a Gram-positive bacterial pathogen that hijacks the host actin cytoskeletal machinery to move within and spread directly between host cells. In order to study the role of the actin binding proteins in *Listeria* motility we infected Schneider 2 (S2) cells with *Listeria* and examined actin-based *Listeria* motility in wild-type cells and cells depleted of various actin binding proteins by RNA interference (RNAi). Using an automated tracking algorithm we focused on two main parameters: velocity and actin tail length. As expected, *Listeria* velocity was severely reduced after depletion of the monomer binding protein profilin (50% reduction) and the depolymerizing protein cofilin (50% reduction). *Listeria* in cofilin-depleted cells also exhibited discontinuous motility; this “stop-and-go” behavior may reflect a temporary accumulation of an actin shell followed by symmetry breaking. We also found unexpected defects for two protein depletions. First, the depletion of actin monomer binding protein cyclase-associated protein (CAP) caused a severe reduction in motility velocity (50% reduction), indicating an important and unappreciated role for this protein in actin-based propulsion. We also found that depletion of the actin crosslinker fascin from S2 cells caused a five-fold increase in the actin tail length and an increase in velocity by a factor of three when compared to wild-type cells. Thus, the use of in vivo motility assays in conjunction with RNAi has allowed us to uncover new roles of proteins in actin-based *Listeria* motility which have not been apparent from reconstituted assay systems.

2194

### Tau Protein's Effect On In-vitro Microtubule-based Transport: Implications For In-vivo Dynamics

S. Gross,[1] M. D. Vershinin,[1] S. J. King[2]; [1]Developmental & Cell Biology, University of California, Irvine, Irvine, CA, [2]Molecular Biology and Biochemistry, University of Missouri-Kansas City, Kansas City, MO

Aberrant functioning of the tau protein is a common feature of many neurodegenerative diseases such as the Alzheimer's disease, and tau misregulation has been linked to impaired neuronal microtubule-based transport. To better understand how tau alters transport, we mimicked some aspects of in-vivo complexity via the use of multiple motors in an in-vitro bead assay. This assay allows us to control both the number of motors per cargo and the concentration of tau on the microtubules (MTs), and to investigate how the motion of cargos changes as a result of the interaction

between these two factors. As expected, we find that cargos driven by multiple kinesin motors on bare MTs exhibit persistent motion over many microns, typically staying attached until reaching the end of the MT. By contrast, in the presence of tau on MTs, the persistence of cargos driven by multiple kinesin motors is severely depressed, and at large tau concentrations can be reduced close to the single-motor limit. However, the presence of tau on MTs does not have a commensurate effect on single-motor driven cargos. Our data suggests that tau does not simply block MT tracks, but rather reduces the number of active motors, by preventing the motors on a cargo from binding or rebinding to the MTs. We therefore propose a novel role for the tau protein: that of regulating MT-based transport by controlling the number of active motors per cargo. Such regulation could be particularly important at axonal branch points, where tau could be regulating cargo switching between MTs, and in growth cones, where local control of the number of active MT-associated motors could influence the transfer of cargos from MTs onto actin filaments.

2195

### The Formation of Antiparallel Microtubule Bundles in Fission Yeast

M. E. Janson, I. Loiodice, P. T. Tran; Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

Cells like neurons, epithelial cells, and myotubes all organize linear arrays of microtubules independent from the centrosome. A clear understanding of how these microtubules are nucleated and spatially organized is lacking. We studied the formation of 'non-centrosomal' microtubule bundles in interphase fission yeast cells. In their simplest form, these structures contain two anti parallel microtubules that are slightly overlapped at their minus ends. Bundle formation started from a single microtubule that was nucleated from a gamma-tubulin complex at the nuclear envelope. Then additional gamma-tubulin complexes bound along the side of this microtubule and nucleated a second microtubule in a direction opposite to initial growth. After this secondary nucleation the minus ends of the two microtubules did slide towards each other, which required the action of minus-end-directed kinesin-14 (klp2p). This finding demonstrates that dispersed microtubule nucleation and microtubule sliding can generate highly organized microtubule arrays. In the absence of klp2p, bundled microtubules still grew in counter opposing directions, but did not slide, suggesting that growth polarity is set by non-motor proteins. A strong candidate for this function is the conserved protein ase1p (homologues to PRC1/MAP65), which we found bundles microtubules *in vitro*. In fission yeast, ase1-GFP localized to zones of anti parallel microtubule overlap in both the spindle midzone and interphase bundles. In interphase *ase1*Δ cells, microtubule sliding was observed, but no stable zones of microtubule overlap were formed. Possibly, microtubule sliding (klp2p) needs to be counteracted by static bundling (ase1p) to achieve well-defined zones of MT overlap. Similar mechanisms may be at work in the mitotic spindle, in which sliding molecular motors and ase1p/PRC1 organize the spindle midzone.

2196

### Structural Intermediates in Microtubule Dynamics and Their Role in Cellular Function

E. Nogales; Molecular and Cell Biology Department, Howard Hughes Medical Institute, University of California, Berkeley, Berkeley, CA

The dynamic behavior of microtubules relays on changes in the assembly properties of tubulin driven by its nucleotide state. Using cryo-electron microscopy we have analyzed the structure of stabilized intermediates in the microtubule assembly and disassembly processes. Bound to GDP the tubulin dimer is kinked and can only associate longitudinally into curved protofilaments that are unable to form functional lateral interactions. Our GDP-conformation of tubulin shows for the first time differences between the intra and inter dimer interfaces and it suggests the effect of destabilizing factors. Using a non-hydrolyzable GTP analogue we have temperature-trapped an early state in assembly that precedes microtubule closure and nucleotide hydrolysis. Our study shows that upon GTP binding the shape and association of tubulin dimers straightens enough to allow for the formation of lateral contacts in open sheets with alternating native and modified lateral interfaces in a transient polymer that subsequently rolls into a close microtubule. The existence of these structural intermediates is suggestive of a functional role in which specific cellular factors may recognize these distinctive tubulin platforms for spatial/temporal localization. Additionally, the active conversion between conformations can be used, as in the case of the bending of protofilaments during microtubule depolymerization, as a source of energy to power the movement of cellular components (e.g. the yeast kinetochore complex Dam1).

## Epithelial Morphogenesis & Polarity (2197-2202)

2197

### Mechanisms of AP-1B-dependent Targeting of Basolateral Transmembrane Proteins in Polarized Epithelial Cells

H. Fölsch; Northwestern University, Evanston, IL

Cellular asymmetry in epithelial cells manifests itself in the organization of two distinct plasma membrane domains. To maintain this intrinsic polarity, the cells have to faithfully sort transmembrane proteins to the apical or basolateral plasma membrane during biosynthetic or endocytic protein delivery. To fulfill some of these functions, epithelial cells express the clathrin adaptor complex AP-1B. In contrast to the ubiquitously expressed AP-1A, which is involved in endosomal/lysosomal targeting, AP-1B was demonstrated to play an important role in sorting of proteins such as LDL receptors and Tfn receptors to the basolateral membrane (Folsch et al., 1999). Although AP-1A and AP-1B differ only in the incorporation of their medium subunits mu1A or mu1B, respectively, both complexes were found on distinct vesicle populations (Folsch et al., 2003). Furthermore, AP-1B but not AP-1A was found to play a role in the membrane recruitment of subunits of the exocyst complex needed for tethering basolateral vesicles to the fusion site. Interestingly we found that the C-terminus of mu1B is sufficient for Exo70 recruitment. This explains on a molecular level the differential behavior of the closely related AP-1A and AP-1B complexes in exocyst recruitment.

2198

### Septins Regulate Golgi-to-Plasma Membrane Traffic in Polarizing Epithelia

E. T. Spiliotis,[1] S. Hunt,[1] V. Varenika,[1] M. Kinoshita,[2] W. J. Nelson[1]; [1]Molecular and Cellular Physiology, Stanford University, Stanford, CA, [2]Biochemistry and Cell Biology Unit, Kyoto University, Kyoto, Japan

Septins are conserved GTP-binding proteins that associate with cellular membranes, and the actin and microtubule cytoskeleton. In budding yeast, septins are required for polarized membrane growth, but septin function in polarized epithelial cells is unknown. In non-polarized Madin-Darby canine kidney (MDCK) cells, septin 2 (Sept2) was found at sites of membrane fission from the trans-Golgi network. By time-lapse fluorescence

microscopy, CFP-tagged apical and basal-lateral marker proteins exited the trans-Golgi network in tubular membrane carriers that co-aligned with Sept2YFP. Endogenous Sept2 also colocalized with Golgi membrane tubules after treatment with BFA, an inhibitor of membrane fission. Sept2YFP and Sept6GFP were also observed to move along curve-linear pathways with instantaneous velocities (0.4+/-0.2 micrometers/second) resembling those of *bona fide* vesicle markers (eg. VSV-G-GFP); this was consistent with Sept2 presence on purified Golgi vesicles. Moreover, Sept2YFP and Sept6GFP accumulated with E-cadherin-dsRed-labeled membranes at nascent sites of cell-cell contact, which contain the exocyst complex and are presumed to be hot spots of vesicle fusion. To probe for septin function(s) in the establishment of epithelial cell polarity, non-polarized MDCK cells were treated with mock and Sept2 siRNAs for 48 hrs and then plated onto polycarbonate filters at a confluent cell density for 24 hours. In Sept2-depleted cells, development of the lateral membrane domain was impaired. Lateral membranes appeared short and the apical junctional complex marker protein ZO-1 mislocalized to the lower half of the lateral membrane. Significantly, the basal-lateral marker protein VSV-G-YFP accumulated in a post-Golgi intermediate compartment and recruitment of the exocyst complex to adherens junctions was down-regulated. Hence, Sept2 is required for membrane delivery to the growing lateral domain of polarizing cells. Overall, we suggest that septins regulate Golgi-to-plasma membrane traffic by coupling membrane fission/fusion to cytoskeleton-based mechanisms of vesicle transport.

**A Novel Molecular Mechanism by Which PAR-1 Regulates the Epithelial Apico-basal Polarity**

M. Hirata, A. Suzuki, Y. Amano, N. Sakai, K. Shimada, S. Ohno; Molecular Biology, Yokohama City University School of Medicine, Yokohama, Japan

aPKC/PAR system serves as the evolutionarily-conserved, ubiquitous molecular machinery which amplifies various cell polarity signals and links them to the corresponding global cell polarization processes. The system includes three Ser/Thr kinases, aPKC, PAR-1, and LKB1, all of them have been shown to play crucial roles for the development of epithelial polarity. We have shown that aPKC is indispensable for the establishment of the epithelia-specific apical junctional complex (AJC) including adherens junction (AJ) and tight junction (TJ), while one of the mammalian PAR-1 variants, PAR-1b, is essential for the development of the membrane domains which mainly occurs after the AJC establishment. We also found that, at TJ, aPKC suppresses the invasion of basolaterally-localized PAR-1b into the apical membrane in cooperation with PAR-5/14-3-3, and thereby maintains a balance between the apical and lateral membranes. In this work, we report the identification of a membrane-skeletal protein that specifically interacts with PAR-1b. They are asymmetrically co-localized at the basolateral membrane of polarized MDCK cells, and co-precipitated from these cells. RNAi knockdown of this membrane-skeletal protein in MDCK cells resulted in the same polarity defects as PAR-1b showing impaired membrane domain development with compromised cortical actin staining. Unexpectedly, the membrane-skeletal protein is not required for the basolateral localization of PAR-1b, but rather, PAR-1b kinase activity is essential for the basolateral localization of this membrane-skeletal protein. Several lines of evidence suggested that PAR-1b promotes the assembly of extracellular matrix by way of the interaction with this protein, and thereby affects the lateral membrane extension and establishment of membrane polarity. These results provide a novel mechanism by which PAR protein regulates apico-basal polarity of epithelial cells.

**Endocytic control of epithelial polarity and proliferation**

T. Vaccari, D. Bilder; Department of Molecular/Cell Biology, University of California, Berkeley, Berkeley, CA

Acquisition of appropriate cellular architecture is required not only for tissue morphogenesis but also permits proper cell-cell communication. A dramatic example of the coordination between cell architecture and cell signaling is seen in Drosophila 'neoplastic' tumors, wherein loss of epithelial polarity is coupled to an inability to control cell proliferation. To investigate the links between epithelial organization and growth-control signaling, we have carried out a mosaic genetic screen to isolate new mutations that cause neoplastic or malignant tumors in the fly. Through this screen we have identified a number of components that regulate intracellular vesicle traffic. Surprisingly, the largest group of proteins identified act not in the exocytic but the endocytic pathway, revealing a critical role for endocytic traffic in homeostatic control of both epithelial polarity and proliferation. While the polarity phenotypes of many of the endocytic mutants are similar, the effects on cell signaling and cell proliferation can be dramatically different. We will discuss the functions of both known and new members of the endocytic pathway, and how blocks at discrete steps of endocytic traffic alter the activity of specific signaling pathways.

2201

**Hexagonal Packing of Drosophila Wing Epithelial Cells by the Planar Cell Polarity Pathway**

A. Classen,[1] K. I. Anderson,[2] E. Marois,[1] S. Eaton[1]; [1]Max-Planck-Insitute of Molecular Cell Biology and Genetics, Dresden, Germany, [2]Beatson Institute for Cancer Research, Glasgow, United Kingdom

The mechanisms that order cellular packing geometry are critical for the functioning of many tissues, but are poorly understood. Here we investigate this problem in the developing wing of Drosophila. The surface of the wing is decorated by hexagonally packed hairs that are uniformly oriented. They are constructed by a hexagonal array of wing epithelial cells. Wing epithelial cells are irregularly arranged throughout most of development but become hexagonally packed shortly before hair formation. During the process, individual cell boundaries grow and shrink resulting in local neighbour exchanges, and E-cadherin is actively recycled. Successful hexagonal repacking depends on the endocytic recycling pathway, dynamin and on the activity of the planar cell polarity (PCP) proteins. Interfering with Rab11 and dynamin function leads to loss of E-cadherin from epithelial contacts at the time of hexagonal repacking. Epithlial disintegration caused by the lack of dynamin is enhanced by PCP mutants. PCP mutants fail to efficiently assemble boundaries with new neighbours and do not distribute their junctional material symmetrically. We propose that planar cell polarity proteins influence Dynamin-dependent recycling of adhesive components, and suggest that this is a common mechanism for their action in diverse systems.

2202

**Polycystin-1, STAT6 and P100 Function in a Novel Pathway that Transduces Ciliary Mechanosensation to Gene Expression and is Activated in Polycystic Kidney Disease**

S. H. Low,[1] S. Vasanth,[2] C. H. Larson,[3] S. Mukherjee,[4] N. Sharma,[5] M. T. Kinter,[3] M. E. Kane,[6] T. Obara,[6] T. Weimbs[7]; [1]Neuroscience Research

Institute, University of California Santa Barbara, Santa Barbara, CA, [2]School of Biomedical Sciences- Cleveland Clinic, Kent State University, Kent, OH, [3]Cell Biology, Cleveland Clinic, Cleveland, OH, [4]Molecular, Cellular, and Developmental Biology, University of California Santa Barbara, Santa Barbara, CA, [5]Biological Geological and Environmental Science, Cleveland State University, Cleveland, OH, [6]Department of Medicine, MetroHealth Medical Center, Case Western Reserve University, Cleveland, OH, [7]Department of Molecular, Cellular, and Developmental Biology, University of California Santa Barbara, Santa Barbara, CA

Primary cilia are implicated in the pathogenesis of autosomal-dominant polycystic kidney disease (ADPKD) which results from defects in polycystin-1 (PC1) but the function of PC1 and mechanism underlying cyst formation remain poorly understood. Here we show that PC1 participates in a novel signaling pathway that controls the transduction of a mechanical signal from primary cilia to changes of gene expression. PC1 undergoes proteolytic cleavage that results in nuclear translocation of its cytoplasmic tail. Exogenous expression of the human PC1 tail results in renal cyst formation in zebrafish embryos. The PC1 tail interacts with the transcription factor STAT6 and the co-activator P100, and stimulates STAT6-dependent gene expression. Under normal conditions STAT6 and P100 localize to primary cilia of renal epithelial cells. Cessation of apical fluid flow results in nuclear translocation of STAT6. Cyst-lining epithelial cells in ADPKD exhibit highly elevated levels of nuclear STAT6, P100 and the PC1 tail. These results identify a novel mechanism of cilia function and show that this pathway is inappropriately activated in ADPKD.

### FGF-induced Vesicular Release of Sonic Hedgehog and Retinoic Acid in Leftward Nodal Flow is Critical for Left−Right Determination

Y. Tanaka, Y. Okada, N. Hirokawa; Department of Cell Biology and Anatomy, University of Tokyo Graduate School of Medicine, Tokyo, Japan

The precise specification of left−right asymmetry is an essential process for patterning internal organs in vertebrates. In mouse embryonic development, the symmetry-breaking process in left−right determination is initiated by a leftward extraembryonic fluid flow on the surface of the ventral node. However, it is not known whether the signal transduction mechanism of this flow is chemical or mechanical. Here we show that fibroblast growth factor (FGF) signalling triggers secretion of membrane-sheathed objects 0.3−5 μm in diameter termed 'nodal vesicular parcels' (NVPs) that carry Sonic hedgehog and retinoic acid. These NVPs are transported leftward by the fluid flow and eventually fragment close to the left wall of the ventral node. The silencing effects of the FGF-receptor inhibitor SU5402 on NVP secretion and on a downstream rise in $Ca^{2+}$ were sufficiently reversed by exogenous Sonic hedgehog peptide or retinoic acid, suggesting that FGF-triggered surface accumulation of cargo morphogens may be essential for launching NVPs. Thus, we propose that NVP flow is a new mode of extracellular transport that forms a left−right gradient of morphogens.

2204

### Sphingosine-1-phosphate Lyase Promotes Cell Cycle Arrest and Apoptosis Through P53 and P38 Dependent Mechanisms

B. Oskouian, P. Sooriyakumaran, M. A. Lee, J. D. Saba; Children's Hospital Oakland Research Institute, Oakland, CA

Sphingosine-1-phosphate (S1P) is a bioactive lipid with diverse effects on cell fate and function including growth promotion, organismal development, and cell differentiation and death. S1P lyase is the enzyme responsible for irreversible degradation of S1P. Our laboratory is exploring the role that S1P lyase plays in modulating the effects of S1P in cells and organisms. Previously, we reported that overexpression of S1P lyase renders HEK293 cells hypersensitive to serum deprivation by promoting apoptosis. We have recently found that S1P lyase expression enhances apoptotic responses to cytotoxic agents, including the topoisomerase II inhibitor etoposide. Changes in cell cycle progression after etoposide treatment were also markedly different in cells overexpressing S1P lyase, which accumulated in $G_2$/M as determined by flow cytometry and by increased expression of the mitotic marker S10 phosphohistone H3. We have investigated potential mechanisms by which S1P lyase affects these cellular responses to etoposide. Cell cycle changes and enhanced apoptosis in S1P lyase expressing cells were both abrogated by inhibition of p53 function through chemical and molecular approaches, suggesting that both phenomena occur through p53-dependent mechanisms. In contrast, inhibition of p38 MAPK activity with SB203580 reversed the increased apoptosis but not the cell cycle changes in S1P lyase expressing cells treated with etoposide, suggesting that S1P lyase may affect cell cycle and apoptotic responses to stress through divergent regulatory pathways. Importantly, S1P lyase gene expression was found to be upregulated in response to variety of stressful stimuli, including DNA damage. These findings indicate that S1P lyase may play a crucial role in mediating the cellular responses to DNA damage and other stressful conditions.

2205

### Differential Requirements for Sphingosine Kinase Isoenzymes in Cell Migration Toward EGF

S. Spiegel,[1] N. C. Hait,[1] S. Sarkar,[1] A. Mikami,[1] M. Maceyka,[1] S. Milstien[2]; [1]Department of Biochemistry, Virginia Commonwealth University, Richmond, VA, [2]Laboratory of Cellular and Molecular Regulation, NIMH, Bethesda, MD

Sphingosine-1-phosphate (S1P), produced by two sphingosine kinase isoenzymes, SphK1 and SphK2, is the ligand for a family of five specific G protein-coupled receptors that regulate cytoskeletal rearrangements and cell motility. Whereas many growth factors stimulate SphK1, much less is known of the regulation of SphK2. We have now found that similar to PDGF, EGF transiently stimulates SphK1. Importantly, however, EGF also stimulates SphK2. This is the first example of an agonist-dependent regulation of SphK2. Chemotaxis of HEK 293 cells toward EGF was inhibited by N,N-dimethylspingosine, a competitive inhibitor of both SphKs, implicating S1P generation in this process. Overexpression of SphK1 in HEK 293 cells enhanced EGF-mediated cell migration, while expression of SphK2 had no significant effect. Furthermore, catalytically inactive SphK1, but not inactive SphK2, blocked EGF-induced migration of these cells. Moreover, downregulating expression of SphK1 in HEK 293 cells with a specific siRNA also abrogated migration toward EGF, while decreasing SphK2 expression had no effect. Surprisingly, however, in MDA-MB-453 breast cancer cells, downregulation of either SphK1 or SphK2 abrogated migration toward EGF. Collectively, our results suggest that both SphK1 and SphK2 play important roles in migration of MDA-MB-453 cells toward EGF.

### OSBP is a Cholesterol-Regulated Scaffolding Protein in Control of ERK1/2 Activation

P. Wang, J. Weng, R. G. W. Anderson; Department of Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX

OSBP is a Cholesterol-Regulated Scaffolding Protein in Control of ERK1/2 Activation Ping-yuan Wang, Jian Weng and Richard G. W. Anderson Department of Cell Biology, University of Texas Southwestern Medical Center, Dallas. TX 75390-9039 Oxysterol binding protein (OSBP) is the founding member of a family of sterol binding proteins implicated in vesicle transport, lipid metabolism and signal transduction. Here OSBP was found to function as a cholesterol-binding scaffolding protein coordinating the activity of two phosphatases to control the extracellular signal-regulated kinase (ERK) signaling pathway. Cytosolic OSBP formed a ~440 kDa oligomer with a member of the PTPPBS family of tyrosine phosphatases, the serine/threonine phosphatase PP2A, and cholesterol. This oligomer had dual specific phosphatase activity for pERK. These two enzymes each depend on the activity of the other to coordinately remove phosphate from both the threonine and the tyrosine residues of pERK. When cell cholesterol was lowered, the oligomer disassembled and the level of pERK rose. The oligomer also disassembled when exposed to oxysterols. Interestingly, it was reported that OSBP moves from cytosol to the Golgi apparatus under both of the conditions. We found that OSBP binds cholesterol and oxysterol at two different sites. Increasing the amount of OSBP oligomer rendered cells resistant to the effects of cholesterol depletion and decreased the basal level of pERK. In contrast, decreasing the amount of OSBP oligomer by RNA interference of OSBP mRNA caused a sustained activation of ERK1/2. Thus, cholesterol functions through its interaction with OSBP outside of membranes to regulate the assembly of an oligomeric phosphatase that controls a key signaling pathway in the cell.

### Diacylglycerol Incorporation upon Compartment Mixing acts as an Upstream Signal for Actin Assembly during Compensatory Endocytosis in *Xenopus* Eggs

H. E. Yu,[1] W. Bement[2]; [1]Program in Cellular and Molecular Biology, University of Wisconsin -- Madison, Madison, WI, [2]Zoology Department, University of Wisconsin -- Madison, Madison, WI

Exocytosis of cortical granules (CGs) in *Xenopus* eggs is followed by direct membrane retrieval, resulting in compensatory endocytosis. The compartments thus formed become surrounded by actin “coats”, which are generated by Cdc42-dependent actin polymerization (Sokac *et al.*, Nat Cell Biol. 5: 727-32, 2003). Here, we assessed the role of conventional protein kinase Cβ (PKCβ) in the formation of actin coats by using time-lapse confocal microscopy on eggs expressing different fluorescently labeled proteins, in combination with inositol triphosphate ($IP_3$) uncaging to elevate $Ca^{2+}$ and trigger CG exocytosis. Perturbation of PKCβ perturbed actin coat assembly, as well as Cdc42 activation, showing that PKCβ signals via Cdc42 to initiate actin coat assembly. Importantly, incorporation of diacylglycerol (DAG) from the plasma membrane (PM) into the CG membrane during CG-PM fusion sustained PKCβ recruitment on exocytosing CGs, indicating that DAG incorporation is key to actin coat assembly. A parallel study on PKCη revealed that this novel PKC had a different recruitment pattern and when perturbed, did not affect actin coat assembly, but perturbed cortical actin integrity, demonstrating that PKCη plays a different role during exo/endocytosis of CGs. Thus, while DAG incorporation during CG-PM compartment mixing is crucial for PKCβ activation to initiate actin assembly, the interplay between PKCβ and PKCη is also necessary for proper exo/endocytosis of CGs.

2208

### The Role of the Phosphoinositides at the Golgi Complex

M. A. De Matteis,[1] A. Godi,[1] A. Di Campli,[1] G. D’Angelo,[1] E. Polishchuk,[1] R. Polishchuk,[1] D. Alessi,[2] J. M. Lucocq,[3] J. Saus[4]; [1]Cell Biology/Oncology, Consorzio Mario Negri Sud, Santa Maria Imbaro, Italy, [2]Division of Cell Signalling, University of Dundee, Dundee, United Kingdom, [3]MSI/WTB Complex, University of Dundee, Dundee, United Kingdom, [4]Molecular Pathology, Instituto de Investigaciones Citologicas, Valencia, Spain

The phosphoinositides (PIs) act as precursors for second messengers and as membrane ligands for protein modules. Specific lipid kinases and phosphatases are differentially located and regulated in individual cell organelles, thus generating non-uniform distributions of the PIs. At the Golgi complex, the PIs act as key regulators of anterograde membrane traffic via PtdIns(4)P, and of the structure of the organelle via PtdIns(4,5)P2. We have investigated this system using a combination of approaches that range from knock-out of the Golgi-localized PI kinases and phosphatases (by pharmacologically means, or by dominant-negative mutants and siRNAs), through “sequestering” of PtdIns(4)P using PtdIns(4)P-binding domains, to direct interference with the localization/ levels of the PtdIns(4)P targets. We thus show that PtdIns(4)P has a pivotal role at the TGN, and specifically at the crossroads between the endocytic and exocytic pathways. Here, the PtdIns(4)P-generating enzymes and the PtdIns(4)P-binding proteins (such as the FAPPs, OSBP1 and CERT) regulate the transport of cargoes that are destined for the plasma membrane. Finally, we provide evidence that in conjunction with the small GTPase ARF, PtdIns(4)P may also act as a cue for the orienting/ directing of the non-vesicular transfer of lipids from the endoplasmic reticulum to the Golgi complex, and to specific Golgi subcompartments.

## The Membrane Cytoskeleton (2209-2214)

2209

### Ankyrin-G and Assembly of Specialized Membrane Domains

K. Kizhatil,[1] P. J. Mohler,[2] W. Yoon,[1] V. Bennett[1]; [1]Cell Biology, Duke University Medical Center/HHMI, Durham, NC, [2]Pathology, Vanderbilt University, Nashville, TN

The ability of cells to segregate proteins within specialized membrane domains underlies much of vertebrate physiology. For example, generation of action potentials by neurons and heart cells requires excitable membranes. Similarly, transcellular transport by epithelial tissues such as kidney and intestine requires distinct apical and lateral membranes. A central question is whether common mechanisms drive assembly of specialized membranes in these diverse cells. In support of this idea, ankyrin-G, a versatile membrane adaptor, is required for restriction of components of excitable membranes of both neurons and heart as well as formation of lateral membranes of epithelial cells. We have used siRNA to deplete 190 kDa ankyrin-G and beta-2 spectrin in cultured human bronchial epithelial cells. Cells depleted of either protein convert to a squamous morphology, with nearly complete loss of lateral membrane, while the total membrane surface area and apical polarity are preserved. Moreover depletion of either ankyrin-G or beta-2 spectrin also abolishes biogenesis of the lateral membrane during cytokinesis. Mutations of ankyrin-G that abolish spectrin-binding activity also eliminate activity in restoring lateral membranes of ankyrin-G-depleted cells. Ankyrin-G therefore requires beta-2 spectrin for its function in assembly of the lateral membrane. Ankyrin-G and beta-2 spectrin colocalize at the lateral membrane. However, beta-2-

spectrin also is localized separately from ankyrin-G in an intracellular tubulovesicular compartment that is enhanced by Brefeldin A and is distinct from conventional Golgi or ER. Together, these results identify beta-2-spectrin and ankyrin-G as essential participants in a conserved pathway for assembly of the lateral membrane domain. Given roles of ankyrin-G in neurons and heart cells, the ankyrin-spectrin pathway may have a more general function in assembly of diverse membrane domains.

2210

**The Presynaptic Spectrin Skeleton is Essential for Synapse Stabilization**

J. Pielage,[1] R. D. Fetter,[2] G. W. Davis[1]; [1]Department of Biochemistry, University of California, San Francisco, San Francisco, CA, [2]Laboratory of Neural Circuits and Behavior, The Rockefeller University, New York, NY

Precise neural circuitry is established and maintained through a regulated balance of synapse stabilization and disassembly. Currently, little is known about the molecular mechanisms that specify synapse stability versus disassembly. The spectrin-based membrane skeleton has long been considered a candidate for participating in both synapse organization and maintenance. Spectrin is a major component of pre- and postsynaptic assemblies throughout the mammalian and invertebrate nervous systems. We demonstrate that presynaptic spectrin is an essential scaffold that is required to maintain synapse stability at the *Drosophila* neuromuscular junction (NMJ). Loss of presynaptic spectrin leads to synapse disassembly and ultimately to the elimination of the NMJ. Synapse elimination is documented through light-level, ultrastructural, and electrophysiological assays. These combined assays reveal that impaired neurotransmission is secondary to synapse retraction. We demonstrate that loss of presynaptic, but not postsynaptic, spectrin leads to the disorganization and elimination of essential synaptic cell-adhesion molecules. In addition, we provide evidence of altered axonal transport and disrupted synaptic microtubules as events that contribute to synapse retraction in animals lacking presynaptic spectrin. Our data suggest that presynaptic spectrin functions as an essential presynaptic scaffold that may link synaptic cell adhesion with the stabilization of the underlying microtubule cytoskeleton. We will present further data towards the molecules and mechanisms that link the spectrin skeleton to synaptic cell adhesion molecules and to the underlying cytoskeleton. We will also present data that postsynaptic spectrin is required to maintain the postsynaptic density and glutamate receptor clusters.

2211

**Myoferlin Mediates Myoblast Fusion**

K. R. Doherty,[1] A. T. Cave,[2] D. B. Davis,[2] A. J. Delmonte,[2] A. Posey,[2] J. U. Earley,[2] M. Hadhazy,[2] E. McNally[2]; [1]Department of Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, [2]Department of Medicine, University of Chicago, Chicago, IL

Muscle growth occurs during embryonic development and continues in adult life as regeneration. During embryonic muscle growth and the regenerative growth of mature muscle, singly nucleated myoblasts fuse to each other to form myotubes. These processes initiate with cell-cell recognition followed by the alignment and fusion of two apposed lipid bilayers. The large size of mature myofibers and their constant exposure to deformation through muscle contraction necessitates a mechanism for membrane repair in muscle. Dysferlin, the product of the Limb Girdle Muscular Dystrophy type 2 locus, is a membrane-associated protein that is necessary for efficient, calcium-sensitive membrane resealing in muscle (Bansal et al. Nature 2003). The loss of dysferlin leads to an accumulation of submembraneous vesicles. We now show that the related protein, myoferlin, is highly expressed in myoblasts undergoing fusion and that myoferlin is expressed at the site of myoblasts fusing to myotubes. Like dysferlin, we found that the first C2 domain of myoferlin binds phosphotidylserine/phosphotidylcholine in a calcium-sensitive manner. We generated mice with a null allele of myoferlin, and found that myoferlin null myoblasts form large myotubes less efficiently in vitro, consistent with a defect in the fusion of myoblasts to myotubes. In vivo, myoferlin null mice have smaller muscles than littermate controls, and myoferlin null muscle has a marked reduction in the largest diameter myofibers. We also found that expression of myoferlin is greatly increased in acutely injured muscles. Consistent with a role for myoferlin in myoblast-mediated muscle regeneration, myoferlin null muscle regenerates less well than wildtype muscle and instead displays a dystrophic phenotype. These data support a role for myoferlin in the maturation of myotubes and the formation of large myotubes that arise from the fusion of myoblasts to multinucleate myotubes.

2212

**Components Required for Membrane Deposition at the Site of Scission in *C elegans* Embryos**

J. M. Squirrell,[1] K. J. C. Verbrugghe,[2] H. Zhang,[2] J. G. White[1]; [1]Laboratory for Molecular Biology, University of Wisconsin-Madison, Madison, WI, [2]Laboratory of Genetics, University of Wisconsin-Madison, Madison, WI

Previous studies showed that secretion is necessary for the final stage of cytokinesis (i.e. scission) in *C. elegans* (Skop et al.,Curr Biol 2001). We used the plasma membrane probe FM 2-10, in conjunction with multiphoton microscopy, to observe the movements of the plasma membrane and endocytosed vesicles during cytokinesis of *C. elegans* embryos. In wild-type embryos, membrane accumulates at the apex of cleavage furrow shortly following the completion of furrow ingression. This accumulation is altered or absent in embryos depleted for centralspindlin components, all of which are required for scission. In addition, embryos depleted for CAR-1, a protein that localizes to cytoplasmic puncta and is homologous to RNA associated proteins, have abnormal spindle dynamics and no spindle midzone microtubules, lack membrane accumulation at the apex of the late cleavage furrow and fail in scission. In *car-1(RNAi)* embryos, ZEN-4, a member of the centralspindlin complex, is found on the ingressing furrow, a localization that has previously been shown to be sufficient for cytokinesis in the absence of a spindle midzone (Verbrugghe and White, 2004), indicating that in the absence of CAR-1 the furrow localization of ZEN-4 is not sufficient for cytokinesis to complete. *car-1(RNAi)* embryos also show defects in the structure of the endoplasmic reticulum and in RAB-11 distribution. This suggests that endomembrane organization, in conjunction with the spindle midzone microtubules and centralspindlin proteins, is an important component of the mechanisms used in cytokinesis.

2213

**Single Particle Tracking of Murine Polyomavirus-like Particles on Live Cells and Artificial Membranes**

H. Ewers,[1] A. E. Smith,[1] I. F. Sbalzarini,[2] H. Lilie,[3] P. Koumoutsakos,[2] A. Helenius[1]; [1]Institute of Biochemistry, ETH, Zurich, Switzerland, [2]Institute of Computational Science, ETH, Zurich, Switzerland, [3]Institute of Biotechnology, Martin-Luther-University in Halle, Zurich, Switzerland

The lateral mobility of fluorescently labeled murine polyomavirus-like particles (VLPs) bound to live cells and artificial lipid-bilayers was studied by single particle tracking using total internal reflection fluorescence (TIRF) microscopy. The particle trajectories were analyzed according to their

diffusion rates and their modes of motion as described by the moment scaling spectrum. We found that VLPs bound to their ganglioside receptor in lipid bilayers exhibited free diffusion. In contrast, trajectories on live 3T6 mouse fibroblasts revealed three distinct modes of mobility. These were rapid random motion, confined movement to small zones of 30-60 nm in diameter, and confined movement in such zones with a slow drift. After binding to the cell surface, the particles typically underwent free diffusion for 5-10 s before they became confined in an actin filament-dependent manner. Neither clathrin-coated pits nor caveolae were involved in the confinement of the VLPs. While depletion of cholesterol dramatically reduced mobility of VLPs independently of actin, inhibition of tyrosine kinases had no effect on confinement. The results suggested that clustering of ganglioside molecules by the multivalent VLPs induced transmembrane-coupling in lipid rafts that led to confinement of the virus/receptor complex by cortical actin filaments.Single particle tracking provides a powerful tool to analyze the sequence of events during initial virus-host cell interactions.

2214

**Membrane Deforming Properties and Interaction With Dynamin of a Family of Actin Regulatory Proteins That Contain an F-Bar Domain**

T. Itoh,[1] A. Roux,[1] B. Habermann,[2] H. Werner,[1] K. S. Erdmann,[1] P. De Camilli[1]; [1]Cell Biology, Yale University School of Medicine, New Haven, CT, [2]Scionics Computer Innovation, c/o Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany

Membrane trafficking and cell motility require the deformation of cell membranes. Deformations are achieved both by forces extrinsic to the membrane as well as by structural modifications in the bilayer or at the bilayer surface that favor the acquisition of curvature. BAR domain proteins, for example, bind to membranes and induce or sense (and therefore stabilize) membrane curvature. Via studies in living cells and in cell-free models involving purified proteins and artificial lipid membranes, we have demonstrated that a family of proteins (including Toca-1, FBP17, CIP4, Pacsin1) previously known to function as key regulators of actin nucleation have in addition powerful lipid bilayer deforming properties. Their membrane deforming activity was mapped to an N-terminal module (F-BAR) which shows sequence similarity to the BAR domain and includes the previously defined FCH module. Moreover, several of these proteins bind dynamin, a GTPase implicated both in endocytosis and actin dynamics. Overexpression of the Toca-family proteins CIP4 and FBP17 in COS7 cells induces tubular invaginations of the plasma membrane. In addition CIP4 and FBP17, but not deletion constructs of these proteins lacking the SH3 domain, recruit dynamin to these invaginations. The properties of BAR and F-BAR domain proteins to induce tubular invaginations of the plasma membrane are further enhanced by disruption of the actin cytoskeleton using Latrunculin B. These results suggest a very close interplay between the mechanisms that control actin nucleation and those which mediate plasma membrane deformations underlying endocytosis.

## Neuronal Polarity & Axo-Dendritic Growth (2215-2220)

2215

**Neuronal Polarity and Cytoskeleton**

T. Yoshimura, K. Kaibuchi; Department of Cell Pharmacology, Graduate School of Medicine, Nagoya University, Nagoya, Japan

The neuron is one of the most highly polarized cells and is comprised of two structurally and functionally distinct parts, an axon and dendrites. In cultured hippocampal neurons, neurons extend several minor processes during the first 12-24 h after plating. Then, one of the processes begins to extend rapidly to form an axon, resulting in the morphological polarization of the neuron. The remaining processes result in the morphological features of dendrites. Previously, we showed that collapsin response mediator protein-2 (CRMP-2) is enriched in the growing axon of hippocampal neurons, the overexpression of CRMP-2 induces the formation of multiple axons and elongation of the primary axon, and truncated fragment of CRMP-2 or knockdown of CRMP-2 by RNAi inhibits axon formation. Thus, CRMP-2 appears to play a crucial role in the determination of axon/dendrite fate and axon elongation. We have recently found that CRMP-2 interacts with tubulin heterodimers to promote microtubule assembly for axon growth, and that CRMP-2 binds to Sra-1, an effector of Rac1 to regulate WAVE-dependent reorganization of actin filaments. CRMP-2 links Kinesin-1 to tubulin heterodimers and Sra-1, and mediates the Kinesin-1-dependent transport of tubulin heterodimers and the Sra-1/WAVE complex to developing axons. We have also found that the PAR-6/PAR-3 complex and the Akt/GSK-3β pathway are involved in neuronal polarization downstream of PI3-kinase. The PAR-6/PAR-3 complex mediates the Cdc42-induced Rac1 activation through direct interaction with STEF/Tiam1 (Rac GEF) for axon growth. GSK-3β phosphorylates CRMP-2 and inactivates its tubulin-binding activity. Akt appears to phosphorylate GSK-3β and inactivates its kinase activity, thereby increasing non-phosphorylated active CRMP-2, which promotes axon outgrowth. This time, we summarize and discuss functions of these ‘polarity’ molecules in regulation of neuronal polarity and cytoskeleton.

2216

**Ena/VASP Proteins are Required for Neuritogenesis in Cortical Neurons**

E. W. Dent, A. Kwiatkowski, D. Rubinson, L. Mebane, U. Philippar, M. Barzik, E. M. Kovacs, F. B. Gertler; Biology, MIT, Cambridge, MA

Genetic studies in worms, flies and mice have implicated Ena/VASP proteins in major guidance decisions in developing central nervous system (CNS) neurons. In an accompanying abstract (Kwiatkowski et al.) we describe the phenotype of mice in which all three mammalian Ena/VASP family members (Mena/VASP/EVL) have been deleted. Surprisingly, these mice exhibit very little, if any, axonal growth from the cortical plate in developing neocortex, implicating Ena/VASP proteins in neuritogenesis. We have cultured cortical neurons from triple knockout mice to determine the mechanism by which Ena/VASP family proteins regulates neuritogenesis. Mena/VASP/EVL triple knockout (mmvvee) cortical neurons attach and spread a circular lamellipodia like wild type controls (stage 1). However, the lamellipodia is devoid of filopodia and bundled actin filaments and over 80% of the neurons fail to extend any minor processes (stage 2), even after 48hrs in culture. Nevertheless, they are differentiated neurons because they express the neuron specific BIII-tubulin. Transfection of low levels of either Mena, VASP or EVL can rescue this phenotype, allowing the neurons to extend filopodia, minor processes and subsequently a single axon (stage 3). Addition of laminin, but not fibronectin or collagen, rescues this stage 1 phenotype as well by forming loosely bundled actin filaments in filopodia-like protrusions. Addition of blebbistatin, a specific myosin II inhibitor, also induces neurite extension rather rapidly from mmvvee cortical neurons, apparently by inhibiting retrograde actin flow and compaction of the peripheral F-actin meshwork in the transition zone. The inhibition of actin retrograde flow allows microtubules to extend to the periphery, promoting process extension. These data support a new function for Ena/VASP proteins in neuritogenesis and indicate that Ena/VASP dependent bundled actin filaments in filopodia of stage 1 cortical neurons are necessary for neurite extension.

**AFAP: Regulating the Transition**

L. M. Lanier; Department of Neuroscience, University of Minnesota, Minneapolis, MN

Growth cone motility and neurite branching are dependent on the coordinated regulation of the actin and microtubule cytoskeletons. The peripheral region of the growth cone is dominated by actin-rich filopodia, while the central region contains abundant microtubules and a sparse meshwork of actin filaments. The transition region is a dense actin network that separates the central and peripheral regions and appears to serve as a boundary to microtubule advance. Studies have shown that the stochastic ability of microtubules to cross through the transition region and explore the peripheral region is a key determinant of growth cone turning. While proteins in the central and peripheral region have been identified, little is known about the protein(s) that regulate actin dynamics in the transition region. Here we report that the Actin Filament Associated Protein (AFAP110/120) is specifically enriched in the growth cone transition region. AFAP110, the ubiquitous form of AFAP, was previously identified as a tyrosine phosphorylated protein in Src kinase transformed cells. AFAP110 binds actin filaments, co-localizes with actin stress fibers in fibroblasts and is important for the stretch induced activation of Src. We demonstrate that AFAP120, the neuronal-specific form, is one of the most abundant tyrosine phosphorylation substrates in developing neurons and that Protein kinase C modulates this phosphorylation in a Src kinase dependent manner. The fact that AFAP is a stretch responsive, Src-regulated actin-binding protein in the transition region of the growth cone suggests that it could be involved in regulating actin dynamics and, indirectly, microtubule advance, during growth cone turning and branching. Indeed, preliminary experiments indicate that RNAi knockdown of AFAP alters neurite outgrowth and branching.

**Cdc42 Bioprobes Reveal Signal Integrations within a Single Neuron Undergoing Dendrogenesis**

D. Kamiyama, A. Chiba; Cell and Developmental Biology, University of Illinois, Urbana, IL

Cdc42 is a highly conserved and versatile cytosolic Rho GTPase. In neurons, multiple signaling pathways are thought to converge and diverge at Cdc42 during differentiation. However, little is known about how Cdc42 activities are spatiotemporally regulated and integrated to specific signaling molecules within individual neurons. Here, we show that genetic deletion/disruption of Cdc42 in the *Drosophila* pioneer motoneurons results in their failure to initiate dendrogenesis. Cdc42 is found ubiquitously within the neurons. However, GFP-tagged and/or FRET-based *in vivo* bioprobes reveal that both activation of Cdc42 and localization of its effectors are each regulated dynamically within the neurons. Remarkably, the two display a spatiotemporal coincidence at the onset of dendrogenesis. Further analysis suggests that, whereas Robo receptor is required for activating Cdc42 with a specific temporal restriction, Dscam is responsible for spatially limiting a CRIB-containing effector responsible for initiating dendrogenesis within the neurons. Altogether, our study reveals dynamic spatiotemporal integrations of Cdc42 signaling within a single differentiating neuron *in vivo*.

2219

**Cytoplasmic Dynein Transports Short Microtubules, Aligns Long Microtubules, and Opposes Retraction of the Axon**

K. A. Myers,[1] Y. He,[1] F. Francis,[2] M. M. Black,[2] P. W. Baas[1]; [1]Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA, [2]Anatomy and Cell Biology, Temple University School of Medicine, Philadelphia, PA

We recently reported that cytoplasmic dynein transports short microtubules down the axon. It seems reasonable to posit that the longer immobile microtubules are subjected to these same forces, and hence that cytoplasmic dynein plays a broader role in the organization and disposition of the axonal microtubule array. To investigate this, we determined the effects of suppressing dynein functions in cultured rat sympathetic neurons either by depletion of dynein heavy chain using siRNA or by disruption of dynactin via overexpression of P50-dynamitin. Both methods reduced the anterograde transport of short microtubules in the axon by about half. Axonal growth was fairly normal in both cases, except when the neurons were re-plated after a few days of treatment. After re-plating, axonal growth was stunted, with microtubules appearing dramatically curved and misaligned, particularly in their distal regions. This effect was more profound in the dynein-depleted neurons. When the neurons were treated with donors of nitric oxide, the axons of dynein-depleted neurons showed a marked increase in the degree of retraction, and again, the microtubules were dramatically curved and misaligned. This was not observed in the neurons overexpressing P50-dynamitin, but is reminiscent of earlier studies in which axonal retraction occurred in response to microinjection of higher levels of P50-dynamitin. Taken together, these results are consistent with a model whereby cytoplasmic dynein not only transports short microtubules, but also serves to align the longer microtubules and offset other forces that tend to compress the microtubules and cause the axon to retract.

2220

**Mechanisms of Developmental Axon Pruning**

E. D. Hoopfer, A. Penton, R. Watts, L. Luo; Howard Hughes Medical Institute and Department of Biological Sciences, Stanford University, Stanford, CA

Pruning of exuberant axons and dendrites is a widespread mechanism in vertebrates and invertebrates for achieving the mature pattern of neuronal connections. Axon pruning may also occur in response to injury or disease. In *Drosophila*, mushroom body (MB) gamma neurons undergo developmental pruning of their axonal projections in response to the cell-autonomous action of the steroid hormone ecdysone. Using these neurons as a model for axon pruning we have shown that MB axons are pruned through local degeneration of axon branches, and that this process requires the intrinsic activity of the ubiquitin-proteasome system. In addition, through the use of a genetically encoded electron microscopic (EM) marker to selectively label neuronal or glial populations in the MB, we find that degenerating axon fragments are engulfed by glia for degradation via the endosomal-lysosomal pathway, suggesting an extrinsic role for glia in axon pruning. What are the molecular mechanisms that regulate developmental pruning of axons? Recently, we conducted two screens to identify new genes involved in developmental axon pruning of MB neurons: (1) a systematic gain-of-function screen in MB neurons, and (2) a microarray screen to identify genes differentially regulated by ecdysone signaling. Both screens independently identified *boule*, a gene encoding an RNA binding protein, as being involved in axon pruning. We find that *boule* expression is rapidly down-regulated by ecdysone signaling at the onset of axon pruning and that overexpression of Boule is sufficient to inhibit axon pruning. Together these studies suggest that Boule is a critical regulator of developmental axon pruning. We also address the broader question of the molecular relatedness between axon pruning during development and after axon injury.

## Protein Folding & Quality Control (2221-2226)

2221

### Genome-wide Screens Uncover the Essential Cellular Functions and Substrates of the Hsp90 Molecular Chaperone

A. J. McClellan,[1] B. Y. Xia,[2] A. M. Deutschbauer,[3] R. Davis,[3] M. Gerstein,[2] J. Frydman[1]; [1]Biological Sciences, Stanford University, Stanford, CA, [2]Molecular Biophysics & Biochemistry, Yale University, New Haven, CT, [3]Biochemistry, Stanford University, Stanford, CA

Molecular chaperones are essential mediators of cellular folding. Yet, little is known about their respective contributions to folding in the eukaryotic cell. The molecular chaperone Hsp90 is ubiquitous throughout eukaryotes and comprises 1-2% of total cytosolic protein. Hsp90 is required for viability, even under non-stress conditions. However, only a handful of confirmed folding substrates for the Hsp90 chaperone have been identified. In order to uncover the scope of requisite cellular functions and substrates of Hsp90, we have conducted whole-genome screens in yeast using an Hsp90-inhibiting drug and the available yeast deletion collections. Data from the homozygous deletion pool experiments allowed the construction of an in-depth Hsp90 protein interaction network. Interestingly, analysis of Hsp90 function conducted at both 30 °C and 37 °C revealed that, while some deletion strains exhibited a dependence on Hsp90 for viability at both temperatures, some functional processes were uniquely affected at only one of these temperatures. These data suggest that Hsp90 carries out distinct cellular functions at normal and elevated growth temperatures. Surprisingly, a role for Hsp90 in various avenues of cellular transport was uncovered at 30 °C, while at 37 °C a dependence on Hsp90 for aspects of signal transduction, cell cycle, meiosis and cytokinesis was observed. As many essential proteins may be Hsp90 “clients”, genomic screens were also conducted using pooled heterozygous deletion strains. Numerous potential Hsp90 substrates have thus been identified and ongoing biological and bioinformatic analyses, in combination with the homozygous data, will permit us to build a complete picture of Hsp90 function in yeast. The high degree of conservation between yeast and mammalian Hsp90 enables the translation of these new data to humans, allowing for a better understanding and treatment of human diseases linked to Hsp90-dependent targets.

### Role for Chaperones in Recognizing Substrates for ER Associated Degradation (ERAD), Demonstrated by *in vitro* Reconstitution of Ste6p* Ubiquitination

K. Nakatsukasa,[1] G. Huyer,[2] S. Michaelis,[2] J. L. Brodsky[1]; [1]Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA, [2]Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD

Endoplasmic reticulum associated degradation (ERAD) clears the secretory pathway of aberrant or misfolded proteins, and these proteins are ultimately degraded by the ubiquitin-proteasome system. Ubiquitination of aberrant proteins provides a signal for their delivery to, and degradation by, the proteasome. While many components involved in the ubiquitination and proteasomal delivery of ERAD substrates have been identified, little is known about how ERAD substrates are selected for ubiquitination, especially in the case of misfolded integral membrane proteins. We have developed Ste6p*, a mutant form of Ste6p, as a model ERAD substrate in yeast. Ste6p is a multispanning membrane protein with 12 transmembrane spans and is a member of the ATP-binding cassette superfamily that also includes the cystic fibrosis transmembrane conductance regulator (CFTR). In yeast, ERAD of Ste6p* depends on Ubc6/7p (ubiquitin E2 enzymes), Doa10p (an ER integral membrane ubiquitin E3 ligase), and cytosolic molecular chaperones (the Hsp70, Ssa1p and two Hsp40s, Ydj1p and Hlj1p). To define how Ste6p* is recognized and targeted for degradation, we have reconstituted Ste6p* ubiquitination *in vitro* using microsomes and cytosol prepared from yeast. Upon incubation of Ste6p*-containing microsomes with cytosol and ATP, Ste6p* is poly-ubiquitinated, and ubiquitination is diminished when the ubiquitination machinery (Ubc6/7p and Doa10p) is mutated. Importantly, mutation of the chaperones Ssa1p or Ydj1p/Hlj1p also reduces ubiquitination of Ste6p*, suggesting that these chaperones are involved in recognizing Ste6p* for ERAD. Similar requirements are observed for the poly-ubiquitination of CFTR *in vitro*. Experiments are currently underway to define other recognition factors that act upstream of the ubiquitination machinery. The poly-ubiquitinated Ste6p* also provides a starting material for studying how misfolded integral membrane proteins are degraded by the proteasome.

2223

### ER Export and Misfolding Disease - A New View of Protein Secretion

R. L. Wiseman,[1] Y. Sekijima,[1] J. Matteson,[2] J. W. Kelly,[3] W. E. Balch[4]; [1]Department of Chemistry, The Scripps Research Institute, La Jolla, CA, [2]Department of Cell Biology, The Scripps Research Institute, La Jolla, CA, [3]Department of Chemistry and The Skaggs Institute of Chemical Biology, The Scripps Research Institute, La Jolla, CA, [4]Department of Cell Biology and The Institute for Childhood and Neglected Diseases, The Scripps Research Institute, La Jolla, CA

A number of human diseases, including the familial transthyretin (TTR) amyloidoses, are associated with the misfolding and aggregation of destabilized protein variants outside the cell. Using a combined biophysical and cell biological approach, we demonstrate that both secretion through the exocytic pathway and amyloidogenicity of TTR variants correlate with the global protein energetics - defined by the kinetic and thermodynamic stability of the protein fold. These results show that proteins significantly destabilized relative to the wild-type benchmark can be secreted from the cell with full efficiency. Based on these results, we propose a new view of protein export from the ER that builds on the initial concept of quality control (QC). Instead of treating ER export as a QC test of protein functionality, we propose that each cargo protein utilizes an ER export mechanism that can be more correctly defined by the competitive interactions between the components comprising ER-assisted folding (ERAF), ER-associated degradation (ERAD), and ER-mediated export (ERME) pathways. By moving beyond the inherent limitations of QC focused on protein functionality, a new energetic based model of ER export is proposed where cargo partitioning between the ERAF, ERAD, and ERME pathways dictates export thresholds imposed by the local cellular environment. This mechanistic approach allows for a better appreciation of the general operating principles of the ER in the context of cellular physiology, protein misfolding diseases, and eukaryotic evolution.

2224

### A New Role for Ire1 in the Unfolded Protein Response in *Drosophila* Cells

J. Hollien, J. S. Weissman; Cell. and Molecular Pharm., UCSF, San Francisco, CA

The unfolded protein response (UPR), originally identified as a stress response associated with the accumulation of unfolded proteins in the endoplasmic reticulum (ER), plays an important role in the development of metazoans and in differentiation of cells specializing in secretion. A

key sensor in this response is Ire1, an ER transmembrane protein that participates in the splicing and activation of the transcription factor XBP1. To better understand the role of Ire1 and XBP1 in the UPR, we have individually depleted the mRNAs encoding these proteins in *Drosophila* S2 cells, and measured the effects on global UPR-regulated gene expression using DNA microarrays. We find that although Ire1 and XBP1 have similar effects on genes that are activated by the UPR, Ire1 additionally regulates a subset of mRNAs that are repressed by the UPR. This repression is independent of XBP1 and is not mediated transcriptionally, indicating a new role for Ire1 in regulating mRNA decay. The targets of this repression are enriched for membrane protein-encoding mRNAs, suggesting that this effect may alleviate stress by reducing the load on the ER. We are currently determining the *cis*-requirements for targets of this effect and exploring the possibility that Ire1 may directly cleave target mRNAs.

2225

**Unfolded Protein Response**

P. Walter; Department of Biochemistry/Biophysics, HHMI/UCSF, San Francisco, CA

The protein folding capacity of the endoplasmic reticulum (ER) is regulated by the unfolded protein response (UPR). Induction of the UPR leads to transcriptional upregulation of genes, including those encoding ER resident enzymes and chaperones, phospholipid biosynthetic enzymes, components involved in ER associated protein degradation, and components acting downstream of the ER in the secretory pathway. Together, these changes affect about 5% of the genes in yeast and lead to a restructuring of the secretory pathway according to the need of the cell. Studies of the UPR have revealed many surprising new ways by which eukaryotic gene expression can be controlled, including non-conventional cytoplasmic mRNA splicing, translational control by an mRNA intron, and the use of a protein kinase module as an intramolecular conformational switch. Many of the salient features of the UPR are conserved from yeast to mammalian cells.

2226

**The Yeast Unfolded Protein Response (UPR) Sensor Ire1 uses Three Functional Domains to Transmit an Unfolded Protein Signal across the Endoplasmic Reticulum Membrane**

F. R. Papa,[1,2] J. Credle,[3] P. Walter[4,3]; [1]Medicine, UCSF, San Francisco, CA, [2]California Institute for Quantitative Biomedical Research (QB3), UCSF, San Francisco, CA, [3]Howard Hughes Medical Institute (HHMI), UCSF, San Francisco, CA, [4]Biochemistry and Biophysics, UCSF, San Francisco, CA

Unfolded proteins in the endoplasmic reticulum (ER) activate the ER transmembrane protein Ire1 to trigger an adaptive pathway called the unfolded protein response (UPR). Ire1 transmits this unfolded protein signal using three functional domains: (1) an ER lumenal unfolded protein-sensing domain, and on the cytosolic side of the ER membrane (2) a protein kinase and (3) an endoribonuclease that initiates nonconventional splicing of *HAC1* messenger RNA, leading to production of the Hac1 transcription factor whose downstream targets expand ER protein-folding capacity. To refine our understanding of the structural and functional relationships between Ire1's three domains in this unique signal transduction pathway, we used mutational analyses and overexpression methods to perturb signaling by Ire1. We learned that the ER lumenal domain, whose crystal structure has been recently solved, likely uses a central cavity created by dimerization of two monomers to recognize unfolded proteins. Recognition of unfolded proteins by the ER lumenal domain leads to oligomerization of Ire1 in the plane of the ER membrane, causing trans-autophosphorylation by the kinase activity and inducing the endoribonuclease activity. Furthermore, Ire1's kinase domain requires occupancy of its active site with an adenosine nucleotide ligand to throw a conformational switch which activates the endoribonuclease; this conformational change can be mimicked with an ATP-competitive drug in drug-sensitized Ire1 mutants. Together these results suggest that unfolded proteins may cause clustering of Ire1 at the ER membrane, followed by conformational rearrangement(s) of the kinase and endoribonuclease that allow propagation of the unfolded protein signal to the nucleus.

## RNA Silencing Mechanisms (2227-2232)

2227

**Two Novel Proteins, Dos1 and Dos2 Regulate Heterochromatic RNA Interference and Histone Modification**

F. Li,[1] D. Goto,[2] M. Zaratiegui,[2] X. Tang,[1] R. Martienssen,[2] W. Z. Cande[1]; [1]Department of Molecular & Cell Biology, University of California, Berkeley, Berkeley, CA, [2]Cold Spring Harbor Laboratory, Cold Spring Harbor, NY

In fission yeast, chromosomal behavior such as sister chromatid cohesion during mitosis, and telomere clustering during meiosis, depends in part on heterochromatic modifications such as histone H3 lysine-9 di-methylation (H3mK9). These modifications are also required for gene silencing via Swi6, a homolog of Heterochromatin Protein 1 (HP-1), which recognizes Histone H3 dimethyl-lysine 9 (H3K9me2), silences transcription and retains cohesin at the pericentromeric repeats. H3K9 is methylated by the methyltransferase Clr4, which depends on RNA interference of transcripts derived from centromeric repeats. Rik1, a WD-40 repeat-containing protein, acts in a complex with Clr4 to promote H3K9 di-methylation but the mechanism underlying this interaction is poorly understood. Using a cytological screen we have identified two novel genes, *dos1*$^{+}$ and *dos2*$^{+}$, which are required for localization of Swi6. Deletions of these two genes results in mitotic and meiotic chromosome missegregation and defects in mitotic centromere and meiotic telomere clustering, as well as loss of heterochromatic silencing. Dos1 is predominantly located in the nucleus in a Dos2-dependent manner, and forms a complex with Rik1 that recruits Clr4. Each of these genes is required for the association of H3K9me2 with centromeric repeats, as well as for the production of small interfering RNA. Our findings suggest a mechanism for the recruitment of Clr4 in the RNAi-dependent heterochromatin pathway, in which Dos1 and Dos2 play essential roles.

2228

**Targets and Functions of Plant MicroRNAs**

B. Bartel,[1] A. C. Mallory,[2] D. V. Dugas,[1] D. P. Bartel[3,4]; [1]Department of Biochemistry and Cell Biology, Rice University, Houston, TX, [2]Whitehead Institute for Biomedical Research, Whitehead Institute, Cambridge, MA, [3]Whitehead Institute for Biomedical Research, Cambridge, MA, [4]Biology, Massachusetts Institute of Technology, Cambridge, MA

MicroRNAs are ~21-nt riboregulators that direct cleavage of mRNAs or attenuate productive translation. Plant microRNAs have a strong propensity to direct the regulation of transcription factors involved in cell fate determination, but the extent to which microRNAs control

development is only beginning to be understood. We have uncovered some of the developmental roles of microRNAs in the Arabidopsis model system. By overexpressing microRNAs and expressing microRNA-resistant target genes, we have exposed a posttranscriptional layer of gene regulation for several gene families and have assigned developmental and molecular roles to some of the microRNA:target mRNA relationships. Some of the developmental defects resemble phenotypes previously observed in plants expressing viral suppressors of RNA silencing and plants with mutations in genes important for microRNA biogenesis or function, providing molecular rationales for phenotypes previously associated with more general disruptions of miRNA function.

2229

### A Gene With Two Tudor Domains Regulates RNA-related Events in *C elegans*

N. Le Bot, J. Ahringer; The Gurdon Institute, Cambridge, United Kingdom

Generation of asymmetry in *Caenorhabditis elegans* embryo establishes the anterio- posterior axis of the animal. The microtubule cytoskeleton plays an important role in the asymmetric localisation of conserved polarity proteins to anterior or posterior cortical domains. These proteins in turn control the positioning of the first cleavage through regulation of microtubule function. To identify new genes required for these early events, we carried out a genome-wide RNA mediated interference (RNAi) screen in *C.elegans*. *F22D6.6* is a gene whose inactivation results in the misplacement of the first cleavage. *F22D6.6* codes for a protein of unknown function containing two Tudor domains, which are thought to mediate protein-protein interaction. These domains are found in proteins involved in RNA processing such as TSN, the micrococcal nuclease of RISC, a component of the RNAi machinery. Interestingly, *F22D6.6* was also identified in a genome wide screen looking for new components required for RNAi using an engineered RNAi sensor strain of *C.elegans (1).* RNAi related mechanims are known to mediate a variety of phenomena such as heterochromatin formation, silencing of transposable elements or developmental patterning. Two studies have also found that the silencing of a germline specific transgene is impaired by *F22D6.6(RNAi)(1, 2).* Analysis of *F22D6.6(RNAi)* oocytes and embryos showed that their cytoskeleton is abnormal. Several proteins required for normal microtubule function, like the centrosome associated protein TAC-1 are up-regulated. We are now examining the RNA levels of these proteins in *F22D6.6(RNAi)* animals as well as the distribution of different histone modifications in their germlines. The results of these studies will allow us to assess if this gene controls gene expression by regulating transcription. 1. Kim, J.K., et al., Science, 2005, 308:1164-1167. 2. Robert, V.J.P. et al., Genes and Development, 2005, 19:782-787.

### Muscle Specific MicroRNAs miR-206,-1 and -133 Promote Muscle Differentiation by Post-transcriptional Downregulation of Targets by mRNA Degradation

A. Dutta, H. K. Kim, Y. S. Lee, U. Sivaprasad; Biochemistry, University of Virginia, Charlottesville, VA

The muscle specific miRNAs, miR-206, -1, and -133 are induced during differentiation of C2C12 myoblasts into myotubes in vitro. We show that differentiation from myoblast to myotube is accelerated by the introduction of these miRNAs. This is accompanied by the direct down-regulation of some but not all computationally predicted targets of the microRNAs: Connexin 43, Bind-1 and Mmd. We identify DNA polymerase alpha as a direct target and show that downregulation of the polymerase and of DNA synthesis precede the G1 arrest and cdk2 inhibition seen upon microRNA transfection. Conversely, depletion of the miRNAs by 2'-O-methyl oligonucleotide inhibits differentiation of C2C12 myoblasts and allows them to persist in active DNA replication. This is accompanied by a decrease in MHC positive cells and failure of the few MHC positive cells to elongate into long spindle shaped cells as in normal differentiation. For one of the direct targets, Bind-1, we demonstrate that the downregulation is at the post-transcriptional level and is dependent on sites that match the first 8 nucleotides (but not the entire 22 nucleotides) of the miRNA. The downregulation is however not effected by mRNA cleavage at the match site. Instead RACE-PCR identifies degradation products with multiple ends that are not restricted to the miRNA recognition sequences. This pattern differs from an siRNA-like cleavage mechanism and is consistent with the microRNAs recruiting the target to a different degradation machinery that either cleaves the mRNA at multiple sites or promotes the progressive digestion of the mRNA with several pause sites. Our results suggest that muscle-specific miRNAs promote skeletal myogenesis through direct down-regulation of many target genes by a machinery that differs from the siRNA like cleavage mechanism.

2231

### Disassembly of GW Bodies Disrupts Mammalian RNA Interference

A. Jakymiw,[1] S. Lian,[1] T. Eystathioy,[2] M. Satoh,[3] J. C. Hamel,[1] M. J. Fritzler,[2] E. K. L. Chan[1]; [1]Oral Biology, University of Florida, Gainesville, FL, [2]Biochemistry and Molecular Biology, University of Calgary, Calgary, AB, Canada, [3]Medicine, University of Florida, Gainesville, FL

The human GW182 protein is characterized by multiple glycine(G)/tryptophan(W) repeats and a classical RNA recognition motif. GW182 was initially demonstrated to associate with a specific subset of messenger RNAs (mRNAs) and reside within discrete cytoplasmic foci named GW bodies (GWBs), which are enriched in certain proteins involved in mRNA degradation. GWBs were identified as unique electron dense cytoplasmic structures of 100-300 nm diameter, which vary in number and size during the cell cycle; and are enlarged and more abundant in proliferating cells. *In vitro* gene knockdown of GW182 has demonstrated that GW182 functions as a matrix or scaffold, on which GWBs and their components are assembled. Recent reports have shown that exogenously introduced hAgo2 are also enriched in GWBs suggesting that RNA interference (RNAi) function may be linked to these structures. We demonstrate that endogenous hAgo2 and transfected Cy3-labeled small interfering RNAs (siRNAs) and microRNAs (miRNAs) are also present within these cytoplasmic bodies and that the GW182 protein interacts with hAgo2. Furthermore, during the process of analyzing the structural domains of GW182 and hAgo2, our laboratory noted that the N-terminal 1/3 fragment of GW182, as well as the C-terminal 1/2 fragment of hAgo2 upon transient transfection into HeLa cells disrupted endogenous GWB formation. Disruption of these cytoplasmic foci in HeLa cells, using these dominant interfering constructs impaired the silencing capability of siRNA specific to lamin A/C. *In vitro* gene knockdown of GW182 similarly disrupted GWBs and impaired RNAi functionality, thus independently verifying the results observed with the dominant interfering constructs. Our data support a model whereby the GW182 protein and/or the microenvironment of the cytoplasmic GWBs contributes to the RNA-induced silencing complex (RISC) and RNA silencing activity.

2232

### RNAi, MicroRNAs, and Human Disease

S. Hammond; Cell and Developmental Biology, University of North Carolina, Chapel Hill, NC

MicroRNAs are short, noncoding RNAs that post-transcriptionally regulate gene expression. Over 200 microRNA genes have been identified in humans, however the specific cellular pathways they regulate are largely unknown. We have developed tools to study microRNA function in mammalian systems. We have identified a cluster of microRNAs, miR-17-92, that is overexpressed in a wide range of tumor derived cell lines. Ectopic expression of these microRNAs in a mouse model for lymphoma accelerates tumorigenesis. We have identified cell cycle and apoptotic mRNA targets of these oncogenic microRNAs. We are characterizing the biological pathways these microRNAs regulate in the context of tumorigenesis.

## Stem Cell Niches (2233-2238)

2233

### The *C elegans* Distal Tip Cell Niche, its Development and Function

N. Lam,[1] B. E. Thompson,[2] S. L. Crittenden,[3] J. Kimble[1,3,2]; [1]Department of Biochemistry, University of Wisconsin-Madison, Madison, WI, [2]Program in Cellular and Molecular Biology, University of Wisconsin-Madison, Madison, WI, [3]Howard Hughes Medical Institute, Madison, WI

The *C. elegans* distal tip cell (DTC) is a well-defined and simple niche that controls germline stem cells. We will describe our current understanding of how the DTC is specified and how it functions to maintain stem cells. The DTC is specified, at least in part, by Wnt signaling: no DTCs are produced in mutants lacking Wnt pathway components, including POP-1/TCF and SYS-1/β-catenin; moreover, extra DTCs are made when SYS-1/β-catenin is expressed ectopically. We have identified a homeodomain-encoding gene that controls the generation of DTCs and is a direct target of Wnt/MAPK signaling. We used in vitro, tissue culture and transgenic reporter experiments to show that POP-1/TCF and SYS-1/β-catenin act directly to control the gene, and we used genetic and transgenic experiments to show that this homeodomain transcription factor is both necessary and sufficient for DTC specification. The DTC caps the end of the germline "mitotic region". BrdU experiments demonstrate that mitotic region cells are capable of self-renewal and contribute to the pool of differentiating gametes. The DTC promotes mitotic divisions by Notch signaling and a downstream network of RNA regulators. We previously showed that FBF/Pumilio is essential for maintenance of adult germline stem cells. We now find that FOG-1/CPEB acts in a dose-dependent manner to promote mitoses at a low dose and specify the sperm fate at a high dose. FOG-1/CPEB is kept low near the DTC, and increases as germ cells enter meiosis, a spatial distribution established by FBF/Pumilio. The DTC, Notch signaling and RNA regulators provide a plastic circuit to control number of mitotic cells and number of sperm.

2234

### A Rap-GEF/Rap GTPase Signaling Controls Stem Cell Niche Formation through Regulating Adherens Junctions in the *Drosophila* Testis

S. X. Hou, H. Wang, S. Singh, Z. Zheng, S. Oh, X. Chen; Laboratory of Immunobiology, National Cancer Institute, Frederick, MD

Stem cells will undergo self-renewal to produce new stem cells if they are maintained in their niches. The regulatory mechanisms that recruit and maintain stem cells in their niches are not well understood. In *Drosophila* testes, a group of 12 nondividing somatic cells, called the hub, identify the stem cell niche by producing the growth factor Unpaired (Upd). Here we show that a Rap-GEF/Rap signaling controls stem cell anchoring to the niche through regulating DE-cadherin-mediated cell adhesion. Loss of function of a *Drosophila* Rap-GEF (Gef26) results in loss of both germline and somatic stem cells. The stem cell loss phenotype of *Gef26* mutation can be enhanced by the *Drosophila Rap* mutations. Gef26 and Rap1 are enriched at the interface between the hub and stem cells. The *Gef26* mutation specifically impairs adherens junctions at the hub-stem cell interface, which results in the stem cells "walking away" from the niche and losing stem cell identity. The Rap-GEF/Rap signaling may identify an extrinsic signal that regulates the polarized niche formation for asymmetric stem cell division.

2235

### Differential Segregation of Mother and Daughter Centrosomes During Asymmetric Stem Cell Division in the Drosophila Male Germ Line

Y. M. Yamashita, M. T. Fuller; Developmental Biology, Stanford University, Stanford, CA

Stem cells are the source of highly-differentiated but short lived cells such as blood, skin and sperm. The critical balance between stem cell and differentiated cell populations are crucial for long-term maintenance of functional organs. Stem cells maintain this balance by choosing two alternative fates: stem cell self-renewal or commitment to differentiation. The *Drosophila* male germ line stem cells (GSCs) divide asymmetrically, giving rise to one stem cell and one gonialblast that initiates differentiation, thus keeping balance between stem cell and differentiating cell populations. In adult male testes, 8-10 germ line stem cells surround the somatic apical hub. The hub functions as stem cell niche by secreting a signalling ligand, unpaired (Upd), which activates the JAK-STAT pathway in GSCs to specify stem cell identity. In this signalling microenvironment, GSC orients its mitotic spindle perpendicular to the hub such that one daughter cell remains attached to the hub while the other is displaced away from the hub, thereby ensuring the asymmetric outcome of the division. We have shown that stereotyped positioning of the centrosomes during interphase plays crucial role in orienting GSCs toward the hub cells: One centrosome is always positioned close to the hub, while the other centrosome migrates toward the opposite side of the nucleus during interphase, thereby setting up the perpendicular orientation of the mitotic spindle. We found that it is always that mother centrosome stays close to the hub, while the daughter migrates. This suggests that the difference(s) between mother and daughter centrosomes may be functionally exploited to achieve the asymmetric outcome of the stem cell division.

### Different Types of Niches Regulate Epithelial and Germline Stem Cells in *Drosophila*

B. Ohlstein, E. Decotto, T. Kai, T. Nystul, A. Spradling; Department of Embryology, HHMI/Carnegie Institution of Washington, Baltimore, MD

*Drosophila* germline stem cells (GSCs) at the tip of each ovariole, and at the apex of the testis, are maintained and regulated by neighboring stromal cells that generate an essential microenvironment known as a stem cell "niche." A small number of non-dividing, differentiated cap cells in the female or hub cells in the male, play critical roles by adhering to the stem cells, and by providing GSCs with local signals that control their

growth and development. Recently, we have identified and begun to analyze three types of epithelial stem cells and their niches. Ovarian escort stem cells strongly resemble the cyst progenitor stem cells of the testis, and interact with both stromal cap cells and GSCs. Adult intestinal stem cells (ISCs) maintain multiple cell types in the adult gut that strongly resemble mammalian gut lineages. ISCs contact basement membrane and mature tissue cells, but not a specialized niche cell. We have also been unable to find a stromal niche cell analogous to the cap cell in the vicinity of the ovarian follicle stem cell (SSC). Our studies argue that tissues contain multiple types of stem cell niches with distinctive regulatory regimes.

2237

**The Mammary Stem Cell Niche Modulates the Repertoire of Testicular Stem Cells**

C. A. Boulanger, D. L. Mack, B. W. Booth, G. H. Smith; MBTL, NCI/NIH, Bethesda, MD

Evidence for somatic stem cell niches has been clearly defined in several biological systems. To determine if a stem cell niche occurs in the mouse mammary gland and if it displays tissue-specific dominance, we mixed wild type mammary epithelial cells with testicular cells isolated from a WAP-Cre/R26R male donor at a 1:1 ratio and inoculated them into the cleared inguinal fat pads of immune-compromised Nu/Nu female hosts The host mice were bred 6-8 weeks later and examined 20-30 days post involution. This approach allowed for growth of mammary tissue, transient activation of the WAP-Cre gene, recombination and constitutive expression of Lac Z from the Rosa 26 promoter. Whole mount analysis was done on the inguinal glands from the injected mice. In all, 50% (n=15/30) were successful and produced mammary epithelial outgrowths. Of these 80%(n=12/15) contained blue cells. PCR analysis of the DNA from outgrowths containing blue cells confirmed the presence of both transgenes and Y chromosome-specific alleles. No LacZ-positive cells were observed in epithelial outgrowths collected from non-breeding hosts (n=6/10) indicating that pregnancy was essential for activation. The presence of male cells in significant numbers throughout mammary epithelial outgrowths suggests the following scenario: mammary epithelial cells recombine to assemble growth-competent cellular microenvironments, occasionally chimeras are formed which include male cells; development proceeds. The male cells not only contribute significantly to mammary epithelial growth but also differentiate during pregnancy activating the WAP-Cre gene and concomitantly the LacZ reporter. Both casein-positive luminal cells and myoepithelial cells were LacZ-positive within the secretory alveoli. We conclude that uncommitted testicular cells capable of self-renewal and multiple cell fates, enter mammary epithelium-specific niches and adopt the function of similarly endowed mammary cells. These results imply the tissue-dominance of stem cell niches.

2238

**Blood Island Formation in the Murine Yolk Sac**

M. J. Ferkowicz, M. C. Yoder; Pediatrics, Indiana University School fo Medicine, Indianapolis, IN

Yolk sac blood islands are the first site of hematopoiesis and vascular development in the vertebrate embryo and the first hematopoietic stem cell niche to form. The mesoderm-derived hematopoietic and endothelial lineages emerge from a common precursor, the hemangioblast and require yolk sac visceral endoderm-derived factors for blood island formation. As commonly described, undifferentiated mesodermal cells migrate into the blood island region of the yolk sac and proliferate into mesodermal masses nestled between the outer visceral endoderm and inner mesothelial cell layers. Blood islands arise as mesodermal masses differentiate into a primitive erythroblast core surrounded by endothelium. The objective of this study was to examine blood island formation in the murine yolk sac using defined cell lineage marking. FACS sorting and primitive erythroid colony forming assays reveal that primitive erythroblast progenitors are uniquely $CD41^+$ ($\alpha_{IIb}$ integrin). Flk-1 (fetal liver kinase, VEGFR-2, kdr) and VE-Cadherin (CD144) are expressed on the entire endothelial lineage including hemangioblasts. Confocal microscopy of staged murine embryos (E7.0-E8.5) reveals that committed $CD41^+$ primitive erythroblast and Flk-$1^+$/VE-Cadherin$^+$ endothelial progenitors arise near the primitive streak and subsequently migrate into the blood island region. Blood islands begin as a single circumferential band of primitive erythroblast progenitors in the blood island region of the yolk sac that completely lacks an endothelial covering. The sparse endothelial progenitors of the blood island region initially reside between the blood band and the overlying visceral endoderm. Within 6-8 hours of the onset of circulation, endothelial cells circumscribe and subdivide the blood band into a series of blood filled vascular channels. These data indicate that a new paradigm of murine blood island formation is necessary to understand the formation of this early stem cell niche.

## Signal Transduction III (2239-2265)

**Functional Studies of SUMO-1 in Stress Responses, Reactive Oxygen Species Generation and Cell Death**

J. Lee, H. Hong, K. Lee; Center for Cell Signaling Research, Division of Molecular Life Sciences and College of Pharmacy, Ewha Womans University, Seoul, Republic of Korea

Small ubiquitin-like modifier (SUMO) is a member of the superfamily of ubiquitin-like polypeptides that become covalently attached to various intracellular target proteins as a way to alter their function, location, and/or half-life. Even though SUMO is the structurally related to ubiquitin molecule for protein degradation, its biological functions are distinct to ubiquitin, yet poorly understood regulatory signal. Protein ubiquitinations accumulated by various signals including cytokine treatments and cellular stresses (hypoxia and heat shock etc.), induce protein degradation in proteasome. Simultaneously, cellular accumulations of polyubiquitinated proteins by cellular stresses can induce the cell death. In this study, we examined whether protein sumoylation counteracts to the protein ubiquitination. We found that the overexpression of SUMO protects the cell death induced by various stresses including heat shock and growth factors. SUMO was overexpressed in response to stresses and sumoylation reduced reactive oxygen species (ROS) generation induced by various stresses. This suggests that sumoylation has the opposite function of ubiquitination in response to various stresses even with similar molecular structure. The exact biological function of SUMO should be further studied.

2240

**Oxidative Regulation of Nm23-H1, Tumor Metastasis Suppressor, in Rac1-Induced Reactive Oxygen Species Generation**

A. Kim, S. Kim, K. Lee; Center for Cell Signaling Research, Division of Molecular Life Sciences, Ewha Womans University, Seoul, Republic of Korea

Nucleoside diphosphate kinase (NDPK, Nm23), known as tumor metastasis suppressor, is considered a housekeeping enzyme catalyzing transfer of

terminal phosphate from nucleoside triphosphate (NTP) to nucleoside diphosphate (NDP). Nm23 has been implicated as a multifunctional protein involved in cellular differentiation and development as oncogenesis and tumor metastasis. Recently, Nm23 has been reported to act as guanine nucleotide exchange factor (GEF) of Rac1 activation in reactive oxygen species (ROS) production. However, the regulatory mechanism of Nm23 is poorly understood. In our study, we found that enzymatic activity of Nm23 is damaged by oxidation in cysteine residues and repaired by NADPH-thioredoxin reductase-thioredoxin system. Here we have examined whether oxido-reduction of Nm23 could regulate the Rac1 activation in ROS generation by using Nm23 mutants. The results will demonstrate the regulatory mechanism of Nm23 in various biological processes.

2241

**Overexpression of Ref-1 Suppresses NO Synthesis by Reducing Oxidative Stress in LPS-Stimulated Macrophages RAW2647**

S. Park,[1,2] M. Kim,[1] Y. Kang,[1] Y. Yoo,[2] S. Seo,[3] Y. Park,[1] Y. Park[1]; [1]Microbiology and Immunology, Pusan National University College of Medicine, Busan, Republic of Korea, [2]Anatomy and Cell Biology, Dong-A University College of Medicine, Busan, Republic of Korea, [3]Microbiology, Dong-A University College of Medicine, Busan, Republic of Korea

Redox factor-1 (Ref-1) is a ubiquitously expressed protein with proven roles as a modulator of redox-sensitive transcription, and as an endonuclease in the base excision repair pathway of DNA damaged by oxidative stress. Our previous studies indicate that Ref-1 inhibits nitric oxide (NO) synthesis and apoptosis in LPS-stimulated murine macrophages, but the molecular mechanism of Ref-1 in regulating NO synthesis is not known. We successfully overexpressed Ref-1 protein by introducing adenovirus encoding full length Ref-1 or Ref-1 in DsRed expression vector. Intracellular NO and reactive oxygen species (ROS) were detected by fluorescence of DAF-2 DA and DCF-DA using a confocal laser scanning microscope, respectively. Here we report that forced overexpression of Ref-1 in macrophages suppressed ROS generation by the inhibition of LPS-stimulated NADPH oxidase activity that is the most important system for ROS generation in phagocytes. In parallel with this, Ref-1 also mitigated NF-κB transcriptional activity, NO production with changing NO synthase expression, and apoptosis. Our findings provide a functional connection between inhibition of NO synthesis mediated by NF-κB and decrease of intracellular ROS via the inhibition of NADPH oxidase in the activation of macrophages.

2242

**Type 5 Adenylyl Cyclase Disruption Increases Longevity and Protects Against Stress**

L. Yan, D. E. Vatner, A. Ivessa, J. Liu, J. Thaisz-Warden, J. P. O'Conner, M. Brimacombe, H. Ge, W. Chen, I. Yoshihiro, J. Sadoshima, S. F. Vatner; Cell Biology and Molecular Medicine, UMDNJ-New Jersey Medical School, Newark, NJ

In this study, we attempt to reveal the molecular mechanisms mediating longevity in our novel mouse model of longevity in which type 5 adenylyl cyclase (AC-5) is knocked out (AC-5 KO). Kaplan-Meier survival analysis revealed that the median lifespan was increased by 10 months ($p<0.01$) in AC-5 KO mice (34 months) compared to wild type (WT) mice (24 months). Aging AC-5 KO mice also exhibit maintained bone integrity and resistance to the development of aging cardiomyopathy, e.g. hypertrophy and apoptosis. Using a proteomic-based approach including 2D gel electrophoresis, mass spectrometry, and western analysis, we demonstrated a significant activation of the Raf/MEK/ERK signaling pathway and upregulation of cell protective molecules, including the anti-oxidant Mn-superoxide dismutase (MnSOD). Raf-1, p-MEK, p-ERK, and MnSOD were increased by 3 fold, 50%, 6 fold, and 40% respectively, $p<0.05$. Fibroblasts isolated from AC-5 KO mice, when treated by $H_2O_2$ (50-400 μM) or UV light (25 and 100 mJ/cm$^2$), exhibited enhanced resistance to oxidative stress with increased cell survival and reduced apoptosis. The inhibition of ERK activation with the inhibitor PD98059 reduced oxidative stress tolerance and the level of MnSOD in AC-5 KO mice, suggesting ERK activation mediates resistance to oxidative stress and SOD acts as a downstream enzyme of the ERK signaling pathway. Furthermore, we used yeast as a model to study the effects of ERK activation on longevity. Overexpression of mammalian ERK2 in budding yeast resulted in extended lifespan and resistance to heat shock and oxidative stress, supporting our hypothesis that Raf/MEK/ERK signaling pathway plays an important role in regulating longevity. The current investigation suggests that disruption of AC-5 mediates activation of the Raf/MEK/ERK signaling pathway, which in turn results in protection from oxidative stress and apoptosis, leading to lifespan extension.

2243

**Thrombin-Stimulated Interleukin-8 Activation in Human Macrophages is Mediated by Rho/ROCK/JNK Pathway and the NFκB/AP1 Transcription Regulators**

L. Zheng, M. Martins-Green; Department of Cell Biology and Neuroscience, University of California, Riverside, CA

Wound healing is orchestrated by a variety of cell types with macrophages playing crucial roles in chemokine. Inflammatory chemokines, such as interleukin-8 (IL-8), are known to be induced by local cues at wound site and contribute to chemotaxis, tissue remodeling and angiogenesis. We have investigated the molecular mechanisms of thrombin-induced IL-8 expression in human THP-1 macrophages. Immunoblot analysis and RT-PCR show that thrombin stimulates IL-8 in a rapid and dose-dependent manner and that this stimulation occurs via the PAR1 receptor. Various inhibitors were used to delineate the pathways involved in this stimulation. We find that inhibitors of the c-Jun N-terminal Kinase (JNK) strongly inhibit thrombin-induced IL-8 production. JNK is phosphorylated in response to thrombin treatment confirming its crucial function as a mediator. Using affinity pull-down assays we find that that Rho GTPase is activated by thrombin; Rho kinase(ROCK) inhibitor can inhibit both the IL-8 production and JNK phosphorylation suggesting that Rho/ROCK/JNK are involved sequentially in this activation cascade. We are using retrovirus-based tet-on systems to study the Rho function in more detail. Antisense oligos targeting c-Jun and c-Fos block IL-8 production, suggesting that AP-1 is important, which is further confirmed by EMSA. In addition, the NFκB inhibitor dexamethasone strongly inhibits thrombin-induced IL-8 stimulation and the p65 subunit of NFκB translocates into the nuclei after thrombin stimulation. Further test of NFκB EMSA confirmed its role in IL-8 transcription activation. We are currently using ChromatinIP to confirm the interaction of NFκB and AP-1 with IL-8 promoter *in vivo*. Our study broadens the horizon of inflammatory chemokine regulation and may help develop pharmaceutical methods to manipulate such conditions.

2244

**Two Ubiquitin-conjugating Enzyme Variants Regulate Different Cellular Stress Responses**

P. L. Andersen, H. Zhou, W. Xiao; Microbiology and Immunology, University of Saskatchewan, Saskatoon, SK, Canada

The ubiquitin conjugating (Ubc) enzyme, Ubc13, in concert with the ubiquitin conjugating enzyme variant (Uev) Mms2 is essential for DNA error-

free post-replication repair (PRR) in budding yeast by promoting noncanonical lysine-63 ubiquitin polymerization of PCNA. Mammalian cells contain two Mms2 homologs, Uev1A and Mms2, with greater than 90% amino acid sequence identity to the core region and both are able to interact with Ubc13. Furthermore, both Mms2 and Uev1A are capable of substituting for the yeast Mms2 mutant, suggesting the presence of Ubc13-Uev mediated error-free PRR in mammalian cells. Alternatively, in mammalian cells Ubc13 is reported to interact with a Uev (Uev1A or Mms2) to regulate the NF-kB signal transduction pathway by poly-ubiquitinating NEMO/IKKgamma. Based on the above observations, we hypothesized that the Ubc13 activity to ubiquitylate different substrates is dependent on its physical interaction with different Uevs. Using RNA interference (RNAi), myc-tagged constructs and immunocytochemistry, we demonstrated that suppression of either Ubc13 or Uev1A resulted in loss of NEMO polyubiquitination and NF-kB translocation to the nucleus while suppression of Mms2 has not effect. Alternatively, repression of Ubc13 or Mms2, but not Uev1A, resulted in increased numbers of Rad51 positive nuclei, indicating the increase in spontaneous DNA damage. Additionally, Ubc13 co-localizes with myc-tagged Mms2 in response to DNA damage, while myc-tagged Uev1A was not observed to form nuclear foci. Furthermore, removal of the N-terminal unique region of Uev1A resulted in its co-localization with Ubc13 nuclear foci after DNA damage, reminiscent of the Ubc13-Mms2 nuclear foci. We conclude that Mms2 and Uev1A serve as regulatory subunits of the Ubc13-Uev complex and direct it to two distinct pathways, namely the DNA repair pathway to deal with genotoxic stress and the NF-kB pathway in response to non-genotoxic stresses such as bacterial or viral infection.

2245

**IL-4 Induces the Expression of Suppressor of Cytokine Signalling 3 (SOCS3) Complete Isoform in Human Neutrophils and in DMSO-Differentiated PLB-985**

C. Ratthé, D. Girard; INRS-Institut Armand-Frappier, Pointe-Claire, PQ, Canada

Neutrophils are implicated in the inflammation process. Some cytokines can modulate their functions via the Jak/STAT pathway. It was recently discovered that the Jak/STAT pathway was regulated by suppressor of cytokine signalling (SOCS) that provide a feedback mechanism toward the Jaks and/or cytokine receptor. Among the SOCS, SOCS3 seems to be a major player in the negative regulation of neutrophil functions. The objective of this study was to evaluate the expression and modulation of SOCS3 protein following cytokine stimulations in human neutrophils and differentiated PLB-985 cells (PLB-985D). Neutrophils were obtained from healthy blood donors and PLB-985 cells were differentiated toward the neutrophil phenotype with DMSO. Cells were incubated with G-CSF, GM-CSF, IL-2, IL-4 or IL-6. RT-PCR was used to study SOCS mRNA expression and protein expression was studied by Western Blotting after 1D or 2D gel electrophoresis. The results showed that mRNA expression of SOCS3 in neutrophils was increased after 1h of stimulation with G-CSF, GM-CSF and IL-4. IL-6 also increased SOCS3 mRNA in PLB-985D. The mRNA expression was correlated with protein expression in Western Blot experiments. The increased expression of SOCS3 was observed when cells were pre-treated with the MG132 proteasome inhibitor. Cycloheximide reversed the increase expression of SOCS3. Western Blot experiments showed two different bands after 1D-SDS-PAGE, corresponding probably to the two recently identified SOCS3 isoforms. IL-4 increased the complete isoform and this was confirmed by immunoblotting after running 2D-SDS-PAGE. We conclude that SOCS3 mRNA and the complete isoform of the protein have an increased expression in both neutrophil and PLB-985D cells following stimulation with G-CSF, GM-CSF and IL-4. We also suggest that the increased SOCS3 expression depend on *de novo* protein synthesis.

2246

**Interleukin-8-Induced Endothelial Cell Permeability and Transactivation of Vascular Endothelial Growth Factor-2**

M. L. Petreaca, M. Yao, M. Martins-Green; Cell Biology and Neuroscience, University of California, Riverside, Riverside, CA

Permeability of the endothelium occurs early in the angiogenic process due to endothelial cell de-adhesion and contraction, resulting in gap formation. One of the cytokines involved in this process is the angiogenic chemokine Interleukin-8 (IL-8/CXCL8). We found that IL-8 induces permeability in a receptor-dependent manner that results in activation of Vascular Endothelial Growth Factor Receptor-2 (VEGFR2/Flk-1/KDR). This activation is dose-dependent, occurs over time and involves the phosphorylation of VEGFR2 independently of VEGF. These results indicate that IL-8-induced VEGFR2 activation occurs by transactivation of this receptor. To investigate possible mechanisms of transactivation, we investigated whether physical interaction between VEGFR2 and the IL-8 receptors was needed by performing co-immunoprecipitation assays. We found that CXCR2 interacts with VEGFR2 following IL-8 treatment and that the time course of this interaction is comparable to that of VEGFR2 phosphorylation. We are currently determining whether similar interactions occur with CXCR1. We have also found that Src kinases are important in VEGFR2 transactivation, as an inhibitor of these enzymes prevents both IL-8-induced endothelial permeability and VEGFR2 phosphorylation. Therefore, we hypothesized that Src kinases might stimulate transactivation by mediating VEGFR2-CXCR1/2 interactions. However, Src inhibition did not prevent these interactions, suggesting that Src kinases are involved in transactivation, but are not required for the interaction of the two receptor types. We are currently investigating the nature of IL-8-induced, Src-mediated VEGFR2 phosphorylation/activation. In addition, we are elucidating the role of this transactivation in downstream signaling events important in endothelial permeability, such as phosphorylation of adhesion molecules present at the endothelial cell junctions and the activation of molecules involved in endothelial cell proliferation and migration. These findings shed light into the molecular mechanisms of key processes involved in angiogenesis.

2247

**Angiotensin II Induces Tyrosine Phosphorylation of Glucose Regulated Protein-75 in Rat Liver Cells**

J. B. Gunaje, T. Samikkannu, S. Malaroviyam, J. J. Thomas, T. J. Thekkumkara; Pharmaceutical Sciences, Texas Tech University Health Sciences Center at Amarillo, Amarillo, TX

Angiotensin II (AII) is a peptide hormone that exerts a variety of effects on the cardiovascular system. These include regulation of salt and fluid homeostasis, induction of gene expression and promotion of cell growth. Acting through a seven-transmembrane, G-protein coupled receptor, this octapeptide elicits signal transduction pathways, including stimulation of phospholipase C, protein kinase C, Raf-1 kinase, and MAP kinase and components of the JAK-STAT pathway. Since caveolins are know to be involved in receptor mediated signaling by acting as scaffolding proteins, in this study, we initially determined the effect of angiotensin II on caveolin-1 tyrosine phosphorylation in rat liver WB cells. A time course study showed that instead of caveolin-1 protein, the phospho-specific (tyrosine) anti-caveolin-1 antibody cross-reacted distinctly with a 74 kDa protein. We performed studies to establish the identity of this protein. We demonstrate that in Ang II treated cells the 74 kDa protein rapidly undergoes

tyrosine phosphorylation. Its activation by Ang II was detected as early as 5 min, reached maximal at 15 min; however, significantly declined at 30 min. Cell fractionation experiment showed that it is predominantly localized to the cytoplasm. Cytokines/ growth factors (interleukin-6 and epidermal growth factor) failed to induce its tyrosine phosphorylation; however, pervanadate, a stress inducing agent stimulated its tyrosine phosphorylation. Mass spectrometric analysis of the immunoprecipitated protein showed that the 74 kDa protein is glucose regulated protein-75 (GRP75), a member of stress response protein family. Consistent with this data, we observed that GRP-75 undergoes tyrosine phosphorylation in Ang II treated cells. This novel pathway may contribute to Ang II-induced effects in cells expressing Ang II receptors.

2248

**Activation of Signaling Molecules in *Klebsiella pneumoniae*-Infected Human Hepatoma Cells, HepG2**

J. H. Wu, L. Hong, E. Tsai; Microbiology and Immunology, Chang Gung University, Tao Yuan, Taiwan Republic of China

The enterobacterium *Klebsiella pneumoniae* (KP) usually causes urinary tract infection or pneumonia, however in recent years, the bacterium causes severe liver abscess in diabetic patients due to hospital-acquired infection. How this emerging virulent KP strain causes liver abscess is not known. The study investigates signaling pathways in HepG2 cells (as a model cell system) infected by virulent KP. Confluent cell sheets were infected with bacteria suspended in phosphate buffered saline. Cells were harvested at various time intervals and screened for signaling molecules by Western blotting. Inhibitors were also used to examine the pathway. Our results showed that Toll-like receptor (TLR) 2 and 4 are increased 3 min postinfection and the amount continues to increase at 6 h postinfection. Phosphorylated signaling molecules mitogen-activated protein kinase (MAPK) kinase (MEK) 1,2, extracellular- regulated protein kinase (ERK) and p90 ribosomal S6 kinase (p90RSK) were observed and this pathway was inhibited by MEK1,2 inhibitors, U0126 and PD98059. Phosphorylation of another pathway MEK3,6, p38 MAPK and activating transcription factor-2 (ATF-2) was also observed and this pathway was inhibited by p38 MAPK inhibitors, SB203850 and SB202190. The c-Jun NH2-terminal kinase (JNK) pathway and caspase 3 were not activated. Signaling molecule E1K, MAPK- activated protein kinase-2 (MAPKAPK-2) and heat shock protein (HSP) 27 were also not activated. We conclude that the virulent KP infection in HepG2 cells activates signaling pathways through TLR2 and TLR4. Two MAP kinase pathways, the p38 MAPK and ERK pathways, but not the JNK pathway, are involved in the downstream. The infected cells eventually die and the caspase-3 is not involved in the cell death.

2249

**A Conserved Processing Mechanism Regulates the Activity of Transcription Factors Cubitus Interruptus and NF-kB**

L. Tian, A. Matouschek; Department of Biochemistry, Molecular and Cellular Biology, Northwestern University, Evanston, IL

The proteasome degrades most of protein substrates completely into small peptides**.** However, some proteins, such as transcription factors Cubitus interruptus and NF-κB**,** can be degraded partially to generate biologically active protein fragment. Here we have identified and characterized the signals in the substrate proteins that cause processing. The minimum processing signal consists of a sequence stretch with simple amino acid composition preceding a tightly folded domain in the direction of degradation. The strength of the processing signal depends on the complexity of the simple sequence regardless of identity of amino acid, the resistance of the folded domain to unraveling by the proteasome, and an appropriate spacing between the simple sequence and folded domain. We show that two unrelated transcription factors, Cubitus interruptus and NF-κB, utilize this mechanism to undergo partial degradation by the proteasome *in vivo*. These findings suggest that the mechanism is conserved evolutionarily and that processing signals may be widespread in regulatory proteins.

2250

**Lysophosphatidic Acid Inhibits Diarrhea Through CFTR-dependent Protein Interactions**

C. Li,[1] K. Dandridge,[1] A. Di,[2] K. Marrs,[1] E. Harris,[1] J. Jackson,[3] N. Makarova,[1] D. Nelson,[2] G. Tigyi,[1] A. Naren[1]; [1]Physiology, University of Tennessee Health Science Center, Memphis, TN, [2]Neurobiology, Pharmacology and Physiology, The University of Chicago, Chicago, IL, [3]Comparative Medicine, University of Tennessee Health Science Center, Memphis, TN

**OBJECTIVE:** Cystic fibrosis transmembrane conductance regulator (CFTR) is a chloride channel localized at the luminal or apical surfaces of epithelial cells lining the airway, gut, etc., and it is well established that CFTR plays a pivotal role in cholera toxin-induced diarrhea. Lysophosphatidic acid (LPA), a phospholipid present in blood and foods, has been reported to play a vital role in a variety of conditions including gastrointestinal wound repair, inflammatory bowel disease, and diarrhea. The aim of this study was to investigate how LPA-elicited signaling might regulate CFTR function in the gut, and to evaluate the therapeutic utility of LPA in alleviating cholera toxin-induced secretory diarrhea in mice. **METHODS:** A series of cellular and molecular techniques including RT-PCR, immunofluorescence microscopy, pull-down assay, co-immunoprecipitation, surface biotinylation, cAMP measurement, macromolecular complex assembly, peptide delivery, and electrophysiological techniques including iodide efflux assay, short-circuit current measurement, whole cell-attached patch clamping, as well as *in vivo* intestinal fluid secretion measurements in animal models, were used in this study. **RESULTS and CONCLUSIONS:** We show that type 2 LPA receptors ($LPA_2$) are expressed at the apical surfaces of intestinal epithelial cells, where they form a macromolecular complex with $Na^+/H^+$ exchanger regulatory factor-2 (NHERF2) and CFTR through a PDZ-based interaction. LPA inhibited CFTR-dependent iodide efflux through $LPA_2$-mediated $G_i$ pathway, and LPA inhibited CFTR-mediated short-circuit currents in a compartmentalized fashion. CFTR-mediated intestinal fluid secretion induced by cholera toxin in mice was significantly reduced by LPA administration, and disruption of this complex using an $LPA_2$-specific peptide reversed LPA inhibition of CFTR function. Our study is the first one to show that the macromolecular complex (CFTR-NHERF2-$LPA_2$) formed *in vitro* is also physiologically and functionally relevant *in vivo*. Therefore, LPA-rich foods may represent an alternative method of treating certain forms of diarrhea.

2251

**AWP1 Interacts with TRAF2 and Involves in NF-kappaB Activation**

E. Chang, J. Ha, K. Han, Z. Lee, H. Kim; Department of Cellular and Developmental Biology, Institute of Dentistry, College of Dentistry and Brain Korea 21 Program, Seoul National University, Seoul, Republic of Korea

TRAF2 (TNF receptor associated factor 2) transduces signals from members of TNF (tumor necrosis factor) receptor superfamily and is involved in the activation of NF-kappaB, JNK and apoptosis. In yeast two-hybrid screening for TRAF2 binding proteins, we found a novel TRAF2 binding

protein, AWP1, which had been known to be a PRK1 binding protein. AWP1 has the TRAF2-binding consensus sequences at amino acid residues 149-189. FLAG-tagged TRAF2 was co-immunoprecipitated with HA-tagged AWP1 from 293 cell lysate, and in vitro binding assay using the deletion mutants of AWP1 showed that AWP1 directly binds to the TRAF domain of TRAF2. Wild type of AWP1, when overexpressed in MG63 cells, led to NF-κB activation in response to TNF-α and that activation was decreased by dominant negative TRAF2. Together, AWP1 increased IκB-α phosphorylation and degradation but not JNK activation. However, AN1 mutant carrying a deletion of TRAF2 binding domain failed to activate NF-κB, indicating that AWP1 activated NF-κB through binding to TRAF2. More importantely, overexpression of AN1 mutant increased TNF-α-induced apoptosis and decreased the induction of anti-apoptotic molecules including $FLIP_S$ and cIAP-2. These results suggest that AWP1 may be involved in TRAF2-NF-κB signaling pathway, leading to the induction of anti-apoptotic molecules.

2252

**SXXE Motif Phosphorylation within the Death Domain of TNFRI is Critical for TNF-α Signaling**

Y. Guan, Z. Yang, E. Chin; Department of Surgery and Department of Molecular and Cell Biology, Brown Medical School/Rhode Island hospital, Providence, RI

Tumor necrosis factor-α (TNF-α) activated TNF receptor I (TNF-R1, p55) recruits TRADD, which in turn recruits FADD and RIP to form a signaling complex via homologous death domain-death domain interaction. This death domain signaling complex formation is essential for both NF-κB activation and apoptosis induction. To explore whether death domain post-translational modification events are involved in TNF-R1 -TRADD interaction and NF-κB activation, we performed site-directed mutagenesis, protein-protein interaction analysis and *[$^{32}$P]*orthophosphate labeling assay. Our results present here showed that neither of two previously reported phosphotyrosine motifs $Y^{360}$XXV and $Y^{401}$XXL of the TNF-R1 death domain is critical for TNF-R1 in NF-κB activation and apoptosis induction. Instead, we identified an SXXE motif, i.e., $S^{381}$DHE sequence, critical for TNF-R1-TRADD complex formation. TNF-R1 with $S^{381}$->A or $E^{384}$->A substitution, or $S^{381}$XXE motif deletion abolished TNF-R1 -TRADD complex formation and subsequent NF-κB activation or apoptosis induction. The association of TNF-R1 and TRADD was disrupted by a phosphorylated-peptide of TNF-R1 $S^{381}$DHE motif sequence. TNF-R1 phosphorylation on $S^{381}$ site in response to TNF-α treatment was further confirmed in different cell types by using a specific antibody prepared to recognize phospho-$S^{381}$DHE motif of TNF-R1. Moreover, The $S^{215}$ XXD and $S^{296}$XXE motifs of TRADD death domain were responsible for FADD and RIP association, respectively. Therefore, the "SXXD/E" motif-death domain interaction functions as a signaling module during the death domain interaction. The "SXXE" motif phosphorylation within the death domain of TNF-R1 is critical for TNF-α Signaling. .

2253

**Large-Scale Organization of Intracellular Membranes Relevant to Receptor-Mediated Ca2+ Mobilization**

D. Holowka, L. Vasudevan, S. Hammond, B. Baird; Chemistry and Chemical Biology, Cornell University, Ithaca, NY

Immunofluorescence microscopy reveals a novel pool of PIP/PIP2 -containing membranes in RBL mast cells that is proximal to the plasma membrane and contains key proteins that control Ca2+ mobilization, including phospholipase Cg, inositol trisphosphate receptors, SERCA 2, and the a1 subunit of L-type Ca2+ channels. These membranes are typically localized in one or more micron-sized plaques per cell that are sensitive to dispersion by detergents and organic fixatives. Low molecular weight GTPases, including members of the Arf and Rho families, are also localized to these plaques. Several lines of evidence indicate that these plaques participate in IgE receptor-mediated Ca2+ mobilization, including loss of Ca2+ responses in parallel with the loss of these plaques after incubation of cells at 4oC, and the loss of Arf association with these plaques in mutant RBL cells that are defective in Ca2+ mobilization. Similar plaques are detected in a wide variety of cultured mammalian cells and are commonly localized at nodes of axonal-like projections in differentiated N2A neuroblastoma cells. Membranes in these plaques appear to insert into the plasma membrane in response to appropriate stimuli, such as IgE receptor activation.

***Cyclic* Amp and Calcium Interplay as Second Messengers in Melatonin Dependent Regulation of *Plasmodium Falciparum* Cell-cycle**

F. H. Beraldo,[1] F. M. Almeida,[2] A. M. Silva,[2] G. R. S. Celia[3]; [1]Parasitology, São Paulo University, São Paulo, Brazil, [2]Biochemistry, São Paulo University, São Paulo, Brazil, [3]Physiology, São Paulo University, São Paulo, Brazil

The host hormone melatonin increases cytoplasmic $Ca^{2+}$ concentration and synchronizes *Plasmodium* cell cycle (Hotta et al, 2000). Here we show that in *P. falciparum* melatonin induces an increase in cAMP levels and PKA activity (40% and 50% respectively). When red blood cells infected with *P. falciparum* are treated with cAMP analogue 6-Bz- cAMP there is an alteration of the parasite cell cycle. This effect appears to depend on activation of PKA (abolished by the PKA inhibitors 8-BrcAMP-RP isomer, PKI - cell permeable peptide - and H89). An unexpected cross talk was found to exist between the cAMP and the $Ca^{2+}$ dependent signalling pathways. The increases in cAMP by melatonin are inhibited by blocker of phospholipase C U73122, and addition of 6-Bz- cAMP increases cytosolic $Ca^{2+}$ concentration, through PKA activation. These findings suggest that in *Plasmodium* a highly complex interplay exists between the $Ca^{2+}$ and cAMP signalling pathways, but also that the control of the parasite cell-cycle by melatonin requires the activation of both second messenger controlled pathways.

**Mutational Analysis of the Hsp90 co-chaperone Sti1/Hop**

J. L. Johnson, G. Flom, L. Rosen, J. Williams, J. Weekes; Microbiology, Molecular Biology and Biochemistry, University of Idaho, Moscow, ID

The molecular chaperone Hsp90 plays an essential role in the regulation of numerous signal transduction pathways by promoting the proper folding of interacting client proteins. Through simultaneous interactions with Hsp70 and Hsp90 via separate tetratricopeptide repeat (TPR) domains, the co-chaperone protein Hop/Sti1 has been proposed to play a critical role in the transfer of client proteins from Hsp70 to Hsp90. However, no prior mutational analysis demonstrating a critical in vivo role for the TPR domains of Sti1 has been reported. We used site-directed mutagenesis of the TPR domains combined with a genetic screen to isolate mutations that disrupt the function of Sti1 in Saccharomyces cerevisiae. We found that mutations in the carboxy-terminal DP2 domain or deletion of a conserved residue in TPR2A, previously shown to interact with Hsp90, completely disrupted Sti1 function. Surprisingly, mutations in TPR1, previously shown to interact with Hsp70, were not sufficient to disrupt in vivo functions unless mutations in TPR2B were present within the same protein, suggesting that TPR1 and TPR2B have redundant or overlapping in vivo

functions. Furthermore, overexpression of mutant Sti1 has dramatically different effects on growth of a yeast strain expressing distinct Hsp90 mutant alleles. We are now determining the effect of mutation on interaction of Sti1 with Hsp70 and Hsp90 in vivo and in vitro. These studies will provide critical information about the in vivo importance of the interaction of Sti1 TPR domains with the carboxy-termini of Hsp70 and Hsp90. We will also gain novel insights about the function of the poorly understood TPR2B and DP2 domains of Sti1 and how Sti1 interacts with Hsp90 to regulate its function.

2256

**Genetic Resolution of the Signal Transmission Through the Modular Membrane Receptor**

S. Bibikov; Protein R&D, EMD Biosciences, San Diego, CA

Both eukaryotic and bacterial membrane receptors are comprised of several modules, often parts of the same protein. These modules normally include the sensor, the intermediates, and the response element. The signal is transmitted between the sensor and the response element as a conformational wave, inducing a change in the structure of the protein and resulting in the miniscule movements of its backbone and side chains. Bacterial receptors have a long alpha helical stretch connecting the membrane-embedded part of the protein with the response part, which is used for activation of the histidine kinase CheA. The helices form the dimers, which in turn form the trimers of dimers. Using the E.coli Aer protein as a model we genetically traced the importance of some residues for the signal translocation inside the protein. We developed a plate assay, which allowed fast collection of mutants with various defects in the Aer function. By testing these defects in two different backgrounds we distinguished the mutations, which can be corrected by altering the background rotational pattern of bacterial flagella, and mutations where the defects to Aer transmission were not repairable. Genetic studies associated with the high-throughput mutagenesis might be useful for studies of the signal transmission in large receptors.

**Penetrating-Antibody Functions *in vivo***

Q. Qian,[1] D. Zhang,[2] H. Li,[2] Y. Ke,[2] W. Zhu,[2] B. Jasti,[1] X. Li[1]; [1]Pharmaceutics and Medicinal Chemistry, University of the Pacific, Stockton, CA, [2]Epitomics. Inc, Burlingame, CA

To deliver functional antibody into cells. Purified rabbit monoclonal antibody against procaspase3 (ECA61) was concentrated to 5mg/ml for conjugation. TAT peptide was chemically conjugated to ECA61 using Sulfosuccinimidyl 4-[N-maleimidomethyl] cyclohexane-1-carboxylate (SMCC). The TAT conjugated ECA61 (TAT-ECA61) was incubated with U937 cell line for 2 hours. The extent of intracellular delivery was evaluated by Cell-ELISA: the cells after incubation were washed by PBS, and then fixed by 4% para-formaldehyde, and permealized by 0.1% triton-X100. Subsequently, IHC blocking buffer and anti-rabbit 2$^{nd}$ antibody were applied. DAB Solution was used to visualize the delivered antibody inside cells. Intact ECA61 and TAT-ECA61 without permealization treatments were used as controls in the studies. To verify the function of delivered TAT-ECA61, after incubation with TAT-ECA61, U937 cells were treated with Etoposide at 50μg/ml for 3.5 hours to induce apoptosis. The treated cells were measured for caspase3 activity according to the instruction of Caspase3 Cellular Activity Assay Kit. Rabbit IgG conjugated with TAT was studied as control. From the cell morphology, the TAT-ECA61 had no cytotoxicity on cells, even with high concentration and long incubation time. Three groups of cells were used to demonstrate the antibodies were delivered inside cells. The first group incubated with TAT-ECA61 and followed by permealization showed very strong staining with anti-rabbit antibody. In contrast, the second group incubated with TAT-ECA61 but without permealization treatment and the third group incubated with unconjugated ECA61 didn't show any staining. This result indicated TAT-ECA61 was delivered intracellularly, but not on cell surface. The activation of caspase3 of U937 incubated with TAT-ECA61 was affected, compared with control group incubated with control rabbit IgG-TAT conjugate. The TAT peptide can facilitate efficient delivery of rabbit antibody into cells without influence on cell viability, and TAT-ECA61 can keep its function after delivery process.

**Computational Analysis of Transient Signals Governing Cell Behavior**

B. B. Aldridge,[1] G. Haller,[2] P. K. Sorger,[3] D. A. Lauffenburger[1]; [1]Biological Engineering, MIT, Cambridge, MA, [2]Mechanical Engineering, MIT, Cambridge, MA, [3]Biology, MIT, Cambridge, MA

Computational models of signaling pathways are tools that help us explore complex signaling networks quantitatively. One method to decipher entangled signals is to characterize the signals that influence cell fate. For differential equation models, several common methods exist to analyze system behavior in terms of steady-state signals. However, signal transduction networks influence cell decisions via transient signals that dissipate and return to an inactive steady state. Here, we describe a computational method derived from dynamical systems and fluid mechanics with which to analyze quantitatively transient signals and relate them to cell fate changes. As an example, we applied our method to part of the apoptosis-versus-survival decision network, which is controlled by transient caspase signals. Our analysis method allows us to define a separatrix, which separates the signaling-space into regions destined for cell survival or death where steady state analysis was inadequate.

**Calcium Signaling Protein Complexes in Oligodendrocyte Precursor (OP Cell) Membranes Isolated from Rat Cortices**

S. H. Weerth, J. Hauser, J. T. Russell; SCBST, NICHD, NIH, Bethesda, MD

Calcium imaging studies indicated the existence of specialized calcium release sites in OP cells. At these microdomains calcium waves are generated as puffs or sparks. To further investigate the complex machinery underlying calcium signaling events, we analyzed calcium signaling microdomains in membranes of cultured primary glial cells (OP cells and astrocytes). Caveolin-enriched microdomains were isolated from crude membranes by solubilization in 1% Triton-X100 followed by separation on an isotonic Optiprep™ density gradient. Co-localization of calcium signaling proteins located in the plasma membrane, M1, P2Y1, TRPC1, as well as ER receptors IP3R2 and RyR and the scaffolding proteins Homer and Gq with caveolin-1 was demonstrated by analyzing gradient fractions on SDS-PAGE and western blots. We therefore hypothesized, that calcium signaling proteins are organized in signaling complexes connecting microdomains at the plasma membrane and ER. Immuno-precipitaton studies of astrocyte lysates revealed, that the plasma membrane ion channel TRPC1 co-immunoprecipitated together with the ER calcium channel IP3R2 and the scaffolding protein Homer as a complex. In order to verify the existence of such calcium signaling protein

complexes in intact brain, we immuno-purified OP cell membranes from homogenates of rat cortices with an antibody against NG2, a cell surface marker of OP cells. Co-immunoprecipitation studies of solubilized membranes confirmed the interaction of IP3R2, Homer and TRPC1 in these membranes isolated from brain. Future experiments will test the existence of additional calcium signaling proteins in the signaling complex by immunoprecipitation and western blots or analysis of the immunoprecipitate by Mass spectrometry.

**Dynamic Ensembles of Macromolecules Organized in Nanostructures (DEMONS): A New Paradigm for Intracellular Regulation**

I. I. Moraru,[1] G. Huber,[1] J. H. Carson,[2] A. E. Cowan,[2] C. W. Wolgemuth,[1] L. M. Loew[1]; [1]Cell Biology, University Connecticut School of Medicine, Farmington, CT, [2]Molecular, Microbial, and Structural Biology, University Connecticut School of Medicine, Farmington, CT

Many cellular functions depend on the activities of complex multi-molecular structures that can be of two fundamentally different types: (1) highly ordered stoichiometric nanomachines with defined molecular structures, which are typically effectors of specific functions; examples are ribosomes, proteosomes, nuclear pores, flagella, and molecular motors. (2) dynamic ensembles of macromolecules organized into nanostructures (DEMONS), with variable size, composition, structure, and turnover of individual components, which are typically regulators of specific functions; examples are RNA granules, nuclear bodies, signaling platforms, lipid rafts, and MPF aggregates. We hypothesize that DEMONS have common underlying design principles and represent a novel paradigm for flexible regulation of cellular processes. We developed models that predicted the experimentally observed size distribution of DEMONS by using two alternative physical principles. The first is free energy minimization of opposing forces (short range attractions and long range repulsion) similar to recent approaches in the physics of cluster phases. The second is mass action kinetics of multiple ($\geq$ 3) low affinity binding sites with combinatorial connectivity adjusted for steric screening. Both models reveal similarities in critical parameters for assembly of DEMONS of disparate functions, such as MPF aggregates, which regulate cell cycle control, and RNA granules, which are intermediates in RNA trafficking. Specifically, the data highlight that the assembly/disassembly equilibrium is regulated by the relative size and different binding properties between the aggregate's core and its surface, as well as the requirement for multiple types and/or sites of low affinity interactions. Further refinement of these models could be used to suggest strategies for experimental manipulations influencing assembly and functions of DEMONS. Supported by NIH PN1-EY016530.

**Aggregation of Mast Cell Specific Derivatives of the Ganglioside GD1b Alters Lyn and Syk Distribution and Inhibits Activation via FcepsilonRI**

R. O. Castro, F. Matioli, A. M. M. Souza, M. C. Jamur, C. Oliver; Molecular and Cell Biology, FMRP-USP, Ribeirão Preto, Brazil

Lyn is known to be associated with the mast cell specific derivatives of the ganglioside GD1b that are recognized by mAb AA4. Upon cross-linking, FcepsilonRI rapidly translocates into lipid rafts, where it is phosphorylated by Lyn. The present work investigates the relationship between Lyn and Syk and the derivatives of the ganglioside GD1b during mast cell activation via FcepisilonRI. Unstimulated RBL-2H3 cells are spindle shaped and their surface is covered with microvilli. By immunofluorescence Lyn and the derivates of the gangliosides $GD_{1b}$ are homogeneously distributed along the plasma membrane, but rarely colocalize. Fourty five minutes after stimulation, the cells are spread on the substratum and their surface is covered with membrane ruffles. Lyn is now colocalized in the ruffles with the GD1b ganglioside derivatives. A similar analysis was made for Syk, the second protein kinase activated during signal transduction. In unstimulated cells Syk is localized in the cytoplasm. Forty five minutes after stimulation, Syk is recruited to lipid rafts colocalizing with the GD1b ganglioside derivatives in the ruffles. When mAb AA4 is added to cultures of RBL-2H3 cells, at 24h the gangliosides are aggregated into a single cap on the cell surface. Under these conditions, in unstimulated cells there is no colocalization between Lyn or Syk with the capped gangliosides. Forty five minutes after stimulation, little Lyn or Syk is found in the rufles indicating no colocalization with the capped gangliosides. At 24h in the presence of mAb AA4 beta-hexosaminidase release was reduced by 70 % in RBL-2H3 cells stimulated via FcepsilonRI. These data indicate that the aggregation of the derivatives of the ganglioside GD1b alters Lyn and Syk distribution and inhibits mast cell activation via FcepsilonRI.

**Glycogen Particle Formation in the Yeast *Saccharomyces cerevisiae***

K. Tatchell,[1] J. Salamon-Kozubowska,[1] K. S. Thorn,[2] T. Williams-Hart[3]; [1]Biochemistry and Molecular Biology, Louisiana State University Health Sciences Center, Shreveport, LA, [2]Bauer Center for Genomics Research, Harvard University, Cambridge, MA, [3]Biology, Louisiana State University- Shreveport, Shreveport, LA

Glycogen targeting subunits of Type 1 Protein phosphatase (PP1) regulate glycogen metabolism in eukaryotes by tethering PP1 to enzymatic components of the pathway. In mammalian cell types that accumulate high levels of glycogen, glycogen and its enzymatic machinery reside in cytoplasmic glycogen particles. The physiological role of glycogen targeting subunits in glycogen particle formation is not fully understood. The yeast *S. cerevisiae* has four proteins related to mammalian glycogen targeting subunits. Genetic and biochemical studies on one of these, Gac1, have shown that its ability to bind to both PP1 (Glc7 in yeast) and glycogen synthase is necessary for its ability to promote the normal accumulation of glycogen that occurs as cells approach stationary phase. We show here that at least three of these proteins, Gac1, Pig2, and Gip2, have partially redundant roles in regulating glycogen synthesis. Mutant yeast strains deficient in all three proteins fail to accumulate glycogen. Induced expression of a functional GST-Pig2 fusion protein promotes the concomitant accumulation of glycogen and cytoplasmic spots or particles, in which glycogen synthase-GFP and phosphorylase-GFP fusion proteins co-localize with a Glc7-Red Fluorescent Protein fusion protein. Glycogen synthase is necessary for particle formation. The particles are stable in the cytoplasm and do not undergo the saltatory movement common to many vesicle compartments. Rapid recovery of Glc7-GFP fluorescence after photobleaching suggests that the particles are not in an irreversible aggregation. Deletion mutations in GST-Pig2 that are predicted to prevent the binding of Glc7 and glycogen synthase fail to induce glycogen synthesis and prevent or alter particle formation, as does a mutation in Glc7 that fails to associate with Pig2. Together, these results indicate that yeast can be used to investigate the genetics and cell biology of glycogen particle formation.

2263

### Regulated Cell to Cell Variation During the Response of *S cerevisiae* to Mating Pheromone

A. A. Colman-Lerner,[1] A. Gordon,[1] E. Serra,[1] T. Chin,[1] O. Resnekov,[1] D. Endy,[2] C. Pesce,[1] R. Brent[1]; [1]Molecular Sciences Institute, Berkeley, CA, [2]Division of Biological Engineering, Massachusetts Institute of Technology, Cambridge, MA

We studied the quantitative behavior and cell-to-cell variability of a prototypical eukaryotic cell fate decision system, the mating pheromone response pathway in yeast. We dissected and measured the sources of variation in system output analyzing thousands of individual, genetically identical cells. Only a small portion of total cell-to-cell variation was caused by random fluctuations in gene transcription and translation during the response ("expression noise"). Instead, variation was dominated by differences in the capacity of individual cells to transmit signals through the pathway ("pathway capacity") and to express genes into proteins ("expression capacity"). Cells with high expression capacity expressed genes at a higher rate and increased in volume more rapidly. In addition, our results revealed two mechanisms that regulate cell-to-cell variation in pathway capacity. First, the pathway MAP kinase Fus3 suppressed variation at high pheromone while the MAP kinase Kss1 enhanced variation at low doses. Second, pathway and expression capacity were negatively correlated, suggesting a compensatory mechanism by which pheromone-induced gene expression was less influenced by the large variation in expression capacity.

2264

### The Role of Yeh2 in *S cerevisiae* Yeast Mating and Filamentation Signaling Pathways

D. D. Lee, A. D. Palmer, G. G. Hutchins; Biology, Fort Lewis College, Durango, CO

The objective of this study is to characterize the potential role of Yeh2 in the *S. cerevisiae* yeast mating and filamentation signaling pathways. Previous work established Yeh2 as a steryl ester hydrolase in the plasma membrane (JBC 280: 13321-13328). In this study, Yeh2 was found to bind the Ste7 MAP kinase kinase of both mating and filamentation signaling pathways using a yeast 2-hybrid assay. Using a *yeh2* deletion strain, mating efficiency was measured relative to wild type by counting the % cells forming mating projections and undergoing G1 arrest in response to mating pheromone. Localization of Yeh2 protein during formation of mating projections was determined using a fusion of green fluorescent protein (GFP) to Yeh2. Using a cell adherence assay as an index of expression of the flocculation protein Flo11 required for filamentation, the role of Yeh2 in the yeast filamentation response was determined using a *yeh2* deletion either alone or in combination with a *ste5* deletion to minimize cross-talk from the mating pathway. Mating efficiency in a *yeh2* deletion strain was found to be slightly decreased but comparable to wild type. In response to mating pheromone, Yeh2-GFP relocalizes to the tip of the mating projection. In the cell adherence assay , both *yeh2* and *ste5* deletion strains demonstrated increased adherence compared to wild type, whereas a *yeh2 + ste5* deletion strain showed decreased adherence relative to wild type. In summary, Yeh2 appears to be involved in mating pathway signaling given that the *yeh2* deletion strain is modestly decreased in pheromone response relative to wild type and also that Yeh2-GFP localizes to the tip of the mating projection. Yeh2 may also be a regulator of the yeast filamentation response through its involvement in Flo11 expression.

2265

### Expression Profile of Signal Transduction-Related Genes in Phytohormone Treated Sugarcane Plants

F. R. Rocha,[1] F. S. Papini-Terzi1,[1] M. Y. Junior,[1] R. Z. Vêncio,[2] C. S. Rocha,[3] R. Vicentini,[3] V. E. Junior,[4] E. C. Ulian,[5] M. Menossi,[3] G. M. Souza[1]; [1]Instituto de Química - USP, São Paulo, Brazil, [2]Instituto de Matemática e Estatística - USP, São Paulo, Brazil, [3]Centro de Biologia Molecular e Engenharia Genética - Unicamp, Campinas, Brazil, [4]Instituto Agronômico de Campinas, Campinas, Brazil, [5]Centro de Tecnologia Copersucar, Piracicaba, Brazil

The cultivated sweet cane is a hybrid of Saccharum officinarum and Saccharum spontaneum in which a gene can be represented by 10-14 copies. To expedite sugarcane genome research the SUCEST Project sequenced 238 thousand ESTs. Sugarcane's biomass makes it the world's largest crop but despite its economical importance very few studies describe the molecular signaling responses to the environment and the role of phytohormones in this process. The SUCEST-FUN project aims to associate function to sugarcane's genes and to identify putative targets for variety improvement (http://sucest-fun.org). In this work we describe genes responsive to phytohormones that may have a role in the control of metabolic, developmental and defensive processes. cDNA microarrays were used to profile plantlets submitted to methyljasmonate (MeJA) and abscisic acid (ABA) treatments. Sugarcane plantlets were sprayed with a 100 µM MeJA or ABA solution and leaves were collected 0h, 1h, 6h and 12h after treatment. The experiments were conducted with biological replicates and expression profiles clustered by SOM (Self Organizing Maps). Thirty-five differentially expressed genes were selected for their strikingly altered pattern. Among these, we detected 6 genes with no hits in the public databases, 6 stress-related genes and 10 protein kinases (including three receptors). Six of the differentially expressed genes have their transcripts enriched in the leaf tissues. There are three receptors and one protein kinase responsive to the ABA treatment that could not be assigned to known categories based on BLAST searches, but that were assigned to putative families based on a phylogenetic approach. Expression data were validated by real-time PCR. The data presented can be useful in assigning function for the sugarcane genes and reveal potential targets for genetic improvement of sugarcane varieties.

## Cell Cycle Controls II (2266-2291)

2266

### Characterizing the Specificity of the *S cerevisiae* Wee1 Homolog, Swe1p, *in vivo*

M. A. Keaton, D. J. Lew; Pharmacology and Cancer Biology, Duke University, Durham, NC

The execution and proper timing of cell cycle events is due, in part, to the accumulation of specific cyclins that bind and activate cyclin dependent kinases (CDKs). In addition to cyclin binding, CDK complexes are regulated by inhibitors such as the Wee1 family of kinases which phosphorylate a conserved tyrosine residue in the CDK. In most eukaryotes, Wee1 is important for regulating entry into mitosis by inhibiting the mitotic CDK complex. In *Saccharomyces cerevisiae*, overexpression of the Wee1 homologue (Swe1p), arrests cells with duplicated DNA, short spindles, and elongated buds, which is similar to the phenotypes obtained by elimination of the mitotic cyclins Clb1p and Clb2p. This observation combined with studies that have shown that Swe1p preferentially phosphorylates the mitotic Clb2p/Cdc28p complex over the G1 Cln2p/Cdc28p complex *in vitro*, suggests that Swe1 preferentially phosphorylates the mitotic B-type cyclin, Clb1p and Clb2p, complexes. However, the specificity of Swe1p

phosphorylation for the other B-type cyclins has not been evaluated. Using TAP-tag purification and phospho-specific antibodies, we have analyzed the phosphorylation status of a panel of cyclin/Cdc28p complexes *in vivo*. Our results are consistent with preferential phosphorylation of Clb2p complexes over G1 cyclin complexes. We also demonstrate that Clb3p and Clb4p complexes, which are important for spindle formation, are also phosphorylated by Swe1 but to a lesser degree relative to Clb2p complexes. Surprisingly, we found that Clbp5p/Cdc28p complexes have a similar degree of phosphorylation relative to Clb2p complexes when the Cdc28p phosphatase, MIH1, is deleted. This phosphorylation does not appear to inhibit Clb5p/Cdc28p activity since DNA replication is unaffected in *mih1*Δ cells.

2267

**Regulation of Yeast Cbk1 and its Role in Ace2-Driven Transcriptional Asymmetry**

J. Jansen, M. Barry, E. L. Weiss; Biochemistry, Molecular Biology, and Cell Biology, Northwestern University, Evanston, IL

The yeast Ndr/LATS family protein kinase Cbk1 is required for sustained polarized growth and daughter cell specific transcription that occurs during mitotic exit. It is part of a novel signaling pathway called the RAM network, which is at least partly conserved from yeast to mammals. Cbk1 promotes asymmetric segregation of the transcription factor Ace2, likely inhibiting its nuclear export in daughter cells; this function requires the Mitotic Exit Network (MEN). We found that blocking nuclear export eliminates Ace2's asymmetry, but does not affect the distribution of Cbk1. Thus, partitioning of the kinase to daughter cells is likely a primary determinant of Ace2 asymmetry. We found that Cbk1 phosphorylates Ace2 *in vitro*, and have identified a possible site of this modification. Ace2 that cannot be phosphorylated at this site is not fully functional *in vivo*. We have also found that two conserved phosphorylation sites in and just C-terminal to Cbk1's kinase domain are important for the kinase's *in vivo* function. Our *in vitro* studies suggest that one site is probably autophosphorylated, while the other is most likely modified by an unknown upstream kinase. Mutation of either site abrogates Cbk1 function; we are investigating localization of these mutant alleles as well as their interaction with other RAM network components. Using antibodies specific for these two phosphorylated motifs, we found that kinase domain site phosphorylation is relatively constant, while C-terminal site modification is more dynamic. The C-terminal site is most dramatically phosphorylated as cells pass from M to G1, and is dephosphorylated in G1. At mitotic arrest, however, C-terminal site phosphorylation is not detectable, indicating that it occurs during mitotic exit. Thus, differential phosphorylation of Cbk1 regulatory sites may be an important way in which this kinase's *in vivo* function is modulated.

2268

**Characterization of a Pathway Required for Septin Organization in Budding Yeast**

K. L. Artiles, D. Kellogg; MCD Biology, UCSC, Santa Cruz, CA

The septins are a conserved family of proteins that are required for cytokinesis and for bud morphogenesis in budding yeast. The septins appear to execute their functions at the bud neck, and an intricate signaling network is required for cell cycle-dependent changes in septin localization to the bud neck. This network includes the protein kinases Elm1, Cla4, Hsl1, and Gin4. The Gin4 kinase binds to the septins and directly phosphorylates the Shs1 septin; however, the functional significance of Shs1 phosphorylation is unclear. In addition, the mechanisms that lead to activation of Gin4 are largely unknown. Genetic and biochemical data suggest that Gin4 is directly activated by the Elm1 kinase, and that Gin4 regulates septin organization by phosphorylating Shs1. We have found that Gin4 is likely to be activated via phosphorylation of an activation loop in the kinase domain, and we are testing whether Elm1 can directly phosphorylate the activation loop. We are also testing whether Gin4 regulates septin organization through phosphorylation of Shs1. However, biochemical and genetic data thus far argue that Gin4 may regulate septin organization via phosphorylation of proteins other than Shs1.

2269

**Characterization of Distinct Sub-populations from *S Cerevisiae* Stationary-Phase Cultures: Identification of a Programmed, Developmental Response to Carbon Starvation**

C. Allen,[1] S. Büttner,[2] O. Mireilles,[1] J. E. Jaetao,[1] M. Veenhuis,[3] F. Madeo,[2] M. Werner-Washburne[1]; [1]Biology Department, University of New Mexico, Albuquerque, NM, [2]Institute of Molecular Biology, Biochemistry, and Microbiology, Karl-Franzens University, Graz, Austria, [3]Department of Eukaryotic Microbiology, University of Groningen, Haren, The Netherlands

The use of *S. cerevisiae* stationary-phase cultures for studies of important processes such as cell cycle, quiescence, aging, and apoptosis has been limited by the heterogeneous mix of cell types in these cultures. In fact, yeast cells were not thought to have a true quiescent ($G_0$) state because of the budded cells in these cultures. The objective of this study was to separate quiescent cells from other cell types in stationary-phase cultures. Two distinct sub-populations of cells were identified in stationary-phase cultures by density-gradient centrifugation. Cells from the heavier fraction were uniform in size, refractile by phase microscopy, mostly unbudded, resistant to cell-wall digestion, and thermotolerant. TEM revealved that the heavier fraction cells had abundant glycogen stores and lacked many internal organelles. Essentially all of these cells were viable and synchronously re-entered the cell cycle. In contrast, the lighter cell fraction contained a mixture of budded and unbudded cells that were sensitive to heat stress, cell wall digestion, lacked glycogen stores, and a majority were senescent. Microarray analysis identified 16 genes that were highly associated with the heavier fraction including several uncharacterized ORFs. Deletions of some of these genes are known to exhibit long-term growth defects, suggesting that these genes may play as yet uncharacterized roles in stationary phase survival. Twelve of thirty genes highly associated with the lighter fraction were involved in TY element transposition, suggesting that these cells are highly recombinogenic, a finding similar to that seen in tumor progression models. The presence of two very distinct cell populations from stationary-phase cultures suggests there is a programmed developmental process during entry into stationary phase leading to production of quiescent daughter cells and non-quiescent, senescent, necrotic, and apoptotic mother cells.

2270

**Microarray Analysis of Gene Activity in *Saccharomyces cerevisiae* Metallo-Aminopeptidase Gene Deletion Strains**

S. F. Roalofs, D. R. Caprioglio; Biology, Colorado State University Pueblo, Pueblo, CO

Metallo-Aminopeptidase gene family 1 (M1AP) encode for peptidases that cleave 1-3 amino acids from the N-terminus of a peptide. M1AP inhibitors have been used in the treatment of cancers and previous data indicate that M1APs may be involved in the cell cycle. Earlier work from

this laboratory showed a G2/M phase delay in strains lacking one or more of the four M1APs (YHR047c (AAP1'), YKL157w(APE2), YIL137c and YNL045w). To investigate the effects of M1APs in the cell cycle, *Saccharomyces cerevisiae* strains were developed with gene mutations in these open reading frames. Strains lacking either ape2 or aap1' were analyzed for mRNA accumulations using microarrays. The wildtype and strains lacking aap1 or ape2 were grown to a log phase in YPD (1% yeast extract, 2% peptone and 2% dextrose) and collected. Total RNA was purified and cDNA probes were made to hybridize to microarrays. Our data showed that mRNA abundances in cell signaling and spindle/bud formation were affected. Random over expressed and under expressed mRNA abundance identified by microarrays were also analyzed by quantitative reverse-transcriptase PCR. These results are consistent with a role of the aminopeptidases in the G2/M phase of the cell cycle. The identification of changes in mRNA abundance in specific genes involved in cell cycle due to M1AP mutations may provide insights into the molecular events leading to the G2/M phase delay. (Supported by NCI Grant P20 CA91489-01A1 and SFR supported by NCI Cancer Education Grant R25 CA49981)

**Cellular Localization of Kic1 Protein Kinase during the Cell Cycle in *Schizosaccharomyces pombe* Fission Yeast**

Z. Tang, A. Tsurumi, B. Ngo, S. Alaei, H. Palomino, C. Barragan; W.M. Keck Science Center, Claremont Colleges, Claremont, CA

Protein kinase Kic1, the orthologue of mammalian CLK/STY1 (Cdc2-like kinase or serine/threonine/tyrosine kinase), regulates the growth polarity, cell surface and septum formation, as well as the late steps of cytokinesis in *S. pombe* cells. We thus hypothesize that the cellular localization of Kic1 is altered at different stages of the cell cycle to play its specific role in cell growth and separation, as a possible mechanism to regulate Kic1 activity during the cell cycle. We examined this mechanism by using GFP tagging approaches through either ectopical expression of the N-terminal GFP-tagged Kic1 or genomic insertion to generate C-terminal GFP-tagged Kic1. A plasmid containing *GFPkic1*$^+$ gene was transformed into a wild type strain and a number of temperature-sensitive *cdc* (cell-division cycle) mutants. GFP-Kic1 fusion protein was induced for expression and visualized under a fluorescence microscope. The majority of GFP-Kic1 is concentrated in the nucleus of asynchronous wild-type *S. pombe* cells. Interestingly, GFP-Kic1 often appears in the nucleus as three small dots, suggesting that the protein may be associated with the chromosomes. GFP-Kic1 remains in the nucleus during the S phase; however, it moves towards the poles of the dividing cells at metaphase. Furthermore, when *cdc10*$^+$ or *cdc25*$^+$ gene is inactivated at the restrictive temperature and the cells are blocked at $G_1$ or $G_2$ phase, respectively, GFP-Kic1 is excluded from the nucleus or spread throughout the cell. The results can be validated by the genomic GFP-tagging approach. Our data provide the evidence that the cellular localization of Kic1 changes at various stages of the cell cycle and it is dependent on the activities of the important cell cycle regulators, Cdc10 and Cdc25, thereby modulating its activity as a kinase to function in cell growth and separation.

**Swe1p Nucleocytoplasmic Shuttling Ensures Updated Communication Between Bud Status and Mitosis**

A. R. Marquitz, D. J. Lew; Duke University, Durham, NC

The *S. cerevisiae* mitotic inhibitor Swe1p accumulates both in the nucleus and at the mother-bud neck. Neck targeting requires Hsl1p, and triggers Swe1p degradation. When bud emergence is impaired, Hsl1p is inactive, Swe1p accumulates in the nucleus and inhibits mitosis until a bud has formed. This coupling of mitosis to bud formation is called the morphogenesis checkpoint. We show that Swe1p shuttles in and out of the nucleus, and identify the NLS and NES sequences responsible. NES mutation rendered Swe1p constitutively nuclear and resistant to Hsl1p-mediated degradation. NLS mutation rendered Swe1p constitutively cytoplasmic and still subject to Hsl1p-mediated degradation. As the Swe1p-targeted cyclin/CDK is primarily nuclear, we suggest that Swe1p shuttles so that it can sense budding status (in the cytoplasm) and convey that information to its target (in the nucleus). NLS mutation rendered Swe1p ineffective in promoting G2 arrest, presumably because of reduced access to its target. Although mutation of the NES should place Swe1p together with its target, we found that this also rendered Swe1p significantly less potent as a mitotic inhibitor. Possibly, Swe1p needs to shuttle in order to access both nuclear and cytoplasmic pools of its target. However, we found that even combined expression of an NLS mutant and an NES mutant of Swe1p in the same cell did not restore Swe1p potency. These findings suggest that Swe1p must shuttle from nucleus to cytoplasm (rather than simply populating both) in order to be fully active. We suggest that nuclear Swe1p is gradually inactivated, and must periodically return to the cytoplasm for reactivation. This constitutes a "freshness dating " mechanism which ensures that only Swe1p that has sampled the budding status recently can promote arrest.

**A Cortical Microtubule Capture Protein and a Kinesin Monitor Spindle Position and Regulate Mitotic Exit in Budding Yeast**

S. Nelson, J. A. Cooper; Cell Biology and Physiology, Washington University, St. Louis, MO

In budding yeast, the spindle position checkpoint prevents mitotic exit until the mitotic spindle enters the mother / bud neck. The integrity of the spindle position checkpoint depends on Bud6. To investigate how Bud6 contributes to the checkpoint, we disrupted all of the several cellular processes in which Bud6 is known to have a role. Microtubule / cortex interactions mediated by Bud6 appear to be important for the checkpoint, while bud site selection and actin cable formation do not. We observed that the kinesin Kip2 is required for Bud6-microtubule interactions, and that Kip2 is required for checkpoint function. Genetic analysis placed Bud6 and Kip2 in the same pathway with regard to the checkpoint. We investigated the mechanism of Bud6 checkpoint function by deleting regulators of Tem1, the GTPase that activates the mitotic exit network. The *bud6* and *kip2* checkpoint defects depend on the putative GEF, Lte1, suggesting a model in which microtubule / cortex interactions mediated by Bud6 and Kip2 inhibit Lte1 to delay mitotic exit until the appropriate time. Other known regulators of Lte1, including the GTPases Ras1 and Ras2 and the PAK kinase Cla4 have checkpoint defects of the same magnitude and in the same genetic pathway with Bud6. In addition, loss of Lte1 suppresses the checkpoint phenotypes of all of these mutants. We propose that these proteins interact in a signaling network upstream of the mitotic exit network to monitor spindle position and regulate Tem1 activity.

**Expression of Cell Cycle Regulators and Esophageal Squamous Cell Carcinoma**

Y. Sato,[1] F. Casarotti,[1] C. F. Nascimento,[1] S. Ferreira,[1] R. A. Sallum,[2] F. Soares[1]; [1]Department of Anatomic Pathology, Medical and Research Center Hospital do Cancer A.C. Camargo, São Paulo, Brazil, [2]Department of Abdominal Surgery, Medical and Research Center Hospital do

Cancer A.C. Camargo, São Paulo, Brazil
Esophageal squamous cell carcinoma (ESCC) is highly prevalent in Brazil and responsible for high mortality index. There are very few studies on cyclin expression and clinicopathological data in ESCC. Tumorigenesis is related to deregulation of the cell cycle and alterations of proteins involved in cell cycle control are found in this tumor, as cyclins. This study investigated immunohistochemical expression of cyclins A, B1 and D1 in ESCC and correlated with clinicopathological findings of 579 cases. Immunohistochemistry were carried out using polyclonal cyclins A, B1 and D1 antibodies. Cases represented by surgical resections were performed in three tissue microarray paraffin blocks spotted in duplicate and cases with small biopsies without surgical resections were performed individually. The cases were scored according frequency and intensity of staining pattern. Our results showed a significant correlation between cyclin B1 expression and lymphatic invasion (p=0,006) and infiltration level (p=0,033). The cyclin B1 negative cases were more frequent in deeper invasion lesions and in cases with lymphatic invasion. Cyclin D1 immunoexpression correlated significantly with ethnia (p=0,026), being more expressed in caucasian patients. Although it was not statistically significant, there was a tendency to correlate histological grade and this marker (p=0,070), which was more expressed in well/moderate than in poorly differentiated cases. No significant correlation was observed between cyclin A expression and clinicopathological data. It were observed significantly correlations between expression of cyclins A (p<0,0001), B1 (p=0,014) and D1 (p<0,0001) and overall survival. Multivariate analyses revealed that only pT (0,030) and gender (p=0,004) are independent prognostic factors. However, when pT was not considered in multivariate analyses, cyclin D1 (p<0,0001), ethnia (p=0,003) and cyclin A (p=0,023) remained as significant prognostic factors. This findings suggests an essential role for cyclins in ESCC prognosis. Funded by FAPESP 04/12360-2 and CEPID 98/14335-2.

### Posttranslational Arginylation Regulates Cell Cycle and Affects Cell Adhesion and Morphology

M. Kozak, A. Kashina; Department of Animal Biology, University of Pennsylvania, Philadelphia, PA
N-terminal arginylation is a poorly understood posttranslational modification that is critical for embryogenesis, cardiovascular development, and angiogenesis in mammals. To understand the physiological role of protein arginylation, we studied the behavior and morphology of arginylation-deficient mouse embryonic fibroblasts in culture. We found that the absence of protein arginylation results in a dramatic increase in cell proliferation rate. While the M-phase in arginylation-deficient cells is slowed by approximately 25% compared to control, more cells are entering division in such cultures at a given time. This effect is independent on cell density; when the dividing cells reach a monolayer, their proliferation rates remain high, resulting in the formation of multilayered cultures. Thus, arginylation deficient cells display defects in contact inhibition and cell cycle control, possibly by affecting cell adhesion properties and cell cycle checkpoint(s). To study possible changes in cell adhesion, we examined the morphology of individual cells and found that the absence of arginylation results in the decreased ability of cells to spread on the substrate and form a lamella, accompanied by changes in the extracellular matrix and focal adhesions. Immunoprecipitations of several cytoskeletal proteins reveal differences in polypeptide composition between wild type and arginylation deficient cells, suggesting that arginylation affects intracellular properties of the major cytoskeletal components. Detailed studies of cell cycle changes and identification or possible cell cycle regulators affected by arginylation are now in progress.

2276

### RNF2, an E3 Ubiquitin Ligase, Interacts with D-Prohibitin and Is Involved in the CP2-Mediated Transcriptional Pathway

S. Lee, S. Kang; Graduate School of Biotechnology, Korea University, Seoul, Republic of Korea
It has been reported that RNF2, an E3 ligase protein, has a role in the transcriptional regulation as well as in the ubiquitination proteasome system. Here, we found that RNF2 interacts with the D-prohibitin protein, an inhibitor of cell proliferation, in the CP2 transcriptional pathway. Further experiments using RNA interference and immunoprecipitation assays showed that the stability of CP-2 protein is increased by expressing RNF2 and that D-prohibitin forms a trimeric complex with CP-2 through binding to RNF2. Our fractionation experiments showed that the RNF2 proteins are distributed in the mitochondria as well as in the nucleus. Under the apoptosis condition, however, the RNF2 proteins in the nucleus were exported into the cytoplasm. Our results suggest a novel mechanism by which RNF2 modulates the D-prohibitin/CP2-mediated transcriptional pathway and RNF2 might have multiple functions depending on its interacting proteins, which could be determined by the location of RNF2, mitochondria or nucleus.

### Quantitative Analysis of a Cell Cycle Checkpoint Response in *Xenopus laevis* Cell-Free Egg Extracts

I. Auckland, A. Dravid, J. J. Tyson, J. C. Sible; Biology, Virginia Tech, Blacksburg, VA
At the midblastula transition or MBT in *Xenopus laevis* embryos, cell cycle checkpoints are acquired. The mechanism responsible for the initiation of this important feature of the cell cycle is still not fully understood, but depends in part upon the concentration of nuclei. To develop a more quantitative understanding of the role of DNA in cell cycle checkpoint engagement, we investigated effects of nuclear concentration upon the underlying kinetics of the cell cycle engine in cell-free egg extracts. We quantified these effects by evaluating the threshold concentrations of cyclin required to enter mitosis and the lag times between addition of cyclin and entry into mitosis. We determined that 1) the concentration of nuclei affects lag time of entry into mitosis, 2) cyclin B thresholds required to enter mitosis increases with increasing concentrations of nuclei, and 3) elevated cyclin thresholds caused by DNA replication blocks are further increased by increasing the concentration of nuclei. In the developing embryo, the nuclei concentration doubles every 30 minutes and could be responsible for the introduction of gap phases and checkpoints at the MBT. This study examines the effect of nuclear concentration in the *Xenopus laevis* cell-free egg extract system with and without unreplicated DNA. Paired with our ongoing development of mathematical models of cell cycle networks, these studies will help build a quantitative, systems-level view of the regulation of cell cycle and its interaction with checkpoint signaling networks.

2278

### Chk1 Controls DNA Damage-induced Centrosome Amplification

E. Bourke,[1] A. Merdes,[2] L. Cuffe,[1] H. Dodson,[1] G. Zachos,[3] D. Gillespie,[3] C. Morrison[1]; [1]Biochemistry, NUIG, Galway, Ireland, [2]CNRS-Pierre Fabre, Toulouse, France, [3]Beatson Institute for Cancer Research, Glasgow, United Kingdom

Numerical aberrations of the centrosome, the key microtubule organising centre of animal cells, are commonly observed in cancers and in cells with defective DNA repair. Here we show by light and electron microscopy that gamma irradiation induces centrosome amplification in human cells. Such amplification can be abrogated by caffeine in both ATM- and ATR-defective cells, suggesting a complementary role for these two DNA damage-sensitive kinases in permitting this response. We demonstrate that treatment with UCN-01, a CHK1 inhibitor, suppresses centrosome amplification after DNA damage in human cells. Radiation-induced centrosome amplification was abrogated in Chk1-/- DT40 cells, but occurred at normal levels in Chk1-/- cells expressing a Chk1 transgene. Expression of kinase-dead Chk1, or Chk1S345A, through which the PI3K kinases cannot signal, failed to restore the capacity for centrosome amplification, suggesting that both PI3K signalling to Chk1 and Chk1 activity are necessary for centrosome amplification to occur after DNA damage. Using cold treatment to arrest the cell cycle without causing DNA damage, we show that a G2 arrest alone is not sufficient to potentiate significant centrosome amplification, suggesting that a Chk1 signal may act directly on the centrosome in allowing amplification after DNA damage. These findings suggest that Chk1 plays a key role in maintaining genomic integrity through controlling the centrosome cycle in response to DNA damage.

**Mammalian SWI/SNF Complexes Enhance DNA Double-Strand Break Repair by Promoting γ-H2AX Induction**

J. Park, E. Park, J. Kwon; Division of Molecular Life Sciences, Ewha Womans University, Seoul, Republic of Korea

Mammalian SWI/SNF complexes can modulate chromatin structure by utilizing the energy of ATP hydrolysis and their role in transcription has been well established. However, the role of SWI/SNF in DNA repair has remained largely unexplored. Here we provide evidence that the SWI/SNF complexes enhance DNA double strand break (DSB) repair by stimulating γ-H2AX induction. Inactivation of the SWI/SNF complexes via expression of dominant negative core subunit BRG-1 results in reduced DSB repair with transcriptional modulation associated with DNA repair largely unaffected. SWI/SNF defect severely compromises both H2AX phosphorylation and γ-H2AX focus formation after DNA damage without affecting expression of ATM, DNA-PK and ATR, or their activation and recruitment to DNA breaks. In addition, immunofluorescence data indicate that the formation of γ-H2AX foci following DNA damage is inhibited specifically in the subnuclear regions in which the dominant negative BRG-1 is expressed. These results suggest that the SWI/SNF complexes directly participate in promoting γ-H2AX to enhance DSB repair, providing a novel link between ATP-dependent chromatin remodeling and DSB repair in mammalian cells.

**Determinants of Cell Fate Following DNA Replication Fork Stress**

R. Rodriguez Gonzalez, M. Meuth; Institute for Cancer Studies, University of Sheffield, Sheffield, United Kingdom

Cells respond to DNA replication stress by triggering cell cycle checkpoints, repair, or death. To understand the role of the DNA damage response pathways in determining whether cells survive replication stress or become committed to death, we examined the effect of loss of these pathways on cellular response to agents that slow or arrest DNA synthesis. We show that replication inhibitors such as excess thymidine, hydroxyurea, and camptothecin are normally poor inducers of apoptosis although they are effective inducers of a permanent p53-p21-dependent G2 arrest and senescence in some tumor cell lines. However these agents become potent inducers of death in S-phase cells upon siRNA mediated depletion of the checkpoint kinase Chk1. Cells defective in other proteins that are activated in S-phase following replication fork stress such as ATM, p53, and Chk2 do not show the same apoptotic response. p21 deficient cells on the other hand produce a more robust apoptotic response upon Chk1 depletion. p21 is normally induced in G2 phase, late after thymidine treatment. In Chk1 depleted cells p21 induction occurs earlier and does not require p53. Thus Chk1 plays a primary role in the protection of cells from death induced by replication fork stress while p21 mediates through its role in regulating entry into S-phase. These findings are of potential importance to cancer therapy as we demonstrate that the efficacy of clinically relevant agents can be enhanced by manipulation of these signalling pathways.

**Mitotic Delay in Response to DNA Damage in Syncytial *Drosophila* Embryos**

S. Kwak, A. Kelkar, S. Takada, W. E. Theurkauf; Program in Molecular Medicine, UMASS Medical School, Worcester, MA

DNA damage-induced mitotic catastrophe is facilitated by defects in the G1 and G2 checkpoints in mammalian cells. To understand the underlying mechanism, we utilize the early *Drosophila* embryo that has a simple S phase-M phase cell cycle and does not delay progression into mitosis in response to DNA damage. However, these embryos have an elaborate M-phase response to DNA damage that includes active disruption of the centrosome and spindle assembly by a Chk2 kinase-dependent pathway (Sibon et al., 2000; Takada et al., 2003). Here we show that embryos also delay mitotic exit in response to DNA damage. Using time-lapse confocal microscopy, we show that DNA damaging agents lead to cell cycle delays with separated sister chromosomes, elongated spindles, and robust anaphase astral microtubule arrays. In wild type embryos, these delays are induced by relatively high levels of agents that cause DNA strand breaks. By contrast, embryos mutant for the Bloom's syndrome homologue or histone H2AV, which are defective in double strand break repair, are hypersensitive to damage and consistently arrest in anaphase in response to very low levels of DNA damaging agents. During damage-induced arrest, levels of mitotic Cyclin B1 and B3 remain high, indicating that damage blocks Cyclin proteolysis on mitotic exit. Mutations in Chk2 completely suppress damage induced mitotic exit arrest, while mutations in Chk1, ATR and p53 have no effect on this apparent anaphase DNA damage checkpoint. We also show that Cdc20/Fzy is modified by DNA damage in Chk2 dependent manner by 2D gel analysis. We therefore conclude that the *Drosophila* Chk2 tumor suppressor homologue is required for a DNA damage dependent mitotic exit checkpoint that functions during early embryogenesis.

**Inhibition of Calcium-independent Phospholipid $A_2$ Induces a p53-dependent Membrane Phospholipid Turnover Checkpoint**

X. H. Zhang, C. Zhao, K. Seleznev, K. Song, Z. A. Ma; Department of Geriatrics, Mt. Sinai Med Ctr, New York, NY

Phosphatidylcholine (PtdCho) is the most abundant phospholipid in mammalian cell membranes. It is essential for cell viability and its levels vary through the cell cycle. The G1 cells maintain a constant membrane phospholipid content but exhibit a high rate of PtdCho biosynthesis and degradation and this high rate of phospholipid turnover is achieved by the opposing actions between CTP:phosphocholine cytidylyltransferase (CCT) and the group VIA $Ca^{2+}$-independent-phospholipase $A_2$ ($iPLA_2$). However, it is unknown whether this G1 phospholipid turnover is directly

coupled to cell-cycle control. We found that disruption of G1 phospholipid turnover with the $iPLA_2$-specific inhibitor bromoenol lactone, with the expression of the dominant-negative domain of $iPLA_2$, or with siRNA against $iPLA_2$ arrested rat insulinoma INS-1 and human colon carcinoma HCT cells in G1 by activation of the tumor suppressor p53 and expression of the cyclin-dependent kinase inhibitor p21. In contrast, HCT $p53^{-/-}$ cells failed to arrest in G1 in response to inhibition of $iPLA_2$ and HCT $p21^{-/-}$ cells underwent massive apoptosis that can be rescued by downregulation of p53 by siRNA against p53. Furthermore, we found that inhibition of $iPLA_2$-mediated PtdCho degradation induced the rapid phosphorylation of serine-15 of p53 without causing DNA damage, and that this phosphorylation is blocked by caffeine, a specific inhibitor of ATM kinase. Our data indicated that the disruption of phospholipid turnover activates the ATM-p53 pathway, which induces the expression of p21 to prevent CDK activation and subsequent G1 arrest. Thus, we propose that the phospholipid turnover in G1 cells is an intrinsic checkpoint essential for S phase entry, and that this checkpoint is monitored through cooperation of $iPLA_2$ with p53.

**Heterogeneity in Expression and Sequence of SIRT2, p53, and Stat3 Genes in a Spontaneous Canine Model of Breast Cancer**

R. Bird, P. DeInnocentes, L. Ring, L. Li, R. Sanchez; Pathobiology, Auburn University, Auburn, AL

Spontaneous canine mammary cancer (CMT) is the most common malignancy of dogs and a highly homologous model of human breast cancer. We have investigated potential links between genes associated with lifespan, survival and neoplastic potential to better explain changes and loss of proliferative control and expression of the differentiated phenotype associated with neoplastic transformation. Differences in cell lines derived from individual malignant canine mammary tumors were investigated to identify new regulatory genes associated with neoplasia, cell proliferation, apoptosis and senescence. The silent information regulator 2 (SIR2) gene family has been implicated in gene silencing, chromosomal stability, aging and histone deacetylation. SIR2 encodes a multigene family of highly conserved sequences encoding nicotinamide adenine dinucleotide-dependent histone deacetylases. Stat3 encodes a signal-transducer and activator of transcription that is frequently overexpressed in human breast cancer potentiating angiogenesis, regulating cell cycle progression and suppressing apoptosis. Canine SIRT2 rt-PCR revealed abundant transcripts in all cell lines, were most homologous to human SIRT2 and contained non-conserved amino acid substitutions representing mutations or allelic differences and interspecies differences including substitutions of conserved cystein residues in the Zn2+-binding motif. Defects in gene products interacting with SIRT2 were also noted as was an extended G2/M phase. Abundant but variable levels of highly conserved Stat3 were also expressed in these CMT cell lines. Mutations in SIRT2 were coincident with abnormal expression/truncation of p53 its modulator Wip1 and a failure to activate p21/Cip1. This data suggests mechanisms by which regulation of expression could integrate developmental/apoptotic pathways with SIRT2-dependent lifespan and cell proliferation regulation that could promote cell proliferation and reinforce neoplastic transformation. These genes offer promising therapeutic targets that may contribute to transformed and immortalized phenotypes in this spontaneous model of breast cancer.

2284

**Distinct Mechanisms of Cdk Hyperactivity Regulate Invasion and Resistance to Differentiation in Human Neuroblastoma Cell Lines**

E. O'Reilly, F. Barrett, E. Carroll, H. C. Gallagher; Pathology, University College Dublin, Dublin, Ireland

Resistance to differentiation is a key feature of advanced, highly invasive neuroblastoma tumours. This relies on the maintenance of cell cycling, but how the cell cycle machinery controls the critical balance between neuroblastoma proliferation and differentiation is unclear. Here, we dissected the relationship between cyclin signaling and the proliferation, differentiation and invasiveness of four human neuroblastoma cell lines (SH-SY-5Y, SK-N-DZ, SK-N-MC and SK-N-SH). Four cyclin-dependent kinase (cdk) inhibitors (roscovitine, olomoucine, indirubin-3-monoxime and a cdk 4-selective inhibitor) and two pro-differentiative retinoids (all-trans-retinoic acid and 13-cis-retinoic acid) were used. Cell viability/proliferation was assessed by MTT assay and differentiation by neurite outgrowth assay. Invasion assays employed a matrigel matrix. Key cyclins, cdks and inhibitory proteins as well as the profilerative marker, PCNA, and neuronal differentiation markers were analyzed by immunoblotting. We found a strong correlation between hyperactivity of certain cdks and invasiveness in the four cell lines, both basally and in response to drug treatment. In addition, sensitivity to differentiation was drug- and cell line-specific and involved the inhibition of key cdks and their cyclin partners. For example, in SH-SY-5Y cells, cdk4 was over expressed basally and cell cycle exit and differentiation was induced time-dependently by the cdk4 inhibitor and 13-cis-RA, at low micromolar concentrations. However, these cells were more resistant to ATRA, olomoucine, roscovitine and indirubin-3-monoxime (cdk2/5-specific inhibition). SK-N-DZ cells were more sensitive to ATRA than to 13-cis-RA and their differential sensitivity to cdk inhibitors reflected their basal cyclin/cdk expression pattern. Across all cell lines, however, a shut-down in cyclin signaling always accompanied cell differentiation and reduced invasiveness. We suggest that specific mechanisms of cdk hyperactivity in individual neuroblastoma tumours may determine their sensitivity to chemotherapeutic drugs. Moreover, cdk inhibitors may be useful for treating neuroblastoma.

**Cytosolic Phospholipase $A_2$-α Mediates Endothelial Cell Proliferation and is Inactivated by Association with the Golgi apparatus**

S. P. Herbert, S. Ponnambalam, J. H. Walker; Biochemistry and Microbiology, University of Leeds, Leeds, United Kingdom

The formation of new blood vessels from pre-existing blood vessels (angiogenesis) is a multi step process involving endothelial cell (EC) proliferation, migration and differentiation. Arachidonic acid and its metabolites may play a role in a number of these steps. Receptor-stimulated arachidonic acid release is mediated by cytosolic phospholipase $A_2$ ($cPLA_2$), a $Ca^{2+}$-sensitive member of the phospholipase-$A_2$ superfamily of lipolytic enzymes. We tested the hypothesis that $cPLA_2$ activity is linked to the control of EC proliferation. We discovered that $cPLA_2$ plays a central role in the control of EC proliferation (Herbert, S.P. *et al*. (2005) *Mol. Biol. Cell.* Jun-1 [Epub ahead of print]). The specific $cPLA_2$a inhibitor, pyrrolidine-1, inhibits EC proliferation in a dose dependent manner which is reversed upon the addition of exogenous arachidonic acid. Furthermore, only upon proliferation do ECs exhibit any $cPLA_2$ activity. In confluent, non-proliferating ECs $cPLA_2$ is inactivated by a novel mechanism involving association with the Golgi apparatus. Sequestration at the Golgi impedes the association of $cPLA_2$ with its phospholipid substrate at the endoplasmic reticulum. The inability to access substrate effectively inhibits $cPLA_2$ activity by 87% and prevents the functional coupling of $cPLA_2$ with cyclooxygenase enzymes, reducing $PGE_2$ release by 96%. In addition, $cPLA_2$ activity is essential for the re-entry of non-proliferating ECs into the cell cycle. Proliferation will only occur upon activation of $cPLA_2$ by release from the Golgi. We find that $cPLA_2$ activity

then mediates the expression of Ki67, an essential cell cycle regulatory protein. In conclusion, we find that $cPLA_2$ plays a central role in the induction of EC proliferation, a vital aspect of the angiogenic response. Furthermore, $cPLA_2$ activity and thus its ability to induce EC proliferation, is regulated by reversible association with the Golgi apparatus.

### Mitochondrial ATP Synthase Inhibition by 3,3'-diindolylmethane (DIM ) Contributed to the Reactive Oxygen Species (ROS) Production, p38 and JNK Activation and Subsequent $p21^{WAF1/CIP1}$ Upregulation in Human Breast Cancer MCF-7 Cells

Y. Gong,[1] H. Sohn,[1] L. Xue,[2] G. Firestone,[2] L. Bjeldanes[1]; [1]Nutritional Sciences and Toxicology, UC Berkeley, Berkeley, CA, [2]Molecular and Cell Biology, UC Berkeley, Berkeley, CA

Epidemiological evidence suggested that high dietary intake of fruit and vegetables protects against tumorigenesis in multiple organs. Among these vegetables with anticancer properties, those of *Brassica* genus, such as broccoli, cabbage and Brussels sprouts, appear to be very effective in reducing the risks of several types of cancers, including breast cancer. 3,3'-Diindolylmethane (DIM), one of the most abundant and biologically active *in vivo* products derived from *Brassica* vegetables, is a promising antitumor agent. Previous studies in our lab identified $p21^{WAF1/CIP1}$ overexpression as the major trigger of DIM-induced G1 arrest in breast cancer MCF-7 cells. In this study, the upstream events leading to $p21^{WAF1/CIP1}$ overexpression were further investigated. Using pathway specific inhibitors SB203580 and SP600125 and dominant negative expression vectors, we identified stress-activated MAP kinase pathway p38 and JNK as the major upstream pathways leading to DIM-induced $p21^{WAF1/CIP1}$ mRNA transcription. In addition, we demonstrated for the first time that DIM is a strong mitochondrial ATP synthase inhibitor ($IC_{50}$~25μM). DIM treatment induced hyperpolarization of mitochondrial membrane potential and decreased ATP production. Like many other oxidative phosphorylation inhibitors, DIM treatment significantly stimulated mitochondrial ROS production, which led to the activation of redox sensitive p38 and JNK pathway. In further support of the results, when DIM was coadministered with antioxidants vitamin E and C, the activation of p38 and JNK and the overexpression of $p21^{WAF1/CIP1}$ were all attenuated. Our continuing studies seek confirm the role of mitochondrial in DIM-mediated release of ROS and expression of $p21^{WAF1/CIP1}$. The present studies are the first to link mitochondrial ROS release with DIM-induced cell cycle arrest.

### ATP-dependent Proteases Differ Substantially in their Ability to Unfold Globular Proteins

N. E. Jaffe, P. Koodathingal, A. Matouschek; Dept. of Biochemistry, Molecular Biology and Cell Biology, Northwestern University, Evanston, IL

Degradation of proteins by ATP-dependent proteases plays a critical role in several cellular processes, including the cell cycle, gene expression, signal transduction and antigen presentation. Proteins must be unfolded to be degraded by ATP-dependent proteases. My research focuses on the mechanism of protein unfolding and destruction by the proteasome and its functional bacterial analogues, ClpAP, ClpXP, Lon, HslUV and FtsH. Each of these proteases is active as a cylindrical structure composed of one or more oligomeric rings, arranged such that the active sites of proteolysis are sequestered. In addition, all ATP-dependent proteases generally function the same way; degradation of a substrate protein occurs in a stepwise process where the protein is first targeted and bound to one end of the protease. The protein is subsequently unfolded and its polypeptide chain is translocated to the active sites of proteolysis. Despite these similarities, we have found that ATP-dependent proteases differ substantially in their ability to unfold proteins. Our research demonstrates that ATP-dependent proteases display a hierarchical range of strengths for unfolding proteins from either end of their polypeptide chain. A protein's overall lifetime in the cell, or its susceptibility to degradation, is conferred by its intrinsic stability, its structure, and a targeting signal. Our data suggest that differences in protease unfolding strength may also contribute to a protein's lifetime. By regulating the concentration of strong or weak proteases, the cell could achieve an additional level of selectivity in protein destruction.

2288

### Biochemical Characterization of the Interaction Between CPAP and 14-3-3 Protein

C. Chen,[1,2] M. Olayioye,[3] G. J. Lindeman,[3] T. K. Tang[2]; [1]Graduate Institute of Life Sciences, National Defense Medical Center, Taipei, Taiwan Republic of China, [2]Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan Republic of China, [3]The Walter and Eliza Hall Institute of Medical Research, Post Office Royal Melbourne Hospital, Victoria, Australia

CPAP, a centrosomal protein 4.1-associated protein, is a multifunctional protein, originally identified by a yeast two-hybrid screening using protein 4.1 as bait (Mol. Cell. Biol. 20, 7813-7825, 2000). CPAP carries a novel microtubule-destabilizing motif that not only recognizes the plus end of a microtubule but also inhibits microtubule nucleation from the centrosome, suggesting that CPAP may play a role in the regulation of microtubule assembly. Interestingly, CPAP was also reported to interact with STAT5 and RelA, suggesting that CPAP may act as a transcription co-activator. To further examine the putative functions of CPAP, we searched for conserved sequence motifs in CPAP and identified two classical 14-3-3 binding motifs. The 14-3-3 proteins are a family of abundant 28-33-kDa acidic polypeptides that bind and regulate a number of key proteins involved in diverse signal transduction pathways. The interaction of CPAP and 14-3-3 was first confirmed by a yeast two-hybrid system followed by a co-immunoprecipitation experiment. Further analyses revealed that the 14-3-3 binding domain is located at the C-terminal domain of CPAP and Ser-1109 is required for 14-3-3 binding. Mutation of serine 1109 (Ser-1109) to alanine significantly inhibits CPAP binding to 14-3-3. Interestingly, the amount of CPAP/14-3-3 complex was significant reduced in cells arrested at M phase. Furthermore, we observed that Ser-1109 of CPAP can be phosphorylated by calcium/calmodulin-dependent protein kinase II (CaMKII) *in vitro*. Together, these results suggested that the formation of CPAP and 14-3-3 complex is in a cell cycle-dependent manner and possibly through the activation of CaMKII.

### Peptide-based Nano-structure for *in vivo* Delivery of Therapeutic SiRNA Targeting the Cell Cycle Regulatory Protein Cyclin B1

E. Gros,[1] F. Simeoni,[1] M. C. Morris,[1] G. Aldrian-Herrada,[1] Q. N. Nguyen,[2] G. K. McMaster,[2] G. Divita[1]; [1]Molecular Biophysics & Therapeutics, CRBM, Montpellier, France, [2]Genospectra Inc., Fremont, CA

The dramatic acceleration in the identification of new nucleic acid-based therapeutic molecules has provided new perspectives in pharmaceutical research. However, development of these molecules is limited by poor cellular uptake and cellular trafficking or the lack of biological activity of

the compound delivered. With the aim of addressing these issues, we have designed a family of short amphipathic peptides (MPG), which consist of a hydrophobic domain and a hydrophilic domain derived from the NLS of SV40 T-antigen. These carriers when complexed with the siRNA form a stable and reversible "nano-cage" around siRNA through non-covalent interactions, thereby increasing their stability. MPG efficiently delivers siRNA into a wide variety of mammalian cell lines through a process involving membrane disorganization, independently of the endosomal pathway. MPG-carrier is a powerful tool for delivery of siRNA, enabling rapid release of the siRNA into the cytoplasm and promoting robust downregulation of target mRNA. MPG-carriers were applied to the delivery of siRNA targeting the cell cycle regulatory protein Cyclin B1 into cancer cell lines and into a mouse model. When associated with MPG carrier, sub-nanomolar concentrations of siRNA Cyclin B1 significantly knocked down Cyclin B1 protein levels and blocked cancer cell proliferation. Temporal regulation of the siRNA Cyclin B1 was validated by using a novel light-activated, controllable siRNA. Kinetic studies have revealed that siRNA mediated knockdown of Cyclin B1 mRNA results in a cell cycle arrest in early G2. MPG/Cyclin B1 siRNA formulations were shown to block tumor growth in vivo upon intratumoral or intravenous injection. Given the biological properties of these novel vectors , we believe that MPG-based technologies will contribute significantly to the development of fundamental and therapeutic applications.

**Development of a Set of Genetically-Encoded Fluorescent Cell Cycle Biosensors**

A. T. Hahn,[1] J. T. Jones,[2] C. R. Gustavsson,[2] T. Meyer[2]; [1]Molecular and Cellular Phys, Stanford University, Stanford, CA, [2]Molecular Pharmacology, Stanford University, Stanford, CA

In order to monitor the timing of all four phases of the cell cycle in live, unsynchronized cell populations, we developed sensors for G1 and S phases to complement the mitosis biosensor that we designed previously (Jones et al, Nat Biotechnol, 2004). The G1 biosensor consists of the carboxy terminus of human DNA helicase B (Gu et al, Mol Biol Cell, 2004) attached to a fluorescent protein. The S phase biosensor is a modified version of the proliferating cell nuclear antigen construct originally developed by Leonhardt and colleagues to monitor the dynamics of replication foci (J Cell Biol, 2000). Using an epifluorescence microscope equipped with a live cell chamber, we have followed unsynchronized cells for the duration of an entire cell cycle, monitoring the spatio-temporal dynamics of the sensors. In G1, the G1 and S phase biosensors are localized to the nucleus. As the cell enters S phase, the G1 biosensor translocates into the cytoplasm where it remains until M phase, while the S phase biosensor forms nuclear puncta that change location and size during S phase progression. In G2, the large puncta from late S phase disappear and the sensor is again localized homogenously in the nucleus. After nuclear envelope breakdown at the start of mitosis, the G1 and S phase biosensors are localized throughout the cell. Using the visual cues provided by these biosensors, we were able to successfully identify and time the durations of all four phases of the cell cycle, a feat previously impossible using standard methods like FACS and antibody staining. This set of biosensors, together with the tracking and analysis software that we have also developed, enable the high content screening of potential anticancer therapeutics and small interfering RNA for proteins involved in tumorigenesis.

**Down-Regulation of the Tumor Suppressor p53 in HEK Cells by Gravity Mechano-Stimulation**

J. Phillips, N. Fingland, E. A. C. Almeida; Life Sciences Division, NASA Ames Research Center, Moffett Field, CA

The tumor suppressor p53 accumulates in tissues exposed to microgravity (Ohnishi et al. 2000). Similar results are seen in studies with hindlimb-unloaded animals, a ground-based model of microgravity (Siu and Alway, 2005). Previous work also shows that hindlimb-unloaded p53-null animals do not exhibit bone loss normally associated with disuse (Sakai et al. 2002). These studies suggest a role for p53 in regulating bone tissue, where the accumulation of p53 negatively regulates bone mass. Since the removal of mechanical forces due to gravity results in the accumulation of p53, we postulate that increased mechanical load from an enhanced gravitational field will deplete p53 levels. To test this hypothesis we grew HEK cells that express high levels of p53 in a cell culture centrifuge for 24 hours. We then compared p53 levels from cells cultured at 25 times unit gravity (25g), to cells cultured at normal gravity (1g). Western blot analysis of p53 levels reveal that cells exposed to 25g have depleted levels of p53 as compared to cells cultured in 1g. Densitometry analysis shows a 45% decrease in p53 levels in cells exposed to 25g. Culture of primary osteoblasts at 25g for 24h also increased cell proliferation 1.5 fold relative to 1g, in an integrin and extracellular matrix-dependent manner. These results indicate that mechanical cues regulate p53 levels in a bi-directional manner. Loss of mechanical input results in an accumulation of p53 while the present study shows p53 depletion in response to increased mechanostimulation. The role of gravity-induced mechanical forces in regulating p53 levels via a matrix/integrin pathway (Ilic et al. 1998, Almeida et al. 2000) suggests a possible mechanism for the regulation of cell proliferation by mechanical stimuli. Supported by NASA-00-OBPR-01.

**γ-Tubulin Localization in the Mitotic Spindle**

J. Ho, C. D. Yankel, S. A. Endow; Cell Biology, Duke University Medical Center, Durham, NC

γ-Tubulin is thought to function in microtubule nucleation and has been localized to microtubule organizing centers (MTOCs) in a variety of organisms. To investigate the localization of γ-tubulin in the mitotic spindle, we created transgenic *Drosophila* lines that express γ-tubulin-GFP. The *γ-tubulin-gfp* lines show no detectable mutant effects due to the gene insert. Remarkably, γ-tubulin-GFP not only localizes to the centrosome, but also localizes to the spindle in live *Drosophila* embryos during the syncytial blastoderm stages of early embryonic development. γ-Tubulin-GFP does not fully decorate the spindle, but instead appears to be associated with a subset of spindle microtubules in a pattern that resembles the distribution of kinetochore microtubules. γ-Tubulin-GFP fluorescence showed more rapid loss during photobleaching than the spindle-and centrosome-associated microtubule motor protein Ncd, indicating that γ-tubulin differs greatly in its binding to the centrosomes compared to Ncd. γ-Tubulin-GFP also reassociated with centrosomes less rapidly than Ncd after photobleaching. Photobleaching of half or full spindles did not appear to affect cellular division in the *γ-tubulin-gfp Drosophila* line. Our results suggest that γ-tubulin is bound to a substructure of the spindle that may represent the elusive spindle matrix.

**Determinants of Cohesin Localization**

J. L. Gerton,[1,2] C. Bausch,[1] S. Noone,[1] K. Zueckert-Gaudenz,[1] C. Seidel[1]; [1]Stowers Institute for Medical Research, Kansas City, MO, [2]Department of Biochemistry and Molecular Biology, University of Kansas Medical School, Kansas City, KS

In eukaryotic cells, cohesion allows sister chromatids to biorient on the metaphase plate and holds sister chromatids together until they separate into daughter cells during mitosis. Cohesion is mediated by the cohesin protein complex. We have used chromatin immunoprecipitation coupled with microarray analysis (ChIP chip) to produce a genome-wide description of cohesin association with mitotic chromosomes in *S. cerevisiae.* Although the pattern of association is highly reproducible, no consensus binding sequence could be identified. However, we observed a very strong correlation between cohesin sites and regions between convergent transcription units. We have begun to explore the mechanistic relationship between cohesin association and transcription. Transcript elongation into sites with which cohesin is associated results in the disassociation of cohesin. Interestingly, once transcription is halted, cohesin reassociates with its original sites, independent of DNA replication. These results and others indicate that cohesin association with chromosomes is both flexible and dynamic. Our results are most consistent with a model in which cohesin localization is determined by chromatin state.

2294

**Mutual Inhibition of Separase and Cdk1 by Two-Step Complex Formation**

O. Stemmann, I. H. Gorr, D. Boos; Molecular Cell Biology, Max-Planck-Institute of Biochemistry, Martinsried, Germany

Stable maintenance of genetic information requires chromosome segregation to occur with high accuracy. Anaphase is triggered when ring-shaped cohesin is cleaved by separase, a protease regulated by association with its inhibitor securin. Dispensability of vertebrate securin strongly suggests additional means of separase regulation. Indeed, sister chromatid separation but not securin degradation is inhibited by constitutively active cyclin-dependent kinase 1 (Cdk1) and can be rescued solely by preventing phosphorylation of separase. We demonstrate that Cdk1-dependent phosphorylation of separase is not sufficient for inhibition. In a second step Cdk1 stably binds phosphorylated separase via its regulatory cyclin B1 subunit. Complex formation results in inhibition of both protease and kinase, and we show that vertebrate separase is a direct inhibitor of Cdk1. This unanticipated function of separase is negatively regulated by securin but independent of separase's proteolytic activity.

**The Stress-activated G2 Antephase Checkpoint is a General Feature of Normal But Not Transformed Cell Lines**

A. V. Mikhailov,[1,2] C. L. Rieder[1,2]; [1]Molecular Medicine, Wadsworth Center of the NYS Dept of Health, Albany, NY, [2]Biomedical Sciences, SUNY School of Public Health, Albany, NY

Animal cells contain a cell cycle checkpoint during G2, centered on the p38-stress-activated protein kinase, that delays entry into mitosis in response to various stresses that could interfere with the proper segregation of the genome. We have examined the functionality of this checkpoint in normal and cancerogenic (transformed) cells by exposing them during chromosome condensation to low concentrations of the p38 activator, anisomycin. We confirmed p38 activation with p38 phospho-specific antibodies, and used progress through antephase (the first signs of chromosome condensation to the commitment to mitosis near nuclear envelope breakdown) as a visual cue of the cells' progression through G2. In response to anisomycin treatment during antephase, primary and telomerase-immortalized epithelial and fibroblastic cells decondensed their chromatin and returned to G2. However, 4-5 hrs later they then completed a normal antephase and entered mitosis. In contrast, many (e.g., Hela, dormant Hep3, tumorigenic Hep3), but not all (e.g., U2OS), transformed cells progressed through antephase and entered mitosis with normal timing in spite of strong p38 activation. In these cells the defect in the antephase checkpoint must therefore lie downstream of the p38 kinase. Entering mitosis under stressful conditions can lead to chromosome nondisjunction/damage, and to the loss or gain of whole chromosomes or chromosome parts. We propose that defects in the antephase checkpoint in early stage tumors lead to genomic instability. Further, checkpoint functionality may be restored in advanced cancers to stabilize genetic changes and avoid cell death during chemotherapy.

**CENP-E Promotes Chromosome Congression By Lateral Transport Along Microtubule Fibers**

M. A. Lampson,[1] P. Hergert,[2] A. Khodjakov,[2] T. M. Kapoor[1]; [1]Laboratory of Chemistry and Cell Biology, Rockefeller University, New York, NY, [2]Wadsworth Center, New York State Department of Health, Albany, NY

During cell division chromosomes move to the center of the mitotic spindle (congress) as they correctly attach to spindle microtubules and align at the metaphase plate. In mammalian cells most chromosomes are located between the spindle poles after nuclear envelop breakdown and rapidly form attachments to both spindle poles. A few chromosomes cannot readily achieve proper attachments due to their position and are transported to one spindle pole, where they delay anaphase by activating the mitotic spindle checkpoint. The precise steps required for these pole-associated chromosomes to congress and achieve bi-orientation remain unknown. We developed an assay, using reversible cell-permeable small molecule kinesin and kinase inhibitors, to accumulate chromosomes near the pole and examine their congression. Correlative light and electron microscopy allowed a detailed analysis of the early steps of this process. Cells were imaged live to identify chromosomes in the process of congressing from the pole, then fixed, relocated, and analyzed by serial section EM. We find that the leading kinetochores of congressing chromosomes are not attached to the ends of microtubule fibers, as would be expected if bi-orientation preceded congression, but instead are attached to the sides of the fibers. This finding suggests that a microtubule motor located at the kinetochore may drive this congression process by walking along the sides of microtubule fibers. When the mitotic kinesin CENP-E is depleted by RNAi, chromosomes remain at the pole and fail to congress in our assay. The formation of syntelic chromosome attachments in CENP-E-depleted cells indicates that the congression defect does not result from a failure in microtubule attachment alone. We propose that CENP-E promotes congression of chromosomes at the spindle pole by lateral transport along microtubule fibers.

**Identification of Drosophila Spindly, a Novel Factor Required for Cellular Morphology and Mitotic Progression**

E. R. Griffis, N. Stuurman, R. D. Vale; HHMI/CMP, UCSF, San Francisco, CA

We have recently completed a morphology screen in Drosophila S2 cells using a library of over 7200 dsRNAs. Among the novel candidates that we found in the screen, was a protein whose depletion produced defects in lamellar actin and long microtubule rich projections. The sequence of this protein does not reveal obvious homologues in other organisms, and based upon the unusual cell projections after RNAi, we call this protein Spindly. When GFP-tagged Spindly was expressed in S2 cells, we found that it localizes to microtubule tips, to the actin-rich lamella, and on the kinetochores of mono-oriented and unaligned chromosomes. The latter localization suggests a role for spindly in mitosis, and indeed, spindly RNAi results in an elevated mitotic index and abnormal spindles. In live cells, we have observed that as chromosomes achieve biorientation and move towards the metaphase plate, the level of spindly on kinetochores decreases, and a new population of Spindly appears on spindle microtubules and spindle poles. By closely evaluating GFP-Spindly movement during mitosis, we were able to discern discreet particles of the protein tracking along microtubules from kinetochores to the spindle pole. Interestingly, we find that depletion of cytoplasmic dynein stops the mitotic movements of GFP-Spindly, while depletion of the Rough Deal (Rod) checkpoint protein prevents the association of Spindly with kinetochores. Conversely, when we deplete Spindly we have observed that Rod accumulates to high levels on all kinetochores, similar to what is seen after dynein depletion, a likely explanation of the elevated mitotic index. Additionally, codepletion of spindly together with other mitotic factors produces phenotypes similar to those seen after dynein codepletion. From these data, we hypothesize that spindly is a novel dynein or dynactin cofactor.

**A Marine Natural Product that Blocks Mitosis but Does Not Target Tubulin**

M. K. Jung,[1] K. Stewart,[2] K. Yamada,[3] H. Kigoshi,[4] K. Suenaga,[4] C. E. Oakley,[5] B. R. Oakley,[5] E. Hamel[6]; [1]Screening Technologies Branch, SAIC-Frederick, Inc., Frederick, MD, [2]Screening Technologies Branch, National Cancer Institute at Frederick, Frederick, MD, [3]Graduate School of Science, Nagoya University, Nagoya, Japan, [4]Department of Chemistry, University of Tsukuba, Tsukuba, Japan, [5]Department of Molecular Genetics, The Ohio State University, Columbus, OH, [6]Toxicology and Pharmacology Branch, National Cancer Institute at Frederick, Frederick, MD

Although anti-mitotic agents have generally targeted tubulin, we want to identify new anti-mitotic compounds with targets other than tubulin and to use these agents to identify cellular components involved in mitotic control and regulation. Mitosis is a validated anti-cancer target. Besides the clinically important vinca alkaloids and taxoids, current clinical trials include new inhibitors of tubulin, aurora kinases and the kinesin spindle protein, KSP or Eg-5. In a screen to identify compounds that prevent the progression of cells through mitosis, we discovered that aplyronine A, a marine natural product cytotoxic to tumor cells, arrests MCF-7 breast cancer cells in mitosis at sub-nanomolar concentrations. A macrolide isolated from the sea hare *Aplysia kurodai*, aplyronine A does not affect *in vitro* assembly of brain tubulin. Exposure of tissue culture cells to aplyronine A disrupts mitotic spindles, and the resulting spindle morphology differs from what is seen after exposure to classical anti-microtubule agents. The spindle morphology also differs from that seen in cells exposed to inhibitors of aurora kinase or Eg-5. Potential aplyronine A targets include structural components of the mitotic apparatus, centrosomal components, and signaling molecules. There is evidence that aplyronine A interacts with a component of the fungal spindle pole body (the centrosome equivalent), since it supports the growth of a conditionally lethal γ tubulin mutant of the filamentous fungus *Aspergillus nidulans*. **Molecular Composition and Cellular Dynamics of a Mitotic Checkpoint Complex**

J. V. Shah,[1] Z. Wang,[2] G. J. P. Kops,[3] I. McLeod,[4] J. R. Yates,[4] M. W. Berns,[5] D. W. Cleveland[6]; [1]Systems Biology, Harvard University, Boston, MA, [2]Developmental Biology, University of California at Irvine, Irvine, CA, [3]Experimental Oncology, UMC Utrecht, Utrecht, The Netherlands, [4]Scripps Research Institute, La Jolla, CA, [5]Beckman Laser Institute, University of California at Irvine, Irvine, CA, [6]Ludwig Institute for Cancer Research, University of California at San Diego, La Jolla, CA

The mitotic checkpoint guards against chromosome loss by delaying anaphase onset until each and every chromosome is bioriented on the mitotic spindle. This pathway acts through the production of an inhibitory signal from unattached kinetochores that blocks the ubiquitin ligase activity of the anaphase-promoting complex (APC/C). The action of this inhibitory signal is thought to either sequester a mitotic APC/C regulator, Cdc20, to prevent APC/C activity or modulate the APC/C in the context of Cdc20 to prevent its activity against anaphase substrates. Here we demonstrate that within the cytoplasm of mitotic cells with unattached chromosomes Mad2, a central checkpoint protein, forms a robust complex with the APC/C that includes Cdc20 and other checkpoint proteins as detected by mass spectrometry. In vivo measurements of the Mad2-APC/C complex made in living cells, using fluorescence correlation spectroscopy, demonstrate that this complex is silenced by the dissolution of this inhibitory complex below a threshold concentration that permits the transition to anaphase. In addition, this complex is present in interphase, potentially acting as a pre-made anaphase inhibitor upon entry into mitosis. The combined proteomic and live cell spectroscopy approach reveals both composition and temporal kinetics and will prove to be a useful methodology for systematic dissection of signaling pathways.

**A Conditional Mutation of mMps1 Is Embryonic Lethal and Induces Tumors in T Cells**

S. Z. Xie, P. K. Sorger; Biology, Massachusetts Institute of Technology, Cambridge, MA

The mitotic spindle checkpoint ensures accurate chromosome segregation by delaying anaphase onset until all kinetochores have achieved bipolar attachment to the spindle apparatus. Mps1 is a conserved serine/threonine protein kinase essential for proper chromosome segregation. Abrogation of the mammalian mitotic checkpoint through RNAi depletion of hMps1 causes various mitotic errors including chromosomal instability (CIN). A strong correlation between cancer and CIN has made the mitotic checkpoint proteins attractive candidates as tumor suppressors. Few such spindle checkpoint mutations have been found in human cancers, however, and it is possible that complete loss of checkpoint function might result in mitotic lesions that are too severe for tumor development. To determine if the generation of partial-loss of function mutations in checkpoint proteins might result in CIN and cancer in mice, a conditional FLOX (flanked by LoxP) allele of Mps1 was constructed. This allele, Mps1Δ1, removes a highly conserved Mps1 domain that retains proper kinetochore localization but that is lethal by embryonic day 10.5. Since the immune system is both highly proliferative and non-essential, Mps1Δ1-FLOX mice were crossed to a transgenic line expressing a T-cell specific Lck-Cre gene We find that mice carrying a homozygous Mps1Δ1 allele in their T cells have higher than normal number of lymphomas. Intriguingly, 100% of mice combining a hetereozygous deletion of p53 with Mps1Δ1/Mps1Δ1 develop thymomas within 3.5 months. Cell lines derived from these

primary tumors are highly aneuploid but still arrest in mitotis following treatment with the microtubule destabilizing drug nocodazole. We conclude that partial loss of Mps1 creates a CIN phenotype that is greatly exacerbated by p53 haplo-insufficiency and strengthens our recent finding that complete loss of p53 can suppress the lethality associated with deletion of the Mad2 gene in murine fibroblasts.

**Investigating the Spindle Checkpoint in Early *C elegans* Embryos**

A. Essex,[1] A. Dammermann,[2] J. Monen,[1] K. Oegema,[1] A. Desai[1]; [1]Biomedical Sciences, University of California, San Diego/Ludwig Institute for Cancer Research, San Diego, CA, [2]Ludwig Institute for Cancer Research, San Diego, CA

The spindle checkpoint delays anaphase onset until all chromosomes are properly attached to the spindle. Previous studies have shown that BUB-1 is essential for checkpoint activation and have also identified checkpoint-independent functions for this conserved kinase. We are utilizing the early C. elegans embryo to investigate BUB-1 function and to analyze the relationship between kinetochore structure and checkpoint activation. Depletion of BUB-1, but not other checkpoint pathway proteins, results in premature separation of spindle poles in the first embryonic mitosis, indicative of an inability to form kinetochore-microtubule attachments capable of resisting forces pulling on the spindle poles. However, spindle poles move back towards the metaphase plate just prior to anaphase onset, suggesting that this defect is temporal rather than absolute. Anaphase bridges are frequently observed for oocyte-derived chromosomes (which underwent meiosis in BUB-1-depleted cytoplasm), suggesting a role for BUB-1 in meiotic segregation. Consistent with this idea, BUB-1 localizes to the axis of cohesion loss during both meiotic divisions, in addition to co-localizing with outer kinetochore proteins on the chromosome surface. To develop a robust functional assay for checkpoint activation in C. elegans, we have exploited the consequences of depleting ZYG-1, a kinase required for centrosome duplication. Following ZYG-1 depletion, the first mitotic division is normal, but monopolar spindles form in both daughter cells in the second division. The presence of monopolar spindles results in a striking delay in the metaphase-anaphase transition, assessed using chromosome decondensation and onset of cortical contractility in live imaging data. Double depletion of ZYG-1, and Mad1/Mad2 does not affect first division timing but abolishes the delay observed in the second division. We are using this assay to analyze the role of BUB-1, other checkpoint pathway proteins, and conserved outer kinetochore components in checkpoint activation.

2303

**An Enhancer of Myosin Speeds Up Anaphase Chromosome Movements**

L. Fabian, J. Troscianczuk, A. Forer; Biology Department, York University, Toronto, ON, Canada

Inhibitors of actin/myosin block anaphase movements in insect spermatocytes (Forer & Pickett-Heaps 1998, Chromosome Research 6: 533-549; Fabian & Forer *in press*, Protoplasma). We studied the effects of CalyculinA (CalA), which e*nhance*s myosin function: by blocking dephosphorylation by myosin light chain phosphatase (MLCP), CalA causes myosin to stay activated. When CalA is added to anaphase crane-fly spermatocytes the chromosomes speed up (5 times faster); they don't form new nuclei in late anaphase/telophase but they move back toward the equator. When CalA is added during metaphase, chromosomes move faster during anaphase, the same as in anaphase treated cells. When CalA is added during prometaphase, chromosomes move fast up and back in the spindle, jiggle and rotate. In order to confirm that CalA action is on myosin, we treated cells with Y-27632 (a Rho-K inhibitor) and CalA, or with BDM (an inhibitor of myosin motor activity) and CalA. Y-27632 ordinarily slows anaphase movements (Fabian & Forer, *in press*, Protoplasma). We treated anaphase cells with CalA, and then we added Y-27632 (in CalA): the chromosomes still sped up. Y-27632 added before CalA caused chromosomes to slow, as expected, but when CalA (in Y-27632) was added to the same cells, the previously slowed chromosomes sped up, reaching initial speeds or higher. Telophase chromosomes also moved backwards. BDM added to CalA-treated cells, after the chromosomes sped up, caused the chromosomes to slow or to stop. All these results are consistent with the effects of CalA being on myosin dephosphorylation. Immunofluorescence studies show that CalA affects the distribution and organization of spindle microtubules, spindle actin, cortical actin and putative spindle matrix proteins skeletor and titin. Our results suggest an important role for myosin during anaphase.

**Computational Model of Chromosome Motility in *Drosophila* Embryos**

G. Civelekoglu-Scholey,[1] D. J. Sharp,[2] A. Mogilner,[1] J. M. Scholey[1]; [1]Center for Genetics and Development, University of California, Davis, Davis, CA, [2]Department of Physiology and Biophysics, Albert Einstein College of Medicine, Bronx, NY

Chromosome motility during metaphase and anaphaseA is coupled to kinetochore microtubule (kMT) dynamics but the precise mechanism of this coupling is poorly understood. For example, kMTs undergo dynamic instability at their kinetochore bound plus ends but at the same time display persistent poleward flux, driven in part by kinesin-13-dependent depolymerization at their minus ends. In the Drosophila embryo, spindle microtubules (MT) turn over at a remarkably rapid rate giving rise to a FRAP half-time of ~5 sec as they rapidly flux polewards at ~ 0.05 μm $sec^{-1}$ (Brust-Mascher et al. 2004). AnaphaseA chromatid-to-pole motility rate is also remarkably fast (~ 0.1 μm $sec^{-1}$) and depends upon a combined flux-pacman mechanism (Rogers et al. 2004). Here we develop a force-balance model of chromosome motility based on the antagonistic and complementary action of polymer ratchets and motor-generated forces that are thought to operate at kinetochores and spindle poles in *Drosophila* embryo, coupled to kMT plus end dynamics regulated through forces and MT-based motors (Rogers et al. 2004, Sharp et al. 1999, Yucel et al. 2000, Rogers et al. 2001). The model shows that (i) both the metaphase positioning and rapid anaphaseA chromosome motility can be described in a unified framework, based on the action of motor proteins coupled to MT dynamics; (ii) high dynein activity at the kinetochore is required to ensure sustained metaphase kinetochore-MT attachment if the flux rate and MT dynamics are high as in *Drosophila*; (iii) high dynein activity at the kinetochore also results in rapid anaphaseA rates and dampens the metaphase chromosome oscillations. Finally we address the generality of the proposed *Drosophila* pacman motor (Mennella et al., 2004) and consider the minimal structural and molecular properties of kinetochores and MTs that correlate with chromosome motility events observed in different organisms.

2305

**Condensin is Essential to Prevent Premature Chromosome Decondensation in Anaphase**

P. Vagnarelli, D. F. Hudson, W. Earnshaw; Wellcome Trust Centre for Cell Biology, University of Edinburgh, Edinburgh, United Kingdom

The mechanisms underlying the establishment of mitotic chromosome condensation and its maintenance until the end of mitosis remain two of the classic unanswered questions of cell biology. It has recently been proposed that two protein complexes called condensin I and II are important for this condensation, and are essential for topoisomerase II to separate sister chromatids during anaphase. We have used a gene targeting analysis to determine the essential function of condensin in chicken DT40 cells. Our results differ significantly from those predicted by present models of condensin function. Condensin is not essential for mitotic chromosomes to adopt an orderly higher-order structure, for normal cohesin dynamics or for sister chromatid separation during anaphase. Neither is it essential for topo II function at centromeres or on the chromosome arms. Instead, condensin is essential for vertebrate chromosomes to remain condensed throughout anaphase. In condensin-depleted cells chromatids abruptly decondense while still moving during anaphase B. However, chromatids can remain condensed and segregate normally provided that CDK levels are kept high during mitotic exit. Our results identify a new activity, RCA (regulator of condensation in anaphase), that cooperates with condensin to maintain mitotic chromosome condensation in anaphase.

2306

**Mps3p, a Nuclear Membrane SUN-Domain Protein, Mediates Telomere Repositioning to Form the Meiotic Bouquet**

C. Y. Lee, M. N. Conrad, J. L. Wilkerson, M. E. Dresser; Molecular, Cell and Developmental Biology, Oklahoma Medical Research Foundation, Oklahoma City, OK

The meiotic chromosome bouquet forms when telomeres associate with the nuclear envelope and cluster adjacent to the centrosome. The bouquet is well-conserved, indicating an important role in meiosis, but the molecular mechanisms involved are poorly understood. In *Saccharomyces cerevisiae*, bouquet formation requires the meiosis-specific telomere-binding protein Ndj1p. Ndj1p interacts in two-hybrid assays with Mps3p, an essential nuclear envelope protein and component of the spindle pole body (the centrosome-equivalent). We have identified and deleted an Ndj1p interaction domain of Mps3p (amino acids 2-64). *Mps3*$^{\Delta 2\text{-}64}$ mutants are fully viable but defective in bouquet formation. Furthermore, *ndj1Δ*, *mps3*$^{\Delta 2\text{-}64}$ and the *ndj1Δ mps3*$^{\Delta 2\text{-}64}$ double mutant all have similarly delayed chromosome pairing and elevated chromosome nondisjunction. These results identify *MPS3* as the second gene in the *NDJ1* pathway of bouquet formation and establish a specific, direct interaction between telomeres and the spindle pole. During meiotic prophase, Mps3p localizes to the spindle pole body but also accumulates and colocalizes with clumps of telomeres along the nuclear envelope. This colocalization is dependent on Ndj1p, arguing that Ndj1p connects or stabilizes the interaction between telomeres and Mps3p. As a member of the SUN family of proteins implicated in nucleus-cytoskeleton interactions, Mps3p may link telomeres to cytoplasmic structures that provide poleward forces during bouquet formation. Htz1p, a histone-like chromatin protein, also interacts with Mps3p in two-hybrid assays. We find that *htz1Δ* has no delay in homologous chromosome pairing but nevertheless has elevated nondisjunction. Early evidence suggests that *htz1Δ* is defective in bouquet formation, suggesting that timely homologous chromosome pairing may not require formation of a stable bouquet.

2307

**The Human Ubiquitin Conjugating Enzyme, UBE2E3, is Required for the Completion of Cytokinesis**

K. M. Ross,[1] K. S. Plafker,[1] A. L. Oldham,[1] G. J. Gorbsky,[2] S. M. Plafker[1]; [1]Cell Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK, [2]Molecular, Cell, and Developmental Biology, Oklahoma Medical Research Foundation, Oklahoma City, OK

Cell cycle progression is governed by the coordinated activities of protein kinases and the ubiquitin proteolytic system. This interplay of phosphorylation and ubiquitylation drives unidirectional movement through and between each cell cycle stage and is essential for maintaining genomic stability. Experiments in yeast as well as reconstitution studies using oocyte and mammalian somatic cell extracts have identified several key ubiquitin enzymes that control cell division. However, considerably less in vivo evidence has been generated in mammalian cells to determine if other ubiquitin enzymes might also be involved. Here we report on our studies of the human ubiquitin conjugating enzyme, UBE2E3. We have found by RT-PCR and western blot analyses that this evolutionarily conserved enzyme is expressed in a variety of organs including brain, liver, lung, and kidney and that the levels of UBE2E3 appear to be constant throughout the cell cycle. We have used RNA interference in HeLa cells to investigate the function of the enzyme and demonstrated that depletion of UBE2E3 results in multi-nucleated cells, pleomorphic nuclei, decreased cell proliferation, changes in cell shape, and cell death. Time-lapse video microscopy revealed that loss of UBE2E3 leads to a failure of cells to resolve the cytokinetic midbody. The multi-nucleated cells result from retraction of the midbody and fusion of the daughter cells following the failure of midbody abscission. Together, these data demonstrate that UBE2E3 is expressed in numerous tissues and functions to maintain genomic stability at least in part by promoting abscission of the midbody during the terminal stage of cytokinesis.

**Phospholipase D-Generated Phosphatidic Acid and GGAs in *Saccharomyces cerevisiae* Sporulation**

R. Mendonsa,[1] J. Engebrecht[2]; [1]Cell and Developmental Biology Graduate Group, Section of Molecular and Cellular Biology, University of California, Davis, Davis, CA, [2]Section of Molecular and Cellular Biology, University of California, Davis, Davis, CA

Gametogenesis is an essential, conserved process in all organisms that reproduce sexually. In budding yeast sporulation, meiosis must be tightly coupled to spore morphogenesis to ensure the production of viable gametes. Spindle pole bodies associated with meiotically dividing nuclei form thickened plaques next to the nuclear surfaces and serve as fusion sites of Golgi-derived vesicles, leading to the formation of the spore plasma membrane precursor, the prospore membrane. The forming prospore membrane remains closely associated with nuclei while additional spore wall materials are deposited in successive layers, and eventually the nuclei are completely enclosed as individual spores within the original plasma membrane. The activity of yeast phospholipase D, or *SPO14*, has been shown to be essential for prospore membrane formation. Spo14p catalyzes the cleavage of phosphatidylcholine into phosphatidic acid (PA) and choline. PA is thought to be involved in membrane trafficking events, although the mechanism of its action in spore morphogenesis is unknown. Using an *in vitro* proteomics approach to find downstream effectors of Spo14p-generated PA, we recently identified an interaction between PA and both Gga1p and Gga2p, which are multi-domain proteins involved in ubiquitinated protein trafficking from the trans-Golgi network. We constructed isogenic *gga* deletion strains and observed reduced sporulation in the double *gga* mutant compared to wild-type. We also tested double *gga* mutant spores for ether sensitivity, as vegetative cells and aberrant spores are ether-sensitive while wild-type spores are ether-insensitive, and the double *gga* mutant was shown to be sensitive to ether exposure. These observations suggest that GGAs may be downstream effectors of Spo14p-generated PA and are involved in the production of viable spores.

**Homology-Independent Centromere Coupling and Initiation of Synaptonemal Complex Formation during Meiosis in Budding Yeast**

T. Tsubouchi, S. Roeder; Yale University, New Haven, CT

Segregation of chromosomes at the reductional division of meiosis depends on a series of interactions between homologous chromosomes, including pairing, assembly of the synaptonemal complex (SC) and genetic recombination. These events ultimately lead to the formation of chromatin bridges between homologs that ensure their segregation to opposite poles at the first meiotic division. Through cytological studies, we have discovered a process in meiotic cells of budding yeast, in which chromosomes become joined together in pairs at their centromeres via an SC protein (Zip1). In a mutant defective in the initiation of meiotic recombination, all centromeres are coupled, but almost all couples involve nonhomologous chromosomes. During meiosis in wild-type diploids, centromere couples are initially nonhomologous and then undergo switching until all couples involve homologs. We have also discovered that regions of SC assembled early in meiosis are often centromere associated. SC assembly requires the so-called the synapsis initiation complex (SIC). Our data from immunolocalization studies suggest that the SC often forms unidirectionally, with the SIC at the leading edge of the polymerizing Zip1. We found that Zip3, a component of the SIC, localizes to centromeres at an early stage of prophase in a partially Zip1-dependent manner, prior to the loading of two other SIC components (Zip2 and Zip4). Thus, loading of the SICs at centromeres is preceded by and is at least partially dependent on Zip1 loading. We propose that Zip1-dependent centromere coupling facilitates homolog pairing and ensures synapsis initiation on every pair of chromosomes.

2310

**Mer2 Forms a Complex with Rec114 and Mei4 to Form Meiotic Double-strand Breaks**

J. Li,[1] G. W. Hooker,[1] S. Roeder[2,3]; [1]Molecular, Cellular & Developmental Biology, Yale University, New Haven, CT, [2]Molecular, Cellular & Developmental Biology, Department of Genetics, Yale University, New Haven, CT, [3]Howard Hughes Medical Institute, New Haven, CT

In budding yeast, at least ten proteins are absolutely required for the formation of meiotic double-strand breaks (DSBs). A combination of cytological studies and biochemical analysis was used to investigate the functions of these proteins, with particular emphasis on Mer2. Mer2 protein localizes to meiotic chromosomes, forming distinct foci from zygotene to pachytene, with foci maximally abundant in zygotene. Localization of Mer2 is independent of DSBs and the other proteins required for DSB formation. Mer2 is phosphorylated specifically in meiosis and this modification is independent of a number of known kinases (Mek1, Mec1 and Tel1) and occurs in the absence of DSB formation. Mer2 associates with itself, as demonstrated by the yeast two-hybrid system and biochemical experiments. Previous work in the field has shown that there are two separate complexes involved in DSB formation: Spo11/Rec102/Rec104 and Mre11/Rad50/Xrs2. Here we show that Mer2 forms a complex with Mei4 and Rec114. First, cytological experiments show that Mei4, Rec114 and Mer2 partially colocalize with one another. Second, Mei4 and Rec114 interact in the yeast two-hybrid system. Lastly Mer2, Mei4 and Rec114 coimmunoprecipitate with one another from meiotic cell extracts. The Mer2/Mei4/Rec114 complex is independent of the other two complexes. Mer2 does not colocalize with Mre11, Spo11 or Rec102 and Mer2 does not coimmunoprecipitate with Rec102. We propose that Mer2, Rec114 and Mei4 form an independent complex that is involved in DSB formation.

**Meiotic Cohesin Modulates Chromosome Compaction During Meiotic Prophase**

D. Ding, Y. Hiraoka; Kansai Advanced Research Center, Kobe, Japan

During the mitotic cell cycle the regulated cohesion and segregation of sister chromatids is achieved by the mitotic cohesin complex, and upon entering meiosis, this mitotic cohesin complex is replaced by the meiotic cohesin complex which choreographs the meiosis-specific chromosomal events. The meiotic cohesin, Rec8, is required for sister chromatid cohesion and homologous recombination. By directly measuring chromosome compaction in living cells of the fission yeast Schizosaccharomyces pombe, we found an additional role for cohesin in the compaction of chromosomes during meiotic prophase. In the absence of Rec8, chromosomes were loosened 2 fold when compared with wild-type cells, while the loss of the cohesin-associated protein, Pds5, resulted in Rec8-dependent over-compaction. Both homologous pairing and recombination were defective in the absence of either Rec8 or Pds5. Pds5 also demonstrated a role in maintaining sister chromatid cohesion and in reductional chromosome segregation. In the absence of Pds5, the Rec8 binding on chromosome was decreased, indicating that Pds5 modulate the association of Rec8 with meiotic chromosomes. Thus, the cohesins mediate fundamental changes in global chromatin structure that promote correct meiotic progression.

2312

**Novel Protein Components Bqt1 and Bqt2 Regulate the Transition Between Mitotic and Meiotic Organization of Chromosomes**

Y. Chikashige, Y. Hiraoka; Kansai Advanced Research Center, Kobe, Japan

In many organisms, meiotic chromosomes are bundled at the telomere to form a ‘bouquet’ arrangement. The most striking example of such chromosome reorganization is observed in the fission yeast S. pombe. In this organism, centromeres are clustered at the spindle-pole body (SPB) during the mitotic cell cycle, and telomeres form a cluster at the SPB during meiotic prophase; this clustering of telomeres is important for progression of meiosis, promoting homologous chromosome pairing and recombination during meiosis. However, direct interactions have not been found between the telomere and the SPB. As meiotic telomere clustering is induced by the mating pheromone response, we selected candidate genes that are expressed specifically under mating pheromone signaling based on gene expression profiles in DNA microarray data. To find telomere-SPB connectors, we disrupted each one of the selected 83 genes in S. pombe. All of these gene-disrupted strains were viable in mitotic growth as expected from meiosis-specific expression of the gene. These strains were microscopically observed for telomere clustering in meiotic prophase. Such a genome-wide search found two novel proteins, Bqt1 and Bqt2 (named for ‘bouquet’ formation), which connect Rap1 (a telomere protein) to Sad1 (an SPB protein) when mating pheromone signaling is induced in meiosis. Neither Bqt1 nor Bqt2 alone functions as a connector, but the two proteins together form a bridge between Rap1 and Sad1. Significantly, when both Bqt1 and Bqt2 are ectopically expressed in mitotic cells, they form a bridge between Rap1 and Sad1. As mitotic centromere-SPB connectors are resolved under mating pheromone signaling in meiosis (Asakawa et al., 2005, Mol. Biol. Cell, 16, 2325-2338), expression of Bqt1 and Bqt2 under mating pheromone signaling regulates the transition between mitotic and meiotic chromosome organization.

2313

**Dissociation of the Nuf2-Ndc80 Complex Releases Centromeres from the Spindle-Pole Body under Mating Pheromone Signaling in Fission Yeast Meiosis**

H. Asakawa,[1] A. Hayashi,[1] T. Haraguchi,[1,2] Y. Hiraoka[1,2]; [1]Cell Biology Group and CREST Research Project, Kansai Advanced Research Center, National Institute of Information and Communications Technology, Kobe, Japan, [2]Graduate School of Science, Osaka University, Toyonaka, Japan

In the fission yeast *Schizosaccharomyces pombe*, centromeres remain clustered at the spindle-pole body (SPB) during mitotic interphase. In contrast, during meiotic prophase centromeres dissociate from the SPB. Nuf2 is a centromere protein known as a component of Ndc80/Hec1 complex in eukaryotes. We previously reported the behavior of centromeres correlates with Nuf2 localization in *S. pombe*: Nuf2 is located at the centromere in the nucleus throughout the mitotic cell cycle, but is not observed during meiotic prophase when the centromeres are separated from the SPB. Here we examine the behavior of centromere proteins in living meiotic cells of *S. pombe*, and show that the *S. pombe* Nuf2-Ndc80 complex proteins (Nuf2, Ndc80, Spc24 and Spc25) always located at the centromere during mitotic cell cycle, while they disappear from the centromere in meiotic prophase. Nuf2 interacts with other centromere protein Mis12, but not with Mis6. The Mis12 dissociates from centromeres during meiotic prophase; however Mis6 remains throughout meiosis, suggesting distinct roles of centromere subcomplexes in meiosis. When cells are induced to meiosis by inactivation of Pat1 kinase (a key negative regulator of meiosis), centromeres remain associated with the SPB during meiotic prophase. However, inactivation of Nuf2 by a temperature-sensitive mutation causes the release of centromeres from the SPB in *pat1* mutant cells, suggesting that the Nuf2-Ndc80 complex connects centromeres to the SPB. We further found that removal of the Nuf2-Ndc80 complex from the centromere and centromere-SPB dissociation are caused by mating pheromone signaling. Since *pat1* mutant cells also show aberrant chromosome segregation in the first meiotic division and this aberration is compensated by mating pheromone signaling, dissociation of the Nuf2-Ndc80 complex may be associated with remodeling of the kinetochore for meiotic chromosome segregation.

2314

**Alleles of AFD1 Unravel Stage-Specific Activities of REC8 during Meiosis**

I. N. Golubovskaya, L. Timofejeva, O. Hamant, W. Cande; MCB, UC Berkeley, Berkeley, CA

Maize has four rad21/rec8 genes. Afd1 (absence of first division 1), closest in homology to rec8, controls leptotene chromosome establishment and sister chromatid cohesion (SCC). In two null alleles (afd1-1, afd1-2) an equational segregation of sisters occurs during M I due to a failure of both arm and centromere SCC. AFD1 protein is recruited early, before the leptotene stage, and localizes to the lateral elements of zygotene and pachytene chromosomes. AFD1 is progressively removed from the chromosomes arms during diplotene/diakinesis and is not detected after metaphase I. In two weak afd1 alleles, afd1-3 and afd1-4, leptotene chromosomes are present, however, no homologous pairing occurs. The formation of synaptic structures depends on the severity of the allele: only short condensed synaptic structures (15/nucleus) are observed in afd1-1 and afd1-2, whereas in afd1-3 and afd1-4, their number is increased by 5-10 fold, and fragments of axial elements are visible. In the weak alleles at anaphase I, segregation of chromosomes is neither equational nor reductional, as the cell contains chromatids and X-shape chromosomes, showing that loss of SCC occurs at later in the weak afd1 alleles. Molecular analysis of the weak alleles showed that a wild-type cDNA is produced but at a lower level than in the wild-type. Our analysis shows that afd1 allelic severity impacts differentially leptotene chromosome establishment, and the extent of synapsis and SCC. This suggests that meiosis requires a stage-specific AFD1 activity and that conversely, the meiocyte carefully monitors the activity of AFD1 during meiosis.

**2-Dimensional Gel Electrophoresis Screen of Global Changes in Protein Expression During Progesterone Induced Maturation of *Xenopus laevis* Oocytes**

L. C. Berger, A. Wilde; Medical Genetics and Microbiology, University of Toronto, Toronto, ON, Canada

The *Xenopus laevis* oocyte is an established model system for investigating mechanisms of meiosis and oocyte maturation. We have used a proteomics approach to identify novel components involved in progesterone induced meiotic maturation in this system. Lysates from stage VI oocytes and mature eggs were labeled with CyDye DIGE Fluor minimal dyes and analyzed with 2-dimensional gel electrophoresis. A total of 51 proteins exhibiting statistically significant ($p<0.05$) changes were detected. Changes resulted from either altered level of expression or post-translational modification. Maximal change in expression was approximately 12 fold with the majority of proteins exhibiting decreased expression following maturation. Using matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry we have to date identified a subset of these proteins. In this group are proteins known to play regualtory roles in the maturation process including elongation factor 1 gamma, a substrate of Cdc2 kinase. Subsequent to the identification of additional proteins we intend to select proteins of interest for further functional analysis. This will include microinjection of recombinant proteins, mRNA, antisense morpholinos and antibodies as well as experiments with specific inhibitors. During the course of this work we have also identified a change in the metabolism of the yolk storage proteins during oocyte maturation. Subsequent to germinal vesicle breakdown, the storage and metabolism of yolk proteins was found to be altered. The changes in yolk proteins during oocyte maturation are currently being investigated using techniques to measure changes in the pH of yolk storage platelets, electron microscopic examination of platelets, and immunofluorescence. We are attempting to integrate changes in vitellogenin metabolism within the framework of changes in signal transduction, metabolic, and cell division proteins identified through the proteomics analysis.

**A Model for Bi-stability, Collapse, and Maintenance of Meiotic Spindles**

K. S. Burbank,[1] D. E. Fisher,[1] T. J. Mitchison[2]; [1]Physics, Harvard University, Cambridge, MA, [2]Systems Biology, Harvard Medical School, Boston, MA

We develop a simple model of the meiotic spindle with several novel components, analyze the model mathematically and with simulations, then test novel predictions with experiments. The components of our model are nucleation and sorting of microtubules near the chromosomes, microtubule sliding and bundling due to molecular motors, and loss of microtubules due to dynamic instability. Mathematical analysis shows that these components are capable of robustly forming a steady-state spindle of constant length. Our model recapitulates three important experimental results: When anti-parallel sliding is decreased, simulating Eg5 inhibition with monastrol, the system becomes bi-stable, with short "collapsed" and

long "bi-polar" solutions. When microtubule end bundling is sufficiently decreased, mimicking dynein inhibition, the spindle lengthens at the flux rate. Finally, when both bundling and anti-parallel sliding are inhibited in the model, the tendency towards collapse is lost. We test the model's prediction and experimentally find a previously unobserved dependence of spindle length on the speed of anti-parallel sliding, in good agreement with the model predictions.

### The Drosophila lkb1 Gene is Required for Proper Centrosome Behavior

S. Bonaccorsi,[1] M. Giansanti,[1] B. Bolkam,[2] B. Williams,[2] V. Mottier,[1] M. L. Goldberg,[2] M. Gatti[1]; [1]Genetics and Molecular Biology, Università di Roma, Rome, Italy, [2]Molecular Biology and Genetics, Cornell University, Ithaca, NY

We have isolated lethal mutations in the lkb1 gene, the Drosophila homologue of C. elegans par-4 and human LKB1 mutated in Peutz-Jeghers syndrome. Flies homozygous for lkb1 lethal mutations die at the larval/pupal boundary, allowing cytological analysis of cell division in both mitotic and meiotic tissues. The spindles of lkb1 mutant neuroblasts display small asters and a low microtubule (MT) density, which do not appear to be due to a reduced MT nucleation ability of the centrosomes. As a result of the reduced stability of spindle MTs, lkb1 mutant brains also exhibit a metaphase-arrest phenotype and frequent polyploid cells. In addition, lkb1 mutations disrupt some of the asymmetries that characterize neuroblast divisions, including the different size of the centrosomes during ana-telophase and the positioning of the cleavage furrow. In contrast to mitotic spindles, meiotic spindles of lkb1 mutant males do not exhibit a reduction in microtubule density and/or stability. However, lkb1 spermatocytes are clearly defective in centrosome migration to the opposite cell poles. This is particularly evident in the second meiotic divisions, which often exhibit peculiar bipolar, monastral spindles with two centrosomes at the same pole. Collectively, these results indicate that Drosophila Lkb1 is required for different aspects of mitotic and meiotic cell division, suggesting that this kinase acts on multiple substrates required for proper spindle assembly and centrosome behaviour.

### An RNAi Screen to Identify Genes Required for Meiotic Spindle Formation in *C elegans*

S. M. Wignall, A. Villeneuve; Developmental Biology, Stanford University, Stanford, CA

During cell division in most cell types, duplicated centrosomes nucleate microtubules and ultimately form the poles of the spindle. However, oocytes of many species lack centrosomes and therefore spindle assembly occurs through a different pathway. Our goal is to investigate centrosome-independent spindle formation by identifying proteins that promote spindle assembly and chromosome segregation in *C. elegans* oocyte meiosis. To this end, we have performed a targeted RNAi screen of genes that were previously classified as embryonic lethal in genome-wide screens. This class includes genes known to be required for acentriolar meiotic spindle assembly, such as mei-1 and mei-2 (regulators of microtubule stability) and klp-18 (a kinesin-like protein required for spindle morphogenesis). We visually screened the approximately 800 genes in this class for defects in spindle formation and/or chromosome alignment using worms co-expressing GFP::histone and GFP::tubulin to visualize chromosomes and microtubules simultaneously. As expected, we observed dramatic defects in meiotic spindle morphology following RNAi of mei-1, mei-2 and klp-18. In addition, we have identified a number of other genes whose inhibition alters the appearance of meiotic spindles. These include proteins uncharacterized in meiosis but known to play roles in mitosis, such as CLS-2 (a homolog of the microtubule-associated protein (MAP) CLASP), and the dynein-associated proteins NUD-1 and LIS-1. In addition, we have identified a number of genes uncharacterized in worms. Some of these have putative homologs in other organisms. For example, one is highly homologous to centractin, a component of the dynactin complex, and another shares homology with ASP, a *Drosophila* MAP. Finally, we identified one gene with no obvious homologs in other organisms. Future characterization of the genes identified in our screen may help us better understand the mechanisms involved in centrosome-independent spindle assembly.

2319

### Meiotic Segregation of Holocentric C elegans Chromosomes is Independent of the Centromeric Histone Variant CENP-A

J. W. Monen, P. Maddox, F. Hyndman, K. Oegema, A. Desai; Cellular and Molecular Medicine, Ludwig Institute for Cancer Research/UCSD, La Jolla, CA

Two distinct chromosome architectures are prevalent among eukaryotes: monocentric, in which localized centromeres restrict kinetochore assembly to a single chromosomal site, and holocentric, in which diffuse kinetochores form along the entire chromosome length. During mitosis, both chromosome types use specialized chromatin, containing the histone H3 variant CENP-A, to direct kinetochore assembly. For the segregation of recombined homologous chromosomes during meiosis, monocentricity is thought to be critical to limit spindle-based forces to one side of a crossover and prevent recombined chromatids from being simultaneously pulled towards both spindle poles. The mechanisms that allow holocentric chromosomes to avert this fate remain uncharacterized and are the subject of our investigation. We have found a dramatic difference in the mechanisms that segregate holocentric chromosomes during meiosis and mitosis in the nematode *Caenorhabditis elegans*. In late diakinesis, immediately prior to oocyte meiotic segregation, outer kinetochore proteins are recruited to cup-like structures on the chromosome surface via a mechanism independent of CENP-A. Formation of these structures occurs coincident with oocyte nuclear envelope breakdown; prior to this event localization of outer kinetochore proteins on chromosomes is CENP-A dependent. In striking contrast to mitosis, both oocyte meiotic divisions proceed normally following depletion of either CENP-A or the closely associated centromeric protein CENP-C. These findings highlight a dramatic difference between the segregation of holocentric chromosomes during meiosis and mitosis and demonstrate the potential to uncouple assembly of outer kinetochore proteins from CENP-A chromatin.

### Maintenance of Chromatin Organization Between Meiotic Divisions in Surf Clam Oocytes

O. L. George, M. Johnston, C. B. Shuster; Biology, New Mexico State University, Las Cruces, NM

Meiotic divisions represent specialized cell cycles where cells undergo two reductive divisions without an intervening S phase. During oogenesis, the germinal vesicle breaks down, and following spindle assembly and migration to the cell cortex, the oocyte procedes into anaphase I and extrudes the first polar body. Between meiosis I and meiosis II, the paired sister chromatids remain condensed in contrast to mitotic divisions

where cytokinesis is always accompanied by chromatin decondensation and nuclear envelope reformation. Because other aspects of M phase exit are normal, we sought to dissect the mechanisms that drive cytokinesis while retaining chromatin condensation in Spisula solidissma oocytes. Oocytes were arrested in interkinesis following MI with the protein synthesis inhibitor emetine, and both histone H3 phosphorylation and spindle pole duplication occurred normally in comparison to controls. Neither inhibition of CDK1- nor MAPK activity in arrested oocytes was sufficient to drive chromatin decondensation or nuclear envelope reformation, suggesting that these kinases were not responsible for the maintenance of chromatin condensation. However, inhibition of Aurora B kinase activity resulted in chromatin decondensation, loss of histone H3 phosphorylation and reformation of the nuclear envelope. Inhibition of Aurora B activity during MI resulted in both a failure to extrude polar bodies and loss of histone H3 phosphorylation, two previously reported Aurora B-dependent processes. Together, these results suggest that extended Aurora B activity between meiotic divisions maintains chromatin condensation, thus allowing for the rapid reassembly of the MII spindle and progression through meiosis. Sponsored by U56CA096288.

2321

### Spindle Dynamics, Chromosome Elimination, and Non-disjunction in *Sciara* Male Meiosis

B. de Saint Phalle,[1,2] J. R. LaFountain,[3] R. Oldenbourg,[1] S. Inoue,[1] S. A. Gerbi[2]; [1]ADLC, MBL, Woods Hole, MA, [2]Biomed. Division, Brown University, Providence, RI, [3]Biological Sciences, University at Buffalo, Buffalo, NY

Spindle dynamics and chromosome segregation are unique in the fly, *Sciara*. Our studies utilize polarization microscopy for time lapse imaging of living *Sciara* spermatocytes. The new LC-PolScope is an orientation-independent liquid crystal polarizing microscope that allows quantitative examination of *Sciara* meiosis. A centrifuge polarizing microscope can isolate the meiosis I monopolar spindle. Immunostaining localizes regulatory proteins and motor proteins involved in spindle construction and chromosome motion. In spermatogenesis, the meiosis I spindle is monopolar. Chromosomes move from prophase to anaphase without congressing to a metaphase plate. The chromosomes are imprinted: maternally derived chromosomes and germ line limited chromosomes migrate to the single pole; paternally derived chromosomes move away from the single pole and are expelled in a bud. In meiosis II, a bipolar spindle forms, but it has a centrosome at only one pole. The chromosomes divide normally except for the X dyad, which remains at the pole with the centrosome. The nullo-X product of meiosis II is discarded in a bud. The metaphase checkpoint may not operate in meiosis I and may not apply to the X-dyad in meiosis II. The zygote has 3 X's. Chromosome elimination in an early cleavage division removes one or two paternally derived X's to determine the sex of the embryo. Translocations reveal that the cell recognizes the X dyad in meiosis II and in embryonic cleavages by a control element (CE) that is embedded within the tandem rDNA repeats which only functions in *cis*. In the embryonic cleavage division where X elimination occurs, the CE maintains cohesion of the chromosome arms in anaphase, while allowing separation of the X centromere on the sister chromatids. As a result, the X chromosomes remain on the metaphase plate and are eliminated.

## Cytokinesis II (2322-2339)

### The Nocut Pathway links Abscission to Proper Function of the Spindle Midzone and Prevents Chromosome Breakage by the Cytokinetic Machinery

C. Norden, M. Mendoza, Y. Barral; Institute of Biochemistry, ETH-Zurich, Zurich, Switzerland

Tight coordinated of cytokinesis with chromosome segregation ensures that during cell division each daughter cell receives a full set of chromosomes. In yeast, the onset of actomyosin ring contraction and furrowing depends on activation of mitotic exit network and cyclin-kinase inactivation. Subsequently, abscission resolves the plasma membrane into two independent membranes. We know little about how this last and only irreversible step is controlled. Here, we show that a signalling pathway, which we call NoCut, represses abscission in cells with spindle midzone defects. Cells lacking a functional spindle midzone, such as *ase1*Δ and *ndc10-1* cells and mad2 cells treated with nocodazole, undergo proper actomyosin ring assembly and contraction but fail abscission. This defect depends neither on the lack of kinetochore-microtubule attachment nor on defects of cytoplasmic microtubules. Inactivation of aurora/Ipl1 and the suppressing the midzone assembly defects, indicating that the spindle midzone is not intrinsically required for cytokinesis. Epistasis analyses indicate that Ipl1 and anillins function in a signalling pathway, which we call NoCut, transducing an inhibitory signal from the spindle to the site of abscission. Ipl1 acted upstream of anillins and controlled their translocation from the nucleus to the bud neck in response to spindle defects. Inactivation of NoCut led to premature abscission and breakage of the chromosomes still engaged in the cleavage plane. NoCut inactivation was also lethal in cells with a fragile midzone. We propose that NoCut monitors spindle elongation and chromosome separation to prevent that cytokinesis is completed before the cleavage plane is cleared from chromatin.

2323

### Contractile Ring-Independent Localization of DdINCENP, a Protein Important for Spindle Stability and Cytokinesis

Q. Chen, A. De Lozanne; Institute of Cellular and Molecular Biology, and Department of MCDB, The University of Texas at Austin, Austin, TX

Chromosomal-passenger proteins display a very dynamic distribution during mitosis and cytokinesis and play important roles in cell division. Currently it is not know how chromosomal-passenger proteins localize at the cleavage furrow and what is their precise role in cytokinesis. To explore this question we analyzed the function of the *Dictyostelium* DdINCENP protein. Disruption of the single DdINCENP gene revealed important roles for this protein in mitosis and cytokinesis. DdINCENP null cells lack a robust spindle midzone and are hypersensitive to microtubule depolymerizing drugs suggesting that their spindles are unstable. Furthermore DdCP224, a protein homologous to the microtubule-stabilizing protein TOGp/XMAP215, was absent from the spindle midzone of DdINCENP null cells. Overexpression of DdCP224 rescued the weak spindle midzone defect of DdINCENP null cells. This suggests that DdCP224 is a possible downstream effector of the chromosome-passenger protein complex to stabilize the spindle midzone. In addition, we show that the localization of DdINCENP at the cleavage furrow is not dependent on the contractile ring but is modulated by myosin II. DdINCENP is normally found on the entire cortex region of the cleavage furrow during cytokinesis. In the absence of myosin II, DdINCENP is still localized at the cleavage furrow, but it forms a very narrow band at the equatorial plane of the dividing cell. Finally, analysis of cytokinesis in multinucleate cells demonstrated that while the contractile ring is assembled

at both normal equatorial and ectopic "Rappaport" furrows, DdINCENP only localized at the equatorial furrows. This suggests that the translocation of DdINCENP to the cleavage furrow at the end of mitosis occurs by a mechanism different from that controlling the formation of the contractile ring.

2324

**Regulation of Endosomal Membrane Trafficking is Required During Cytokinesis**

J. K. Schweitzer,[1] E. Burke,[1] H. Goodson,[2] C. D'Souza-Schorey[1]; [1]Biological Sciences, University of Notre Dame, Notre Dame, IN, [2]Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN

Membrane rearrangements are a vital part of cytokinesis. For example, proteins that mediate events such as membrane fusion and exocytosis have been shown to be essential for the successful completion of cytokinesis. In addition, our previous work has shown that ARF6, a key regulator of endosomal trafficking during interphase, is required for cytokinesis. Here we have examined endosomal trafficking during cytokinesis and assessed its importance for the successful completion of cytokinesis. Our results, using both live- and fixed-cell imaging, show that although membrane traffic is inhibited during the early stages of mitosis, endocytosis occurs during cleavage furrow ingression and cytokinesis in a regulated manner. During anaphase and early telophase, endocytic markers are internalized from the plasma membrane near the spindle poles, or polar regions, of dividing cells. However, during late telophase and cytokinesis, markers are actively endocytosed from the plasma membrane at the ingressed cleavage furrow, or midbody. Furthermore, we find that ligands endocytosed from the polar region of a dividing cell are trafficked to the midbody region as cytokinesis progresses. To determine whether or not receptor-mediated endocytosis is important for cytokinesis, we have examined mitotic cells transfected with AP180 or dominant negative Eps15 and found that they induce cytokinesis defects such as excessive membrane blebbing at the cleavage furrow and binucleated cell formation. We have also found that caveolae-mediated uptake may impact the completion of cytokinesis since caveolin-1 localizes to the midbody region during the late stages of cytokinesis and cholesterol depletion using cyclodextrin or filipin blocks the completion of cytokinesis. Taken together, our findings indicate that endosomal membrane trafficking is regulated during the late stages of mitosis and that it is important for the successful completion of cytokinesis.

**The Double Life of the Substrate-Specific Adaptor MEL-26**

S. Luke-Glaser,[1] L. Pintard,[2] C. Lu,[3] P. E. Mains,[3] M. Peter[1]; [1]Biology, ETH Zurich, Zurich, Switzerland, [2]Samuel Lunenfeld Research Institute, Toronto, ON, Canada, [3]University of Calgary, Calgary, AB, Canada

BACKGROUND: The initiation of a cleavage furrow is essential to separate cells during cytokinesis, but little is known about the mechanisms controlling this actin-driven process. Previous studies in *C. elegans* embryos revealed that inactivation of the CUL3-based E3-ligase activator *rfl-1* results in an aberrant microtubule network, ectopic furrowing during pronuclear migration and defects during cytokinesis. RESULTS: Here we show that MEL-26, a substrate-specific adaptor of the CUL-3-based-E3-ligase, is required for efficient cell separation and cleavage furrow ingression during the *C. elegans* early mitotic divisions. Loss of MEL-26 function leads to delayed onset and slow ingression of cytokinesis furrows that frequently regress. Conversely, increased levels of MEL-26 in *cul-3(RNAi)* and *rfl-1* mutant embryos cause a hypercontractile cortex, with several simultaneously ingressing furrows during pronuclear migration. MEL-26 accumulates at cleavage furrows, and binds the actin-interacting protein POD-1. Importantly, POD-1 is not a substrate of the MEL-26/CUL-3 ligase, but is required to localize MEL-26 to the cortex. CONCLUSION: Our results suggest that MEL-26 not only acts as a substrate-specific adaptor within the MEL-26/CUL-3 complex, but also promotes cytokinesis by a CUL-3- and microtubule-independent mechanism.

**Quantitative Analysis of Furrow Ingression during the First Mitotic Division of the *C elegans* Embryo**

L. K. Lewellyn, A. Audhya, A. Desai, K. Oegema; Cellular and Molecular Medicine, Ludwig Institute for Cancer Research, La Jolla, CA

Cytokinesis partitions the cytoplasm and cell surface of a single cell to form two daughter cells following chromosome segregation in anaphase. During cytokinesis, a region of differentiated cortex called the contractile ring, which is enriched in actin and myosin II forms around cell equator. Constriction of the contractile ring changes the shape of the cell to facilitate cytokinesis. To study furrow ingression, we have developed a quantitative assay based on a *C. elegans* strain expressing a fusion of GFP with a PH domain that binds with high affinity to a phosphoinositide lipid ($PI4,5P_2$) that is specifically generated on the plasma membrane. In this method, z-series of the embryo are collected at 20s intervals and 3D reconstructions of the central region of the embryo allow us to monitor the kinetics of furrow ingression in an "end-on" manner. Using this assay even subtle defects in furrow ingression can be detected. In *C. elegans*, the first embryonic mitosis can be imaged following efficient RNA interference (RNAi)-mediated depletion of specific target proteins (under stringent conditions proteins are typically >95% depleted). We are using this capability to compare furrow ingression in control embryos to that in embryos depleted of essential proteins that have been implicated in cytokinesis.

**PtdIns(4,5)P2 Functions at the Cleavage Furrow During Cytokinesis**

S. J. Field,[1,2] N. Madson,[2] M. L. Kerr,[2] K. A. A. Galbraith,[1,2] C. E. Kennedy,[2] M. Tahiliani,[2] A. Wilkins,[2] L. C. Cantley[2]; [1]Medicine, University of California San Diego, La Jolla, CA, [2]Divison of Signal Transduction and Department of Systems Biology, Beth Israel-Deaconess Medical Center and Harvard Medical School, Boston, MA

Phosphoinositides play important roles in the regulation of the cytoskeleton and vesicle trafficking, potentially important processes at the cleavage furrow. However, it remains unclear which, if any, of the phosphoinositides play a role during cytokinesis. Here we report a systematic, unbiased analysis of the role of the phosphoinositides during cytokinesis. We discover that PtdIns(4,5)P2 (but not other phosphoinositides) specifically accumulates at the cleavage furrow in every mammalian cell type examined. An enzyme that generates PtdIns(4,5)P2, PtdIns(4)P-5-kinase-α, similarly localizes to the cleavage furrow. Interference with PtdIns(4,5)P2 disrupts adhesion of the contractile ring to the plasma membrane. Furthermore, four distinct interventions to interfere with PtdIns(4,5)P2 each impair cytokinesis. We conclude that PtdIns(4,5)P2 accumulates at the cleavage furrow and is required for normal cytokinesis. At least one role for PtdIns(4,5)P2 is to function in adhesion of the plasma membrane to the

contractile ring, allowing the contractile ring to carry the plasma membrane inward to bisect the cell.

**Positioning the Cell Division Plane in Fission Yeast: Mid1p, the Nucleus and the Endoplasmic Reticulum**

N. Padte,[1] R. R. Daga,[1] J. Bahler,[2] F. Chang[1]; [1]Microbiology, Columbia University College of Physicians and Surgeons, New York, NY, [2]Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom

In *Schizosaccharomyces pombe*, the position of the pre-mitotic nucleus specifies the cell division plane. Mid1p is a key protein in division site positioning, as *mid1* mutant cells form misplaced contractile rings and septa. Mid1p localizes to the nucleus and to a cortical band of dots overlying the nucleus during interphase. During mitosis, the broad band coalesces with other ring proteins to form the contractile ring. The positioning of the interphase mid1p cortical band is linked to nuclear position. For instance, the mid1p band moves with the nucleus as the nucleus re-centers after cell centrifugation. How mid1p senses the position of the nucleus remains elusive. We hypothesize there exists a physical linkage between the nucleus and the cell cortex which allows mid1p to constantly monitor nuclear position. One candidate for such a linkage is the endoplasmic reticulum (ER). Time-lapse images show that the ER forms dynamic threads between the nuclear envelope and the cell cortex region surrounding the nucleus. An overexpression screen for genes that produce a *mid1*-like phenotype identified a protein implicated in protein sorting and translocation at the ER. We are currently testing the role of the ER and this protein in cytokinesis and division site positioning.

**Induction of Contractile Ring Assembly during Interphase by the Fission Yeast Formin Cdc12p**

A. Yonetani, F. Chang; Microbiology, Columbia University, New York, NY

Successful cytokinesis requires that the assembly and closure of the actomyosin contractile ring are properly regulated during the cell cycle. In *Schizosaccharomyces pombe*, the actin ring assembles in early mitosis and begins to contract in late anaphase. The formin cdc12p is a critical factor in ring assembly, as it nucleates actin filaments within the ring. We are interested in how the cdc12 formin is temporally and spatially controlled. We have found that expression of a truncated cdc12p lacking the C-terminal domain leads to deregulated actin ring assembly in wild type cells. We acquired time lapse movies of ectopic ring formation in cells co-expressing GFP-tubulin as an indicator of cell cycle state. Strikingly, cells expressing truncated cdc12p protein can assemble actin rings during interphase. Some ectopic rings appear to arise from remnants of previous rings, while others form *de novo* in the vicinity of the interphase nucleus. Further, some of these interphase actin rings can contract and even guide septation; while in other cells, rings wait to drive cleavage at the appropriate time in mitosis. Our observations suggest that the misregulation of cdc12p is sufficient to bypass cell cycle controls and to trigger not only F-actin assembly, but the entire process of cytokinesis.

2330

**Counting Cytoskeletal Proteins Molecules Globally and Locally in Fission Yeast**

J. Wu, T. D. Pollard; MCDB, Yale University, New Haven, CT

To understand the cytoskeletal dynamics in living cells one must know the global and local concentrations of the participating proteins. Concentrations indicate stoichiometries, determine rates of biochemical reactions, and are prerequisites for mathematical modeling. Unfortunately, concentrations are rarely available. We used spinning disk confocal microscopy to measure global and local concentrations of 28 cytoskeletal and signaling proteins fused to yellow fluorescent protein (YFP) in the fission yeast *Schizosaccharomyces pombe*. Native promoters controlled expression of these functional fusion proteins. Fluorescence measured by microscopy or flow cytometry was directly proportional to protein concentration measured by quantitative immunoblotting. Global cytoplasmic concentrations ranged from 40 (formin Cdc12p) to 63,000 nM (actin). The concentrations of most proteins are constant across the cell cycle and <50% of each protein is recruited to the division site during cytokinesis. By measuring local concentrations, we find each actin patch consists of ~200 50-nm long actin filaments, half of which are capped, and each crosslinked by 2-3 fimbrins. Fission yeast begin cytokinesis when anillin-like Mid1p exits the nucleus and initiates assembly of at least seven proteins in an equatorial broad band of ~75 dots. Each dot has ~21 molecules of Mid1p, 43 myosin-II Myo2p, 35 myosin regulatory light chain Rlc1p, 289 myosin essential light chain Cdc4p, 23 IQGAP Rng2p, 22 PCH protein Cdc15p, and 4 formin Cdc12p. Thus the stoichiometry of Mid1p to dimeric myosin-II to IQGAP to Cdc15 is close to 1:1:1:1. Formin homodimers nucleate and remain attached to the barbed end of elongating actin filaments. Thus each dot could grow two actin filaments anchored by Cdc12p, sufficient for myosin-II to pull the dots together into a continuous contractile ring early in mitosis. Our approach can be used to measure the global and local concentration of any fusion protein.

2331

**A Role for the Septation Initiation Network in the Formation of the Cytokinetic Ring in Fission Yeast?**

O. Hachet, V. Simanis; Swiss Institute for Experimental Cancer Research, Epalinges, Switzerland

In most eukaryotes, cytokinesis is mediated by a contractile actomyosin ring (CAR). The formation of the CAR depends on the reorganization of the actin cytoskeleton at the onset of mitosis. In *Schizosaccharomyces pombe*, the onset of septation is temporally coordinated with the end of mitosis through the combined action of the septation initiation network (SIN) and the polo kinase Plo1p. The function of the SIN is to trigger the formation of the division septum and the contraction of the CAR after completion of chromosome partitioning. CAR assembly occurs at the onset of mitosis, independently of SIN signaling. However, ectopic activation of *spg1* is sufficient to trigger CAR assembly in interphase, though how this is achieved remains unclear. We are making use of *spg1* overexpression to evaluate the involvement of the SIN in CAR assembly.We characterized the properties of rings induced by *spg1* overexpression in G2 arrested cells. Using ring markers such as cdc15-GFP, rlc1-GFP and myp2-YFP, we found that interphasic *spg1* induced rings are functional in that they can contract, however some fail to be correctly positioned. This observation show that interphasic *spg1* induced CAR lack some spatial information suggesting a bypass of the CAR positioning mechanism or a failure to maintain CAR positioning. Using different genetic backgrounds, we addressed the requirements for the formation of interphasic *spg1* induced CAR. Our results suggest a requirement of the SIN pathway for the formation of such rings. These observations suggest that, although the SIN is not required for ring assembly, the SIN pathway may participate in this process.

2332

**Mutations in the *smoA* Gene Bypass the Requirement of Sin for Septation in *Aspergillus nidulans***

J. Kim, R. Shao, B. Liu; Section of Plant Biology, University of California-Davis, Davis, CA

Many filamentous ascomycetes like *Aspergillus nidulans* form mycelia with multinucleate cells. It is largely unknown how septation is temporally regulated in their mycelia. In *A. nidulans*, the AnMOB1 protein of the septation initiation network (SIN) is essential for septation and conidiation, but is not required for hyphal extension and colony formation. To isolate novel septation regulators, by UV mutagenesis we have isolated suppressor (*smo*) mutations that restored septation and conidiation when AnMOB1 was not expressed. Among more than 100 independent *smo* mutants, four recessive mutations at the *smoA* locus conferred identical phenotype of growth inhibition with wavy hyphae. The *smoA* mutations rendered hypersensitivity to low doses of the microtubule-depolymerizing agent benomyl. In *smoA* mutant cells, cytoplasmic microtubules became shorter than those of wild type. The *smoA* gene was cloned by DNA-mediated complementation, and it encodes a polypeptide of 652 amino acids. Genes encoding SMOA homologs were detected in genomes of other filamentous fungi like *Neurospora crassa*. A functional GFP (green fluorescent protein)-AnSMOA fusion protein localized to the nucleus indicating that AnSMOA was a nuclear protein. Loss-of-function *smo* mutations also suppressed a mutation of the *sepH* gene encoding the central kinase of the SIN in *A. nidulans*. We conclude that AnSMOA and other SMO proteins likely act as regulators antagonizing the SIN pathway in *A. nidulans*. In the absence of the AnSMOA protein, the fungus does not require the SIN for septation and conidiation. This work was supported by the National Science Foundation.

**A Complex Containing the Sm-protein CAR-1 and the RNA Helicase CGH-1 is Required for Embryonic Cytokinesis in *C elegans***

A. Audhya,[1] F. Hyndman,[1] I. X. McLeod,[2] A. S. Maddox,[1] J. R. Yates,[2] A. Desai,[1] K. Oegema[1]; [1]Cellular and Molecular Medicine, Ludwig Institute for Cancer Research, La Jolla, CA, [2]Department of Cell Biology, The Scripps Research Institute, La Jolla, CA

Cytokinesis completes cell division by partitioning the intracellular constituents of one cell to form two topologically distinct daughter cells. Here we describe the characterization of CAR-1, a predicted RNA binding protein whose depletion results in a specific defect in cytokinesis. Consistent with a role in RNA metabolism, CAR-1 localizes to germline-specific RNA-containing P-granules and co-purifies with the essential RNA helicase CGH-1, which controls its localization. The atypical Sm domain of CAR-1, which is predicted to mediate an association with RNA, is dispensable for CAR-1 localization but critical for its function. The failure of cytokinesis in CAR-1 depleted embryos likely results from a pronounced defect in the structure of the anaphase spindle, which normally interacts with the cortex to promote the completion of cytokinesis. In CAR-1 depleted embryos, inter-zonal microtubule bundles that recruit Aurora B kinase and the kinesin ZEN-4 fail to form. Depletion of CGH-1 results in sterility, but partially depleted worms produce embryos that exhibit a nearly identical phenotype to that resulting from depletion of CAR-1. Cumulatively, these results suggest that CAR-1 and CGH-1 function together to regulate RNAs important for anaphase spindle structure and point to a connection between RNA metabolism and cytokinesis.

2334

**A Functional Domain Interference Assay (FDIA) Reveals that Peptide Motifs of Mago Nashi Are Involved in Development in *Marsilea***

C. M. Van der Weele, S. M. Wolniak; Cell Biology and Molecular Genetics, University of Maryland-College Park, College Park, MD

Spermatogenesis in the water fern *Marsilea vestita* is initiated by placing dry microspores in water. The single cell in the microspore undergoes nine successive division cycles to produce 7 somatic cells and 32 spermatids. Thereafter, each spermatid differentiates to become a coiled, ciliated gamete. Mago nashi is a highly conserved protein that functions in the exon-exon junction complex for pre-mRNA splicing, as a component in nonsense-mediated mRNA decay, and as a component in transport/localization of mRNAs for axis formation. The protein consists of several beta-sheet and alpha-helix domains. The beta sheets are exposed on one side of the protein while the opposite face consists of alpha helical domains that interact with the Y14 protein to form a heterodimer. Previously, we found that *Mv*-mago and *Mv*-Y14 are important for the specification of spermatogenous and jacket cells in the gametophyte. RNAi treatments, using dsRNAs made from *Mv*-mago and *Mv*-Y14, induced cytokinesis defects with cells of random sizes and anomalous shapes. Transcripts encoding pre-mRNA processing proteins, and proteins important for gametogenesis failed to localize in spermatogenous initials; instead, both were present in all cells of the gametophyte. Five peptides corresponding to different parts of the mago nashi protein were added to microspores in a series of functional domain interference assays (FDIA) to assess interactions between native proteins and mago nashi *in vivo*. One peptide exerted no effect on development while another induced rapid death, even at low concentrations. With the remaining peptides, development was arrested at specific phases, with characteristic patterns of incomplete cytokinesis and abnormal cell shaping. The FDIA experiments show that different motifs in the same protein affect development at distinct stages. (Supported by NSF grant MCB 0234423 to SMW).

**Filamentous Growth and Septation in *Ustilago maydis***

K. Snetselaar, S. Yerrum, M. McCann; Biology, Saint Joseph's University, Philadelphia, PA

The corn smut fungus *Ustilago maydis* is a dimorphic phytopathogenic basidiomycete. The haploid non-pathogenic form grows asexually by budding, while mating, cell fusion and filamentous growth are required for pathogenicity. At least three morphologically and behaviorally distinct filaments have been observed in *U. maydis*: mating filaments, infection filaments and the filaments that proliferate in planta. Mating and infection filaments both exhibit unipolar growth with nuclei arrested in G2. Filaments formed within the plant are difficult to study, but they are mitotically active and appear to have a bipolar growth pattern. Mutants lacking adenylate cyclase (*uac* mutants) are constitutively filamentous and are used as a model of filamentous growth in *U. maydis*, although they cannot undergo mating, cell fusion or pathogenic growth unless supplemented with cAMP. In this study, we compared features of growth and cytokinesis between these filaments and wild-type cells. Filaments formed by *uac* mutants had unconstricted septa, like wild-type mating and infection filaments, but unlike septa formed during budding or pseudohyphal growth. However, unlike wild-type mating and early infection filaments, filaments of *uac* cells had a bipolar growth pattern similar to that of budding cells. Fluorescence microscopy using strains containing a gfp-beta tubulin fusion showed that unlike in wild-type budding cells, mitotic spindles form in the center of unconstricted cell compartments in *uac* filaments, apparently at the site where the new septum will form. The membrane label FM4-64 and several labels for cell wall components showed that compartments in filaments formed by *uac* mutants are separated by a single septum that

differs in development from both the double septum formed in budding cells and the septum formed in unipolar infection filaments. Filaments formed by *uac* mutants may be more like filaments formed in planta than to other *U. maydis* filaments.

### Role of Centrins in *Trypanosoma brucei* Cytokinesis

A. Selvapandiyan,[1] P. Kumar,[2] J. C. Morris,[3] C. C. Wang,[2] H. L. Nakhasi[1]; [1]Division of Emerging and Transfusion Transmitted Diseases, OBRR, Food and Drug Administration, Bethesda, MD, [2]Pharmaceutical Chemistry, UCSF, San Francisco, CA, [3]Genetics, Biochemistry and Life Science Studies, Clemson University, Clemson, SC

Centrins are calcium binding cytoskeletal proteins involved in duplication and segregation of centrosome/basal bodies in eukaryotes. Recently, we showed that centrin1 in *Leishmania donovani*, a causative agent of fatal visceral leishmaniasis disease in humans, is essential for basal body duplication and cytokinesis (Journal of Biological Chemistry 2004, 279:25703-25710). Similarly we wanted to define the function of centrins in other trypanosomatids. The genome of a trypanosomatid, *Trypanosoma brucei* (www.genedb.org) the parasite that causes the African sleeping sickness in humans, shows the presence of five different putative centrin genes. Using RNAi methodology, we generated individual centrin gene knockdown clones in the procyclic form of *T. brucei*. Knockdown of centrin 1, 2 and 3 but not 4 and 5 expression affected the growth of the parasite *in vitro*. Northern blot analysis on the growth affected cells showed specific reduction in the mRNA levels of respective centrins. Flow-cytometry analysis indicated that the cells were blocked at the G2/M cell cycle stage. Further, loss of centrins 1, 2 and 3 expression resulted in cells with multi-nuclei, having more than one kinetoplast and multi-flagella. These multinucleated cytokinesis arrested cells undergo a form of programmed cell death based on TUNEL assays. The mechanism by which centrins play a role in the cytokinesis in the procyclic form of *T. brucei* will be discussed.

2337

### Mechanism of Cytokinesis Initiation in *Trypanosoma brucei*

P. Kumar, C. C. Wang; Pharma. Chem., UCSF, San Francisco, CA

Polo-like kinase (Plk) typically plays multiple roles in both mitosis and cytokinesis in eukaryotes. We report that TbPlk, the only Plk homolog in the ancient eukaryote *Trypanosoma brucei*, controls cytokinesis but not mitosis. We used RNAi to knockdown TbPlk expression in the procyclic form of *T. brucei* and after the depletion of TbPlk, we observed apparently normal spindle formation, chromosome segregation and nuclear division, with accumulation of multiple nuclei, kinetoplasts, basal bodies and flagella, indicating that duplication and segregation of these organelles proceeded normally. But the cells failed to divide. TbPlk thus apparently does not play a role in either mitosis or kinetoplast segregation. Instead, it controls only the initiation of cytokinesis. The procyclic-form *T. brucei* is also known to continue cell division under mitotic arrest to produce anucleate cells known as the zoids. The fact that no zoids were detected in TbPlk-depleted cells further supports the notion that TbPlk is not involved in mitotic regulation but only cytokinesis initiation. The intracellular localization of TbPlk in the flagellum attachment zones which may constitute the cleavage furrow further supports the conclusion that TbPlk plays an important role in initiating cytokinesis. This is, to our knowledge, the first report of a polo-like kinase that is not associated with mitosis. Our finding provides a new tool for dissecting the role of Plks in initiating cytokinesis and regulating the cell cycle across the broad range of eukaryotes.

### Characterization of Centrin an MTOC's Protein

Z. Sanoguet, M. Campbell, B. Pastrana; Chemistry, University of Puerto Rico, Mayaguez, Puerto Rico

Recombinant *Chlamydomonas* centrin was used as a model protein to understand the effects of phosphorylation on protein conformation. The purified protein was phosphorylated *in vitro* using protein kinase A (PKA). The extent of phosphorylation was determined by Matrix Assisted Laser Desorption Mass Spectrometry (MALDI-MS). The conformational changes and the hydrogen / deuterium (H/D) exchange dynamics at the molecular level were studied using Fourier Transformed Infrared spectroscopy (FT-IR) and two-dimensional correlation analysis. This protein was observed to have a thermal transition temperature (Tm) of 112°C with a pre-transition at 70 °C, using Differential Scanning Calorimetry (DSC). The FT-IR results suggest that changes in the backbone occur prior to any other change when thermally perturbed while for the H/D exchange loops were affected first. Discussion of the results is relevant in describing its biological function and for future studies with sfi 1, a target protein, essential in cell division.

2339

### Calomitric Properties of a Centrosome Associated Protein: Human Centrin 2

V. Meza-Venencia, B. Pastrana-Ríos; Chemistry, University of Puerto Rico, Mayaguez Campus, Mayaguez, PR

Human centrin 2 (Hcen 2) is an acidic centrosomal protein of 19,738 Da, that is comprised of four subdomains, called EF-hands, which represent the calcium-binding sites. Human centrin 2 gene locus is codified on chromosomes X and had been designated as *Hcetn2*. Hcen2 may play a role in centrosome duplication and segregation during mitosis. Transformed bacterial *E. coli* cells with a recombinant molecule containing the Hcetn2 gene were grown in either 2xYT broth or $^{13}C$ isotope enriched minimal media and induced to over-express the Hcen 2 and $^{13}C$-Hcen 2, respectively. These recombinant proteins were then purified by using a of hydrophobic affinity chromatography followed by several anion exchange chromatographic separations. Highly pure Human centrin 2 and $^{13}C$-homogenously labeled protein were obtained for biophysical studies. Differential scanning calorimetric (DSC) study of Hcen 2 showed that this is a very stable protein with a pre-transition temperature around 85 $^{o}C$ and a thermal transition temperature at 120 $^{o}C$.

## Actin Dynamics & Assembly III (2340-2358)

2340

### Molecular Analysis of Filopodia Assembly and Disassembly in Drosophila Cells

S. Rogers; Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Filopodia are specialized, finger-like cellular processes that allow cells to interact with their environment and to communicate with other cells. Best

understood in the context of cellular motility, filopodia detect and integrate guidance cues during migration to direct cells to their proper destination. Filamentous actin forms the core structural scaffolding of filopodia and it is the dynamics of the actin cytoskeleton that drive the cycles of protrusion and retraction that allow them to sample the extracellular space. I have developed a novel model system to study the processes of filopodia assembly and retraction using cultured Drosophila cells. These cells allow direct observation of actin dynamics using high-resolution light microscopy and are susceptible to RNAi-mediated gene inhibition. Preliminary studies indicate that filopodia assembly in this system is consistent with the Convergent Elongation Model that predicts that the balance between capping and anti-capping actin-binding proteins is a key determinant of the architecture of the actin network. I will present data about the function of the anti-capping protein, Enabled, in this system and how its differential regulation may lead to filopodia disassembly in response to extracellular signaling events.

2341

**Ena/VASP Proteins in Filopodia Formation**

D. A. Applewhite,[1] M. Barzik,[2] S. Kojima,[1] M. R. Mejillano,[1] T. M. Svitkina,[3] F. B. Gertler,[2] G. G. Borisy[1]; [1]Cell and Molecular Biology, Northwestern University, Chicago, IL, [2]Biology, Massachusetts Institute of Technology, Cambridge, MA, [3]Biology, University of Pennsylvania, Philadelphia, PA

Ena/VASP proteins control actin dynamics and are important mediators for lamellipodia and filopodia dynamics. (*Cell* (2004) **118**; 363-373; *Annu. Rev. Cell Dev. Biol.* (2003) **19**; 541-64). However, the detailed mechanism of how Ena/VASP proteins enhance filopodia is not known. We determined the domains necessary for filopodia formation and tip targeting using $MV^{D7}$ cell lines with stable expression of Ena/VASP mutants. A filopodia formation assay was developed based on siRNA depletion of capping protein (CP). The parental $MV^{D7}$ line, which is deficient in all three mammalian (Mena/VASP/EVL) homologues, failed to support intense filopodia formation after CP depletion. The EVH2 domain alone restored the ability of filopodia induction as efficiently as full-length VASP and Mena proteins. Further dissection revealed the G-actin binding, the F-actin binding and the coiled-coil motifs within EVH2 domain were necessary for filopodial induction. Interestingly, the EVH2 domain localized along the length of filopodia instead of at the tips as observed for the full-length protein, and the localization was resistant to detergent extraction. The EVH1 domain alone did not support efficient filopodia induction but did correctly localize at the tips of filopodia, and was rapidly removed by detergent. Full length VASP was retained at filopodial tips after detergent extraction, suggesting that VASP at filopodial tips is bound to the actin cytoskeleton through the EVH2 domain. Fluorescence recovery after photobleaching (FRAP) analysis showed that full length EGFP-VASP did not exchange rapidly at filopodial tips but that the EGFP-EVH2 domain exchanged relatively rapidly (within 1 minute) along the length of filopodia. Our data suggest a model in which the EVH1 domain is essential for targeting of Ena/VASP proteins at filopodial tips whereas the EVH2 domain dynamically associates with actin filaments and is required to support filopodia protrusion. Supported by NIH GM64346 (DAA) and NIH GM62431 (GGB).

2342

**Bone Resorption by Osteoclasts Requires Cortactin-based Actin Assembly**

S. Tehrani,[1] R. Faccio,[2] F. P. Ross,[3] J. A. Cooper[1]; [1]Cell Biology, Washington University School of Medicine, Saint Louis, MO, [2]Orthopaedic Surgery, Washington University School of Medicine, Saint Louis, MO, [3]Pathology and Immunology, Washington University School of Medicine, Saint Louis, MO

Osteoclasts are essential for bone dynamics and calcium homeostasis. They form a tight seal on the bone surface, onto which they secrete acid and proteases to resorb bone. The sealing ring contains actin filaments, as do podosomes, which form when osteoclasts are plated on non-osteoid surfaces. Cortactin, a c-Src substrate known to promote Arp2/3-mediated actin assembly in vitro, is expressed in osteoclasts and localizes to the sealing ring and podosomes. To address the role of cortactin and actin assembly in osteoclasts, we depleted cortactin by RNA interference. Cortactin-depleted osteoclasts displayed a complete loss of bone resorption with no formation of sealing zones or podosomes. The cells were remarkably normal in other respects, including differentiation markers and actin-based motility of the cell edge. We found that cortactin localized strongly to the nascent podosome along with dynamin2, early in actin assembly. N-WASp, WASp and dynamin2 localization to the cortical actin cytoskeleton was disrupted in cortactin-depleted osteoclasts. Thus, cortactin has a critical and highly specific role in osteoclast function related to actin-based assembly of podosomes and sealing zones for bone resorption, and cortactin-based actin filament assembly at the sealing zone is necessary for bone resorption.

2343

**Yeast Actin Patches as a Model of the Actin Assembly at the Leading Edge**

V. A. Sirotkin,[1] K. Macmillan,[1] S. Yuan,[2] D. R. Kovar,[1] T. D. Pollard[1]; [1]MCDB, Yale University, New Haven, CT, [2]MBB, Yale University, New Haven, CT

Yeast actin patch assembly depends on Arp2/3 complex and shares many proteins with the leading edge of motile cells, including capping protein, profilin, actin cross-linkers, and cofilin. We used live cell imaging of fluorescent protein-tagged patch proteins to determine the effects of varying concentrations of patch components on patch dynamics. Fission yeast actin patches assemble at endocytic sites since patch assembly starts with recruitment of Pan1p and End4p, known to be involved in endocytosis. Downstream two parallel partially redundant pathways recruit Arp2/3 complex, one using WASp Wsp1p and another using myosin-I Myo1p. Patch dynamics are abnormal in the absence of either Myo1p or Wsp1p. Arp2/3 complex dissociates from these activators and moves centripetally. Coronin Crn1p joins the patch at the onset of mobile phase and remains in the patch longer than Arp2/3 complex. Actin capping protein, fimbrin and App1p accumulate and disperse in parallel with Arp2/3 complex throughout lifetime of the patch, indicating that actin filament capping and crosslinking happen within 1 s of filament nucleation by Arp2/3 complex. This is consistent with a network of short cross-linked filaments. In the absence of capping protein patch dynamics appear normal whereas capping protein over expression slows patch assembly, disassembly, and motility. Reduction in the level of profilin causes cytokinesis defect and depolarizes patches, but with only minor defects in patch dynamics. Elevated profilin concentrations delay Arp2/3 complex recruitment and slow patch motility. The observed changes in patch dynamics may be due to effects of capping protein and profilin concentrations on actin assembly at both actin patches and cables, known to associate with patches. The mechanism of actin assembly in patches appears similar to that at the leading edge of motile cells.

2344

**A Genetic Interaction Map for Actin Binding Proteins and Actin Surfaces in *S Cerevisiae***

J. A. Hendries; Brandeis University, Waltham, MA

Cellular actin networks are all assembled from the same basic building blocks, globular actin subunits, yet there is incredible diversity within actin filament arrays. This diversity is achieved through the combined activities of multiple actin binding proteins (ABPs) working in concert. To understand better how the actions of so many ABPs are coordinated *in vivo*, we performed a genetic screen in *S. cerevisiae* to define surfaces on actin that interact functionally with different ABPs. We tested all possible uni-directional and bi-directional suppression interactions between 23 non-lethal *act1* alleles and 17 different ABPs overexpressed on plasmids. 50 suppression interactions were detected. Some confirm previously identified functional links between specific actin surfaces and ABPs, but most represent new interactions. In addition, a comparison of genetic interaction profiles for individual ABPs with *act1* alleles suggested new and unexpected *in vivo* roles for certain ABPs. We selected a subset of these interactions for further *in vivo* analyses. Together, these data: (1) clarify how tropomyosin (Tpm1) associates with F-actin and the functional role of this interaction *in vivo*; (2) refine our understanding of how cofilin (Cof1) interacts with F-actin; and (3) reinforce the functional relationships among Aip1, Twf1 and Cof1 in promoting actin turnover. These data lend new insights into the mechanisms by which cells regulate actin dynamics and provide important tools for future genetic and biochemical investigations in this area. **Reconstitution of Actin Assembly in Cell-free Extracts and Development of a Functional Map of Actin Cytoskeleton Components in *S Cerevisiae***

J. L. DAgostino, A. L. Goodman, E. Smith, B. L. Goode; Biology, Brandeis University, Waltham, MA

Dynamic behavior of the actin cytoskeleton is regulated by the combined actions of a multitude of proteins having diverse activities on actin and each other. To understand the complete inner-workings of such a complicated biological machine will ultimately require obtaining a map of all of the components and their activities, cellular levels, and interactions. Toward this goal, we have developed a genetically and biochemically tractable assay for reconstituting actin assembly in *S. cerevisiae* cell-free extracts. Nucleation of actin assembly in this assay is dependent on Arp2/3 complex and WASp, but not formins or tropomyosin. The components of the actin structures assembled in extracts were defined by tandem mass spectrometry. They include most actin-associated proteins (AAPs) that reside on mature actin patches *in vivo*. In contrast, the signature component of actin cables, tropomyosin, was absent despite its abundance in extracts. Thus, the cell-free assay mirrors *in vivo* requirements for formation of actin patches, but not cables. In addition, we defined the cellular concentrations of actin and 13 AAPs and examined their physical interactions in stable complexes. We present a working map of the components of yeast actin binding proteins and their *in vivo* levels and interactions. This work represents an important step towards achieving a complete functional map of the actin cytoskeleton in a single living cell.

**Srv2/CAP: The Grand Central Station of Actin Turnover**

O. Quintero-Monzon, B. L. Goode; Biochemistry, Brandeis University, Waltham, MA

Many cellular processes depend on the rapid remodeling of actin structures, including endocytosis, cytokinesis, and cell motility. This requires cells to rapidly disassemble older actin filaments and convert ADP-actin monomers to an ATP-bound assembly-competent state. ADF/coflilin and profilin have established roles in promoting actin turnover, but do not operate alone. Recent studies demonstrate that the highly conserved actin binding protein Srv2/CAP (cyclase-associated protein) plays a critical role in accelerating actin turnover in both yeast and animal cells. Previously, we isolated native yeast Srv2 in a 600kDa complex comprised entirely of Srv2 (53kDa) and actin (43kDa) in a 1:1 molar ratio, suggestive of a hetero-dodecameric structure. Further, our biochemical analyses showed that Srv2 accelerates cofilin-dependent actin turnover by recycling cofilin from ADP-actin monomers and that Srv2 functions with profilin to promote nucleotide exchange on G-actin. Here, we further dissect the Srv2 complex structure and its *in vivo* mechanism of promoting actin turnover. First, we have reconstituted active 600kDa Srv2 complex from recombinant full-length Srv2 expressed in *E. coli* and purified rabbit skeletal muscle actin. Second, we show that Srv2 alone forms a hexamer maintained by interactions of its N-terminal 50 amino acids. Disruption of this domain in vitro leads to dimeric Srv2, and in vivo this causes dramatic changes in cell morphology and actin organization. Thus, Srv2/CAP cellular function requires proper multimerization. Third, we have used specific point mutations to uncouple Srv2 interactions with four ligands (Abp1, profilin, cofilin, and G-actin) and dissect their combined mechanism of promoting actin turnover. Together, our data show that Srv2 forms a Mega-Dalton sized hub that coordinates dynamic interactions with actin and other factors to accelerate actin turnover *in vivo*.

**Contractile Structures Formed during Oocyte Wound Healing Contain Discrete Sub Domains of Actin Dynamics**

B. Burkel, W. Bement; Zoology, University of Wisconsin, Madison, WI

F-actin plays an integral role in both cytokinesis and the closure of cortical wounds. During these events, the cell assembles a dynamic contractile ring of F-actin and myosin 2. While the importance of F-actin in these contractile structures has been established for some time, accurately assessing its temporal and spatial dynamics has been hindered in part by the shortcomings in available probes for imaging F-actin *in vivo*. These shortcomings range from perturbation of filament dynamics to the inability to distinguish F-actin from total actin populations. Here we have characterized a fluorescent fusion protein comprised of the first 261 amino acids of the actin binding protein, utrophin, that overcomes these shortcomings. This fusion protein, $Utr_{1-261}$, accurately reports F-actin populations, but does not alter actin dynamics or impact myosin 2-based contractility. By using this probe in conjunction with various photoactivation techniques, we have been able to establish that these contractile structures are divided into discrete sub domains that differ sharply with respect to their dynamics.

**Involvement of Sterols and Phospholipid Asymmetry in Polarized Organization of the Actin Cytoskeleton Through Endocytic Recycling in Yeast**

T. Kishimoto, T. Yamamoto, K. Tanaka; Division of Molecular Interaction, Institute for Genetic Medicine, Hokkaido University, Sapporo, Japan

Specific changes in membrane lipid composition are implicated in actin cytoskeletal organization, vesicle formation, and control of cell polarity. Most cell types display an asymmetric distribution of phospholipids across the plasma membrane that seems to be regulated by proteins mediating the transbilayer movement of phospholipids. We have previously reported that Cdc50p, a membrane protein in the endosomal/TGN compartments, controls polarized growth in yeast, and that Cdc50p is a non-catalytic subunit of the P-type ATPase Drs2p, which is proposed to translocate phospholipids across the TGN lipid bilayers. In this work, we show that the *cdc50Δ* mutation is synthetically lethal with mutations affecting the late steps of ergosterol synthesis (*erg2* to *erg6*). Defects in cell polarity and actin organization were observed in the *cdc50Δ erg3Δ* mutant. In particular, actin patches, which are normally found at cortical sites, were assembled intracellularly along with their assembly factors, including Las17p, Abp1p, and Sla2p. The exocytic SNARE Snc1p, which is recycled by an endocytic route, was also intracellularly accumulated, and inhibition of endocytic internalization suppressed the cytoplasmic accumulation of both Las17p and Snc1p. Confocal microscopy suggested that the intracellular actin patches were formed on the surface of unrecycled endocytosed membranes that contain Snc1p. These membranes overlapped with filipin-positive sterol-rich structures, suggesting that sterols accumulate in those membranes in the *cdc50Δ erg3Δ* mutant. In conclusion, simultaneous loss of phospholipid asymmetry and sterol structural integrity could lead to a defect in endocytic recycling, bringing about the assembly of cytoplasmic actin patches onto endocytic membranes that may be similar to the plasma membrane in terms of lipid composition.

**Yeast as a Model for Retrograde Flow: Actin Assembly and Tropomyosin-Regulated Type II Myosin Drive the Retrograde Movement of Actin Cables**

T. M. Huckaba, T. G. Lipkin, L. A. Pon; Program in Cell Biology and Pathobiology, Columbia University, New York, NY

Actin cables in budding yeast are bundles that align along the mother-bud axis and serve as tracks for anterograde and retrograde organelle and particle transport. Actin cables undergo retrograde flow from their site of assembly in the bud and bud neck toward the mother cell tip at a rate of 3-4 microns/second. Previously, we showed that the retrograde flow of actin cables depends on actin assembly. Here, we show that the type II myosin, Myo1p, also contributes to actin cable retrograde flow. Deletion of the *MYO1* gene, delocalization of Myo1p from the bud neck, or a conditional mutation in the actin-binding site in the Myo1p motor domain all significantly decrease the rate of actin cable retrograde flow. Conversely, deletion of the *TPM2* gene, which encodes one of the two yeast tropomyosins, significantly increases the rate of actin cable retrograde flow. These findings raise the possibility that Tpm2p regulates Myo1p function in actin cable movement. Consistent with this, 1) yeast carrying mutations in *TPM2* and *MYO1* exhibit the same phenotype as *MYO1* mutation alone, and 2) purified Tpm2p but not Tpm1p inhibits Myo1p-driven microfilament gliding. These data support a model whereby bud neck-localized Myo1p drives actin cable movement, and Tpm2p regulates access of Myo1p to actin cables. Our study reveals novel functions for type II myosin and a tropomyosin isoform in budding yeast. Moreover, we find that retrograde actin cable flow in yeast resembles retrograde actin movement in the leading edge of motile cells: both processes are regulated by a tropomyosin isoform and driven by actin assembly and type II myosin. This suggests that actin retrograde flow occurs by a conserved mechanism that can be modeled in budding yeast.

**Actomyosin Cortex Breaks and Drives Cell Shape Oscillations**

E. Paluch,[1] M. Piel,[2] J. Prost,[1] M. Bornens,[2] C. Sykes[1]; [1]UMR 168, Institut Curie / CNRS, Paris, France, [2]UMR 144, Institut Curie / CNRS, Paris, France

We investigate the spontaneous behaviors of the actomyosin cell cortex when the control of its contractility by microtubules is suppressed. Under these conditions and in the absence of substrate adhesions, the cell cortex spontaneously breaks and a membrane bulge devoid of detectable actin and myosin is expelled through the hole. A constriction ring at the base of the bulge then oscillates from one side of the cell to the other. The movement is accompanied by sequential redistribution of actin and myosin to the membrane. We observe this oscillatory behavior also in cell fragments of various sizes, providing a simplified, nucleus-free system for biophysical studies (1). We conclude that it reveals an intrinsic behavior of the actomyosin cortex. Our observations suggest a mechanism based on active gel dynamics and inspired by our study of symmetry breaking in actin gels growing around beads (2). The proposed mechanism for breakage of the actomyosin cortex may be used for cell locomotion and division. (1) Paluch E, Piel M, Prost J, Bornens M, Sykes C. 2005. **Actin Dynamics Play an Essential Role in Hemoglobin Uptake and Transport by *Plasmodium falciparum***

M. D. Lazarus, T. Schneider, T. F. Taraschi; Pathology, Anatomy, and Cell Biology, Thomas Jefferson University, Philadelphia, PA

Research indicates that host cell hemoglobin (hgb) degradation by intraerythrocytic *Plasmodium falciparum* (*Pf*) malaria parasites is essential for parasite viability. Mechanisms of Hgb uptake and transport by these intraerythrocytic parasites, however, are poorly understood. Hgb internalization begins through a double-membrane invagination located on the parasite's surface membranes, known as the cytostome (CYT). The CYT is internalized, forming a double membrane vesicle which is transported through the parasite cytosol and fuses with the lysosome-like organelle, the food vacuole (FV). Within the FV, cysteine proteases help break down the host-derived Hgb. Treatment of intraerythrocytic *Pf* with the actin filament-stabilizing drug Jasplakinolide (JAS) indicates that actin dynamics play an essential role in the parasite's Hgb uptake and transport pathway. Long-term JAS treatment arrests *Pf* development. These JAS-treated parasites lack internal organelles, as indicated by electron microscopy (EM) and their *Pf*LDH (an intraerythrocytic parasite development marker) is markedly reduced as compared to untreated parasites. *Pf*LDH assays indicate that short-term JAS treatment alters late-stage *Pf* development but does not affect early-stage parasites. Ultrastrucutural characterization of short-term JAS treated parasites reveals multiple CYT as well as unusually large, deranged CYT at the surface of the parasite

compartment. Treatment of intraerythrocytic *Pf* with the cysteine protease inhibitor, E-64, results in enlarged FV containing undegraded Hgb. Simultaneous treatment of *Pf* with JAS and E-64 results in a loss of effect of E-64 on the FV presumably due to the inability of the parasite to uptake and/or transport Hgb to the FV. Taken together, this data indicates that actin dynamics play an essential role in the uptake and transport of RBC Hgb to the FV and that these processes are essential for parasite development.

**Diacylglycerol Kinase-ζ induces Membrane Blebbing in Myotubes via a Rho Kinase-Dependent Pathway**

J. C. Maillet,[1,2] R. Parks,[1,3] M. K. Topham,[4,5] S. H. Gee[1,2]; [1]Center for Neuromuscular Disease, University of Ottawa, Ottawa, ON, Canada, [2]Cellular and Molecular Medicine, University of Ottawa, Ottawa, ON, Canada, [3]Biochemistry, Microbiology and Immunology, University of Ottawa, Ottawa, ON, Canada, [4]Huntsman Cancer Institute, University of Utah, Salt Lake City, UT, [5]Department of Internal Medicine, University of Utah, Salt Lake City, UT

Membrane blebbing is a dynamic event associated with cellular processes such as apoptosis and cell migration. The formation of membrane blebs requires the rearrangement of the actin cytoskeleton, which is mediated in part by the Rho GTPases. We previously showed that diacylglycerol kinase-ζ (DGK-ζ), which phosphorylates diacylglycerol to yield phosphatidic acid, associates with the Rho GTPase Rac1 in areas of C2C12 myoblasts undergoing actin cytoskeletal rearrangements. In muscle, DGK-ζ localization is regulated by its association with syntrophins, a family of scaffolding proteins belonging to the dystrophin glycoprotein complex. Here, we used immunofluorescence microscopy to study the effect of DGK-ζ on the actin cytoskeleton of differentiated C2 myotubes. Adenoviral-mediated overexpression of DGK-ζ induced membrane blebbing in myotubes but not myoblasts. By overexpressing various mutants it was determined that membrane blebbing was not dependent on the kinase activity of DGK-ζ. However, a mutant that does not interact with syntrophins failed to induce membrane blebbing. Furthermore, using inhibitor studies we show that membrane blebbing is dependent on the activity of Rho kinase (ROCK), a downstream effector of RhoA known to induce membrane blebbing via increased cell contractility. Lastly, using GST pulldowns we show that DGK-ζ associates with RhoA. Taken together these results suggest that syntrophins are required for DGK-ζ and RhoA to activate ROCK, resulting in membrane blebbing in myotubes.

**A Role for Tropomodulin 3 in Regulation of F-actin Abundance and Organization in Polarized Epithelial Cells**

K. L. Weber, R. B. Nowak, V. M. Fowler; Department of Cell Biology, The Scripps Research Institute, La Jolla, CA

The intestinal epithelium is composed of highly differentiated polarized epithelial cells, the function of which is dependent on the maintenance of cell polarity. Microvilli, which cover the apical surface of polarized epithelial cells thus imparting an essential increase in cellular surface area, consist of parallel bundles of actin filaments oriented such that the barbed-ends of the filaments are located at the microvillar tip, and the pointed-ends are located in the terminal web in the apical portion of the cell body. Despite the fact that microvillar actin filaments are dynamic, implying active regulation of length, very little data exists regarding binding partners for either their pointed or barbed ends. Caco-2 is an immortalized epithelial cell line derived from a human colon adenocarcinoma that faithfully represents microvilli-forming epithelial cells when cultured *in vitro*. Tropomodulin (Tmod) is an actin filament pointed-end capping protein. We have shown that Tmod3 localizes to the apical surface of intestinal crypt cells *in situ*, and is the sole Tmod isoform present in Caco-2 cells. Immunofluorescence staining of endogenous Tmod3 and infection with adenovirus expressing GFP-Tmod3 reveal that Tmod3 is localized to the apical region of the cell in the terminal web at the base of microvilli, colocalizing with fodrin, a terminal web marker. Tmod3 is also localized to the lateral membranes at cell-cell contacts where it partially colocalizes with E-cadherin. Tmod3 does not colocalize with actin in stress fibers at the basal surface of the cell. Interestingly and unexpectedly, we also saw occasional localization of Tmod3 at the tips of microvilli, where actin barbed-ends are concentrated. Preliminary siRNA experiments suggest a role for Tmod3 in regulating F-actin levels and organization at the apical surface and cell-cell junctions of polarized epithelia.

**VEGF-induced LIM Kinase 1 Phosphorylation and Activation are Required for Actin Cytoskeletal Reorganization and Migration of Endothelial Cell**

M. Kobayashi, M. Nishita, K. Ohashi, K. Mizuno; Graduate School of Life Sciences, Tohoku University, Sendai, Japan

Cofilin plays an essential role for actin reorganization in motile cells. Cofilin is inactived by phosphorylation at Ser3 by LIM kinase (LIMK). Vascular endothelial growth factor (VEGF), which is a major regulator of angiogenesis, induces dynamically change in actin cytoskeletal reorganization and morphology in vascular endothelial cells. LIMK1 is activated through phosphorylation at Thr-508 by ROCK and PAK, which are downstream effectors of Rho and Rac/Cdc42, respectively. In the present study, we investigated the role of LIMK1 in VEGF-induced morphological changes in vascular endothelial cells (HUVECs and MSS31 cells). When the P-cofilin level was estimated by using two-dimensional gel immunoblot analysis with an anti-cofilin antibody, the ratio of P-cofilin increased to nearly equal amount to the unphosphorylated cofilin at 15 min after VEGF stimulation. We obtained evidence that VEGF significantly induces the activation of LIMK1 and cofilin phosphorylation through activation of p38 MAP-kinase and MAPKAP kinase-2 (MK2). Activated p38 and MK2 phosphorylated LIMK1 in cultured cells and in cell-free system at sites other than Thr-508. Activation of p38-MK2 pathway, induced by overexpression of constitutively active MKK6(DE), was sufficient for LIMK1 activation and stress fiber formation. Furthermore, a LIMK1-mutant, which is not phosphorylated by p38 and MK2, blocked VEGF-induced stress fiber formation and suppressed cell migration. These findings suggest that p38-MK2-pathway mediated LIMK1-activation significantly contributes to the VEGF-induced morphological changes and migration of vascular endothelial cells.

**Intravital Visualization of Ischemia Induced Actin Alterations with 2-Photon Microscopy**

S. L. Ashworth,[1] G. A. Tanner,[2] R. M. Sandoval,[1] S. B. Campos,[1] J. R. Bamburg,[3] B. A. Molitoris[1]; [1]Medicine, Indiana University School of Medicine, Indianapolis, IN, [2]Cellular and Integrative Physiology, Indiana University School of Medicine, Indianapolis, IN, [3]Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

Proximal tubule cell (PTC) microvilli microfilament destruction in response to renal ischemia leads to cellular and organ dysfunction. The precise dynamics of the actin cytoskeletal changes during ischemia and reperfusion in a live animal are unknown, but fixed tissue and cell culture studies

support the role of F-actin destruction in microvilli breakdown. To quantitatively analyze the effects of ischemia and reperfusion on the actin cytoskeleton in PTCs, we utilized adenoviral-mediated delivery of a fluorescently-tagged actin cDNA into the live animal and observed actin cytoskeletal changes using intravital 2-photon microscopy. Image stacks were collected of the actin-GFP expressing PTCs under control conditions, during 25 minutes of ischemia induced by clamping the suprarenal aorta, and at 8, 25, and 55 minutes of blood reflow. Metamorph, Voxx and Amira reconstruction softwares were used to quantitatively analyze actin alterations and cell volume changes during ischemia and recovery. Actin-GFP was expressed in PTCs and incorporated into apical microvilli microfilaments and in basal-lateral and cortical actin structures. With induction of ischemia, rapid breakdown of apical microvilli microfilaments occurred. Actin-GFP containing intraluminal vesicles or blebs were observed within ten minutes of ischemia induction. With blood reflow, the actin-GFP-filled blebs flowed down the tubule lumen. A 48% increase in PTC volume occurred during ischemia, which partially recovered to 26% over baseline during reperfusion. These live animal studies demonstrate the rapid dynamic nature and biological importance of F-actin apical microvilli breakdown and bleb formation as a consequence of renal ischemia.

2356

**Tropomyosins Regulate the Response of Actin Filaments to Cytochalasin and Latrunculin**

P. Gunning,[1,2] S. Creed,[1,2] N. Bryce,[1] R. Weinberger,[1] J. Stehn[1]; [1]Oncology Research Unit, The Children's Hospital at Westmead, Westmead NSW, Australia, [2]Discipline of Paediatrics and Child Health, University of Sydney, Sydney, Australia

Tropomyosins form a head-to-tail polymer which lies in the major groove of actin filaments. Over 40 isoforms of tropomyosin have been identified. Gene knock-out studies have shown that tropomyosins perform essential functions in a variety of organisms and that at least some isoforms are not functionally interchangeable. Isoform specific function appears to derive from the intracellular sorting of isoforms to different actin filament populations. In addition, isoforms differ in their ability to regulate actin-myosin and actin-cofilin interactions. In this study, we have addressed the ability of tropomyosins to regulate the response of actin filaments to the drugs cytochalasin and latrunculin in an isoform specific manner. Neuroepithelial cells which over-express specific tropomyosins were exposed to the drugs and actin filament response was measured by visualisation of actin organisation and partitioning of actin between Triton X-100 soluble and insoluble fractions. Tm5NM-1 induces stress-fibre formation whereas Tm3 induces small filipodia. Over-expression of Tm5NM-1 increases and Tm3 decreases partitioning of actin into the insoluble fraction relative to controls. Similarly over-expression of Tm5NM-1 increases the resistance of actin filaments to cytochalasin D and Latrunculin A as judged by Triton X-100 solubility and actin organisation. In contrast, Tm3 increases actin filament sensitivity to these drugs. The results suggest that Tm5NM-1 containing filaments exhibit slower turnover kinetics and are less susceptible to actin severing proteins than Tm3 containing filaments and that the Tms can directly regulate these processes.

**Translocation of Rho Gtpase Activity Zones Occurs via Cortical Flow and Signal Treadmilling**

H. A. Benink, W. M. Bement; Zoology, University of Wisconsin - Madison, Madison, WI

Single-cell wound healing depends on the closure of a dynamic array of actin and myosin-2. Responsible for the formation and closure of this array are segregated RhoA and Cdc42 activity zones that form rapidly upon wounding. Once established, these GTPase activity zones maintain their segregation and translocate in concert with the actin array as the wound closes. To elucidate the means that control zone translocation we have used live 4D confocal imaging of Xenopus oocytes, chemical inhibitors of flow, photoactivatable GTPase activity probes and Fluorescence Recovery After Photobleaching (FRAP). Our results reveal that both cortical flow and signal treadmilling (the result of localized GTPase activation / inactivation within the observed zones of activity) are responsible for GTPase activity zone translocation.

**Analysis of MIM and ABBA1, Two Homologous Regulators of the Actin Cytoskeleton**

P. K. Mattila,[1] J. Saarikangas,[1] M. Varjosalo,[2] J. Taipale,[2] M. Salminen,[1] P. Lappalainen[1]; [1]University of Helsinki, Institute of Biotechnology, Helsinki, Finland, [2]University of Helsinki, Molecular/Cancer Biology Program, Helsinki, Finland

The diverse essential functions of the actin cytoskeleton are regulated by a large number of actin-binding proteins. Two novel regulators of the actin cytoskeleton, MIM (missing in metastasis) and ABBA1, were recently identified from mammals. They are approximately 55 % identical to each other and are composed of an N-terminal actin filament bundling IMD domain and a C-terminal actin monomer-binding WH2 domain. Interestingly, MIM was recently also identified as an enhancer of Gli-dependent transcription of the Shh signalling pathway (Callahan et al., 2004). Our Northern blot and in situ hybridization analyses revealed that MIM and ABBA1 show distinct expression patterns. In adult mouse MIM is especially strongly expressed in liver, kidney and Purkinje cells, whereas ABBA1 is mainly expressed in spine and molecular layer of the cerebellum. Both proteins are also strongly expressed during the development. Over-expression of MIM and ABBA1 in various cell types resulted in the loss of stress fibers and appearance of abnormal actin structures and microspikes. To reveal the biological roles of these proteins, we have generated MIM knockout mice and are currently generating ABBA1 knockout mice. Mice lacking MIM are viable and do not display any gross abnormalities. The lack of obvious developmental defects in MIM -/- mice suggests that this protein does not play a central role in the Shh pathway during embryogenesis. To further investigate the role of MIM in Shh signalling, we carried out an in vitro Gli-lusiferace reporter assay in NIH-3T3 cells. Expression of MIM and ABBA1 had no effect on Hh signalling or on transcriptional activity with Gli1/2 in these cells. Together, these studies suggest that MIM and ABBA1 regulate certain specialized actin-dependent processes in mammals but do not significantly contribute to Shh signalling as previously suggested.

**Aberrant Cytoarchitecture Displayed by Skeletal Muscles Lacking Bpag1 Crosslinking Proteins**

S. Lambert-Giroux,[1] C. Boudreau-Larivière[2]; [1]Human Development Program, Laurentian University, Sudbury, ON, Canada, [2]School of Human Kinetics, Biomolecular Sciences, Laurentian University, Sudbury, ON, Canada

Bullous pemphigoid antigen 1 (Bpag1) crosslinking proteins are thought to interact with microfilaments (MFs), intermediate filaments (IFs) and microtubules (MTs) thereby integrating the functions of these cytoskeletal networks in a variety of tissue types including contractile cells. The objective of the present study was to determine the impact of Bpag1-deficiency on the protein expression levels of MF, IF and MT subunits, and on the subcellular localization of these cytoskeletal elements in skeletal muscle. Western blot analyses revealed significant reductions in the levels of α-actin (40%) and α-tubulin (35%) detected in skeletal muscle homogenates from homozygous Bpag1-deficient mice compared to those obtained from wild-type littermates belonging to the *dystonia musculorum ( $dt^{Tg4}$)* transgenic line. Desmin protein levels remained largely unaffected. Alterations in α-actin and α-tubulin protein levels are likely the result of post-transcriptional events because the levels of their respective mRNAs, as assessed by RT-PCR, were found to be similar in wild-type and Bpag1-deficient skeletal muscle. The subcellular localization of MFs, desmin IFs and MTs was assessed by fluorescence microscopy using longitudinal sections of hindlimb skeletal muscles and antibodies targeting desmin and α-tubulin and rhodamine-conjugated phalloidin to visualize the MF network. A significant number of fibers from the Bpag1-deficient muscles (70%; 150 fibers analyzed) displayed loss of desmin Z-line staining. Attenuated sarcoplasmic, subsarcolemmal and perinuclear α-tubulin staining was also observed in more than 50% (100 fibers analyzed) of muscle fibers lacking Bpag1. Finally, uneven actin sarcoplasmic staining patterns with a dramatic loss of staining within the subsarcolemmal compartment were documented for approximately 70% (250 fibers analyzed) of Bpag1-deficient fibers. Together, the findings suggest that these cytoarchitectural modifications are likely implicated in the development of the post-natal skeletal myopathy that occurs in homozygous *dt* mice. ### Regulation of RLC Phosphorylation by $Ca^{2+}$ Transients During Myofibrillogenesis

J. D. Eskew, M. Terry, H. Kalluri, M. B. Ferrari; School of Biological Sciences, University of Missouri - Kansas City, Kansas City, MO

Intracellular $Ca^{2+}$ transients regulate myofibrillogenesis. While a link between these physiological signals and sarcomere assembly is well-established, the molecular and biochemical links have not been elucidated. Multiple downstream effectors have been proposed, but involvement of the $Ca^{2+}$/CaM/MLCK/RLC cascade in regulating myosin thick filament assembly in embryonic skeletal and cardiac myocytes has the most experimental support. We are attempting to distinguish between two different models: that only MLCK activity (i.e. RLC phosphorylation) is required for myosin thick filament assembly, versus more complicated assembly kinetics involving both MLCK and myosin phosphatase (PP1M) activities. We are using ryanodine to block transients, ML-7 and pseudosubstrate peptides to inhibit MLCK, and tautomycin or M-subunit specific morpholinos to knock down PP1M activity. In addition, we are using caffeine superfusion to test the role of specific $Ca^{2+}$ transient parameters in regulating RLC phosphorylation. Extracts from treated myocytes are compared with paired control extracts using fluorescence 2D differential gel electrophoresis (DIGE). Spots of interest are cut from replicate silver-stained gels for MS identification and phosphopeptide analysis. Several RLC spots show significant pI shifts consistent with differences in phosphorylation state; these shifts are consistent with expectations. For example, ryanodine reduces while tautomycin increases the density of several acidic RLC spot variants, consistent with increased and decreased phosphorylation, respectively. When combined with cell physiological approaches (e.g. superfusion), these powerful proteomics methods enable the discovery and description of biochemical changes resulting from $Ca^{2+}$ transient production. Supported by NIH RO1 AR47579 to M.B.F. .

### FRET Imaging of Z-band Proteins in Living Skeletal Muscle Cells

A. L. Stout, J. Wang, J. M. Sanger, J. W. Sanger; Cell and Developmental Biology, University of Pennsylvania School of Medicine, Philadelphia, PA

In recent years, a large number of proteins associated with Z-bands in skeletal and cardiac muscle have been identified, but the three-dimensional arrangements of most of these proteins in immature and mature myofibrils are largely unknown. By combining sensitized emission FRET (Fluorescence Resonance Energy Transfer) imaging with quantitative analysis techniques, we are gaining new information about these arrangements that complements existing data obtained from in vitro assays such as yeast 2-hybrid experiments. Skeletal myotubes cultured from quail embryos were transfected to co-express CFP and YFP fusions with alpha-actinin, FATZ, telethonin, and myotilin in various pairwise combinations The FRET response, expressed as a percent efficiency, E%, was measured in Z-bodies of premyofibrils and nascent myofibrils and Z-bands of mature myofibrils. Multiple linear regression analysis was used to identify changes in E% that were correlated with CFP location on the protein (C- or N-terminus) after controlling for possible effects of other factors such as fusion protein expression level. Where relevant, we also used this approach to search for changes in E% correlated with the maturity of the myofibril (Z-body or Z-band). For example, in cells coexpressing CFP-FATZ and YFP-alpha-actinin, we found that in Z-bodies, E% was unaffected by the location of CFP while in Z-bands, E% was systematically higher when CFP was on the N-terminus of FATZ than when it was on the C-terminus. This result suggests that the conformation and/or flexibility of the FATZ molecule may change during myofibrillogenesis, possibly because of new protein-protein interactions that arise as Z-bands mature. Similar work was done with the myotilin/alpha-actinin pair, the FATZ/telethonin pair, and the FATZ/myotilin pair. Using our results and published results of in vitro assays, we have constructed a simple model describing the arrangement of these four proteins in Z-bands.

### Myofibrillogenesis in Skeletal Muscle Cells in Zebrafish

J. W. Sanger, A. Du, B. Holloway, J. Wang, J. M. Sanger; Cell and Developmental Biology, University of Pennsylvania School of Medicine, Philadelphia, PA

The premyofibril model that we have proposed to explain myofibrillogenesis suggests that the formation of mature myofibrils is preceded by two intermediary structures: premyofibrils and nascent myofibrils (Du et al., 2003; Sanger et al., 2005). To determine if this model applies to zebrafish, we stained developing embryos at 20 - 25 hours post-fertilization with antibodies to sarcomeric alpha-actinin and muscle myosin II. In the developing somitic muscle the proteins were localized in fibrils in patterns that appeared identical to those in fibrils detected in avian muscle cultures, i.e. premyofibrils, nascent myofibrils and mature myofibrils., Premyofibrils staining positively with phalloidin and with anti-alpha-actinin antibodies extended from end to end in elongated cells in the youngest somites. In older somites with mature myofibrils, premyofibrils were present at the ends of the cells, suggesting that as the cells grew longer, premyofibrils were involved in the elongation of myofibrils that accompanied cell growth. We assembled a plasmid encoding YFP-sarcomeric alpha-actinin with a zebrafish skeletal muscle alpha-actin promoter. Embryos

microinjected with this plasmid expressed YFP-alpha-actinin near the end of one day in Z-bodies and Z-bands in the skeletal muscle cells along the flank of the zebrafish. On day six post-fertilization myofibrils with YFP-alpha-actinin incorporated in Z-bands were visible in the mosaic transgenic zebrafish. The expression of this probe did not affect the contraction of mature myofibrils in the zebrafish. The dynamics of YFP-alpha-actinin measured in the Z-bands with FRAP (Fluorescence recovery After Photobleaching) analysis showed a recovery profile similar to those found for YFP-alpha-actinin dynamics in avian skeletal muscle Z-bands (Wang et al., 2005). These observations indicate that the zebrafish system will allow the details of myofibril formation to be examined directly in a live animal.

**Targeted Disruption of N-RAP Gene Function by RNA Interference: A Role for N-RAP in Myofibril Organization**

A. Dhume, R. Horowits; National Institute of Arthritis and Musculoskeletal and Skin Diseases, National Institutes of Health, Bethesda, MD

N-RAP is a muscle-specific protein concentrated in myofibril precursors during sarcomere assembly. We used RNA interference to achieve a targeted decrease in N-RAP transcript and protein levels in primary cultures of embryonic mouse cardiomyocytes. N-RAP protein knockdown was associated with decreased myofibril assembly, as assessed by alpha-actinin organization into mature striations, while cell spreading was not affected. The effect of N-RAP knockdown on alpha-actinin organization was partially rescued by expression of N-RAP-LIM-IB, a deletion mutant containing the N-RAP LIM domain and simple repeats, but omitting the super repeats. This construct allows normal assembly of alpha-actinin into mature striations, but disrupts sarcomeric actin organization (Carroll et al. *J Cell Sci 117:* 105-114, 2004). N-RAP-LIM-IB expression prevented N-RAP knockdown by siRNA at both the mRNA and protein levels. Therefore, the mechanism by which N-RAP-LIM-IB rescues myofibril assembly is likely to be by its affect on endogenous N-RAP expression. Transcripts encoding the N-RAP binding proteins alpha-actinin, Krp1, and MLP were expressed at normal levels during N-RAP knockdown, and alpha-actinin and Krp1 protein levels were also unchanged. Transcripts encoding muscle myosin heavy chain and nonmuscle myosin heavy chain IIB were also expressed at relatively normal levels. However, decreased N-RAP protein levels were associated with dramatic changes in the encoded myosin proteins, with muscle myosin heavy chain levels increasing and nonmuscle myosin heavy chain IIB decreasing. N-RAP transcript and protein levels recovered to normal by days six and seven, respectively, and the changes in myofibril organization and myosin heavy chain isoform levels were reversed. Our data indicate that myofibril assembly is closely linked to N-RAP protein levels, and that N-RAP protein levels regulate the balance between nonmuscle myosin IIB and muscle myosin by post-trancriptional mechanisms.

**Expression of Muscle-specific Calpain, p94/calpain3, at The N2A and M-line Regions of Connectin/titin during Myogenesis**

K. Ojima,[1,2] H. Sorimachi[1,2]; [1]Department of Enzymatic Regulation for Cell Functions, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan, [2]CREST, JST, Kawaguchi, Japan

Calpains comprise a large family of intracellular $Ca^{2+}$-requiring cysteine proteases, which cleave their substrates at limited and specific sites to modulate their functions, thus called “modulator proteases”. p94/calpain3 is predominantly expressed in skeletal muscles and the defect of its proteolytic activity causes limb-girdle muscular dystrophy type 2A. Furthermore, p94 binds to connectin/titin at the N2A and M-line regions shown by yeast two-hybrid studies, suggesting that p94 plays significant roles as a myofibrillar structural protein as well as a protease. However, it is unclear when p94 is localized to the specific regions of connectin/titin during the assembly of sarcomere structure. In this study, we examined spatio-temporal expression of p94 during myogenesis in relation to that of connectin/titin. RT-PCR and western blot analyses revealed that p94 and its splicing variants were detected immediately after muscle differentiation, and that their amount increased during development. At the early stages of muscle differentiation, p94 was distributed throughout myocytoplasm without any specific localization. One week after differentiation, p94 was expressed in the N2A and M-line regions of connectin/titin. Our results indicate that p94 is incorporated into its proper positions on connectin/titin after sarcomere structures are fully matured.

**Non-Sarcomeric Tropomyosin Isoforms Define Novel Filament Compartments in Skeletal Muscle Fibers**

N. E. Vlahovich,[1] S. Artap,[1] A. Kee,[1] G. Schevzov,[2] P. Gunning,[2] E. Hardeman[1]; [1]Muscle Development Unit, Children's Medical Research Institute, Westmead, Australia, [2]Oncology Research Unit, The Children's Hospital at Westmead, Westmead, Australia

Tropomyosins (Tms), a family of filamentous proteins consisting of over forty isoforms, play an important role in defining the function of actin filaments in both muscle and non-muscle cells. Isoforms are derived from four genes (alpha, beta, gamma and delta) and are produced through the use of alternative promoters and alternate RNA splicing. In non-muscle cells, Tm isoforms have been shown to be functionally distinct, playing roles in diverse processes such as cell growth, differentiation, cell division and vesicle transport. Using western blotting and immunofluorescence techniques with isoform-specific antibodies, we have identified a number of these non-muscle Tms in skeletal muscle fibers. These Tms were found to sort to distinct compartments in both developing and mature muscle cells. Tm5NM1, a product of the gamma gene, was found to localize to the sarcolemma and the Z-line associated cytoskeleton (Z-LAC). An antibody recognizing Tms 1, 2, 5b and 6, from the alpha and beta genes, demonstrated that these isoforms are present at the myotendinous junction. Tm4, from the delta gene, localizes to the myotendinous junction as well as the postsynaptic region of the neuromuscular junction. In addition, and surprisingly, Tm4 is present in a novel longitudinal pattern of immunofluorescence found in a subset of muscles including the extraocular, diaphragm and flexor digitorum brevis muscles. This unique pattern of Tm4 localisation can be induced in the soleus muscle in response to stretch suggesting that this structure is associated with tension or loading. These findings regarding Tm4 distribution may also provide a new classification of muscles based on extra-sarcomeric filament structures. Taken together, our observations suggest that different non-muscle Tms define distinct microfilament populations in muscle fibers.

**Functional Interaction of Protein 41R and M-line Titin in Sarcomere Assembly**

A. Zhou, S. Huang, E. J. Benz; Medical Oncology, Dana-Farber Cancer Institute, Boston, MA

A diverse array of red blood cell protein 4.1 (4.1R) isoforms is expressed in many non-erythroid tissues. In our previous work, we have shown that 4.1R localizes to the A-band of sarcomeres and associates with myosin, tropomyosin and actin. To further understand the role of 4.1R in skeletal

muscle sarcomere structure and function, yeast two hybrid assay and biochemical binding assay were used to characterize the binding ligands of 4.1R in skeletal muscle. We have further identified that 4.1R interacts with M-line titin. In this study, we attempted to understand the functional importance of the interaction between 4.1R and M-line titin. Immunofluorescent staining showed that 4.1R partially co-localized with M-line titin. Furthermore, an in vitro binding assay revealed that the amino acids encoded by exons 17-18 of 4.1R ($4.1R^{ex17-18}$) and the MIg9/10 domain of titin accounted for their interaction. To study the functional association of 4.1R and titin, we used adenovirally mediated gene transfers to over-express $4.1R^{ex17-18}$ in differentiating C2C12. In control GFP-infected myotubes, α-actinin and M8/9 titin assumed a striated distribution at the level of the Z-disk and M-line, respectively. However, over-expression of $4.1R^{ex17-18}$ altered the distribution and organization of M-line titin. The degree of M-line titin disruption correlated with expression levels of $4.1R^{ex17-18}$. Infected cells expressing low levels of $4.1R^{ex17-18}$ showed diffused M-line titin in the myoplasm with occasional striated periodicity in register with the M-line. Infected cells with high levels of $4.1R^{ex17-18}$ significantly reduced M-line titin striation and resulted in disorganized structures or large aggregates of titin in the myoplasm. These findings support the idea that the interaction of 4.1R with M-line titin may play a critical role in the assembly of M-line in striated muscle.

**Opposing Effects of Two Single Amino Acid Point Mutations Within the Myosin Motor Domain**

C. M. Dambacher,[1] A. F. Knowles,[2] W. A. Kronert,[1] J. A. Suggs,[1] S. I. Bernstein[1]; [1]Biology Department and Molecular Biology Institute, San Diego State University, San Diego, CA, [2]Chemistry, San Diego State University, San Diego, CA

Mutations within contractile proteins can engender various phenotypic abnormalities including skeletal muscle hypercontraction and cardiac hypertrophy. We investigated the *in vivo* and *in vitro* properties of two homozygous-viable *Drosophila* myosin mutants, *D45* (A261T) and $Mhc^5$ (G200D). In the case of the *D45* mutation, the single amino acid change resides near β7 (this β-strand and switch-2 flank a region which has been shown to move as a solid body), while the $Mhc^5$ mutation is located at the base of loop 1. Both regions have influence in regulating the rate of nucleotide exchange from the ATP-binding pocket. The mutation *D45* was originally identified as a suppressor of the troponin I (TnI) $hdp^2$ mutation, which causes muscle hypercontraction, resulting in a wings-up phenotype. The $Mhc^5$ mutation is lethal when co-expressed with $hdp^2$, presumably enhancing the hypercontraction phenotype. Ultrastructural analysis of flies expressing MHC containing the suppressor (*D45*) mutation revealed wild-type assembly and stability of myofibrils, while flies expressing myosin with the enhancer mutation ($Mhc^5$) display a severe hypercontraction phenotype visible by two days post-eclosion. Myosin containing the *D45* suppressor mutation has decreased $Ca^{2+}$ ATPase and reduced basal and actin-stimulated $Mg^{2+}$ ATPase as compared to the wild-type indirect flight muscle isoform (IFI). Myosin containing the $Mhc^5$ enhancer mutation showed a greater than two-fold increase in basal $Mg^{2+}$ but similar actin-stimulated $Mg^{2+}$ ATPase as the IFI. The average actin sliding velocity was reduced by two-fold for *D45* myosin, while $Mhc^5$ myosin shows a 15% increase in velocity of actin filament translocation as compared to the IFI. These results suggest that suppression of the TnI hypercontraction phenotype is accomplished by expression of a less-active MHC, while onset and enhancement of muscle hypercontraction can be achieved with expression of an overactive MHC isoform.

**Troponin I Heptad Hydrophobic Repeats (HR): Effect on Calcium Sensitivity of Vertebrate Striated Muscle Contraction**

M. Mukherjea, T. Chaudhuri, J. Randall, S. Sarkar; Anatomy & Cell Biology, Tufts University, Boston, MA

In vertebrates, striated muscle contraction is a $Ca^{2+}$ regulated process which is mediated through troponin (Tn). The Tn complex consists of three different proteins: troponin C (TnC) which binds $Ca^{2+}$, troponin I (TnI) which binds to actin and inhibits acto-myosin interaction, and troponin T (TnT) which attaches Tn to Tm. Among the inter-subunit interactions in the Tn complex, the binary interaction between TnI and TnT as well as its effect on Tn structure and function are not clearly understood. We previously identified and proposed that an evolutionarily conserved HR domain present in both TnI and TnT may be involved in a coiled-coil TnI-TnT heterodimer formation. To study the function of the TnI HR domain, we designed both point and deletion mutations in the HR and tested their influence on TnI-TnT binary interactions. Using different in vitro approaches like yeast-two-hybrid and affinity measurements, we observed that the TnI HR deletion mutants showed 60-70% lesser activity than the wild-type whereas the point mutations showed comparable activity, indicating that the HR domains are involved in TnI-TnT binary interaction. To characterize the biological function of HR motifs in TnI and the functional parameters of TnI-TnT interaction we tested how they regulate the $Ca^{2+}$ sensitivity of muscle contraction. We performed a reconstituted actomyosin ATPase assay to calculate the ATP hydrolysis rate of the myosin motor. We also over-expressed the wild-type and mutant TnIs in mouse myoblast cells and studied the effect of the different HR mutations on the efficiency of the myosin ATPase. Our results show that disruption of the TnI-TnT structural interaction, especially by the deletion mutants, inhibit the formation of the ternary Tn complex and significantly decreases the $Ca^{2+}$ sensitivity of the thin filament during striated muscle contraction.

**Troponin T: Role of the Fetal and α/β Exons on Calcium Sensitivity in Vertebrate Fast Skeletal Muscle during Development**

T. Chaudhuri, M. Mukherjea, S. Sachdev, S. Sarkar; Anatomy & Cell Biology, Tufts University, Boston, MA

In mammalian fast skeletal muscle, constitutive and alternative splicings from a single troponin T (TnT) gene produce multiple developmentally regulated and tissue specific TnT isoforms. Two exons, α and β, coding for two different 14 amino acid peptides are spliced in a mutually exclusive manner giving rise to the adult TnTα and the fetal TnTβ isoforms. In addition, an acidic peptide coded by a fetal (f) exon is specifically present in TnTβ and absent in the adult isoforms. To define the functional role of the f and α/β exons, we constructed different TnT cDNAs from a single human fetal fast skeletal TnTβ cDNA clone to circumvent the problem of N-terminal sequence heterogeneity present in wild-type TnT isoforms, irrespective of the stage of development. Nucleotide sequence of these constructs, viz. TnTα, TnTα+f, TnTβ-f and TnTβ are identical, except for the presence or absence of the α or β and f exons. Our results, using the recombinant TnT isoforms in different functional *in vitro* assays, show that the presence of the f peptide has a strong inhibitory effect on binary interactions between TnT and other thin filament proteins, TnI, TnC and tropomyosin. Tn complexes reconstituted with the four TnT isoforms showed different patterns of $Ca^{2+}$ sensitivities in the actomyosin-ATPase assay. The presence of the f peptide also led to reduced $Ca^{2+}$ dependent ATPase activity in the myofilament assay whereas the contribution of the α and β peptides in the biological activity of TnT was primarily modulatory. These results indicate that the f peptide confers an inhibitory effect on the biological function of fast skeletal TnT and this can be correlated with changes in the $Ca^{2+}$ regulation associated with development in fast skeletal muscle.

**Obscurin Depletion Inhibits Sarcomeric Myosin Integration and Thick Filament Organization in Skeletal Myofibrils of Developing Zebrafish Embryos**

M. O. Raeker,[1] A. Kontrogianni-Konstantopoulos,[2] S. B. Sutter,[1] A. B. Borisov,[1] R. J. Bloch,[2] S. E. Lyons,[3] M. W. Russell[1]; [1]Pediatrics, University of Michigan, Ann Arbor, MI, [2]Physiology, University of Maryland, Baltimore, MD, [3]Internal Medicine, University of Michigan, Ann Arbor, MI

Obscurin is a giant (~800 kD) sarcomere-associated protein whose interactions with titin and ankyrin suggest that it may have an important role in the assembly and structural support of striated myofibrils. To examine the potential role of obscurin during skeletal myofibrillogenesis *in vivo*, morpholino antisense oligonucleotides targeting the obscurin translation initiation site (MO1), the 5'UTR (MO2) or a corresponding control morpholino (5 base pair mismatch to MO1 or MO2) were injected into zebrafish embryos (1-4 cell stage). Injection of either MO1 or MO2 resulted in diminished obscurin expression and significant developmental defects including decreased numbers and marked disarray of skeletal myofibrils compared to controls. At the level of the sarcomere, obscurin depletion appeared to selectively disrupt M band assembly and thick filament organization; Z band architecture and spacing were preserved as documented by a normal pattern of α-actinin immunolocalization. Sarcomeric myosin localized diffusely in the skeletal muscle of the MO1- and MO2-injected embryos and was not organized into well-formed A bands. Interestingly, depletion of obscurin also caused an alteration in its own cellular distribution. Unlike control embryos in which obscurin localized primarily to the M band with some Z band staining, in MO1- and MO2-injected embryos, the M band localization was markedly diminished while the Z band staining was preserved. These results support a critical role for obscurin in the assembly and organization of the myosin thick filament array during vertebrate development. Furthermore, the diminished capacity to generate mature striated myofibrils in response to obscurin depletion suggests that it may have a vital role in the causation of or adaptation to cardiac and skeletal myopathies.

2371

**Localization of Obscurin in Skeletal Muscle Fibers**

A. L. Bowman, A. Kontrogianni-Konstantopoulos, D. H. Catino, H. Gonzalez-Serratos, R. J. Bloch; Physiology, University of Maryland, Baltimore, Baltimore, MD

Obscurin is a giant sarcomeric protein that is critical in the development of the A band and M line in skeletal muscle. Unlike nebulin and titin, obscurin surrounds myofibrils at the level of the M and Z lines. Our laboratory has generated antibodies to different regions of obscurin, the amino terminus, the carboxy terminus, and the Rho-GEF domain. All recognize the ~800 kDa form of obscurin in western blots of skeletal muscle, but they differ in their ability to bind smaller isoforms of obscurin. All three antibodies also recognize smaller bands, between ~75 and 200 kDa, but yield different patterns of these smaller bands. To assess the relationship of obscurin to the Z-disk, we used these antibodies to label extensor digitorum longus muscles stretched to sarcomere lengths ≥3.0μm. Immunofluorescence images revealed a doublet flanking the Z-disk of sarcomeres in stretched samples, but only single lines at Z-disks of sarcomeres at normal resting lengths (~2 μm). Preliminary analyses of the distances between the labeled structures in obscurin and the middle of the nearest Z-line suggest that the antibodies to the Rho-GEF domain label structures that are farther from the Z-line than antibodies to the carboxy terminus. Since these domains should be close enough to each other in the ~800 kDa form of obscurin to be indistinguishable by confocal microscopy, we hypothesize that the antibodies to the Rho-GEF domain selectively label one or more of the smaller isoforms of obscurin, that concentrate at distinct sites with respect to sarcomeres that separate from the Z-disk more readily upon stretching. Supported by a training stipend (T32 GM08181, to ALB), grants from the NIH (RO1 HL64304 and the Muscular Dystrophy Association (to RJB) and a Development Award to AKK from the Muscular Dystrophy Association.

**Expression of Tropomodulin1 in the Heart Rescues Embryonic Lethality of Tropomodulin1 Null Mice**

R. B. Nowak,[1] J. Moyer,[1] K. Fritz-Six,[1] C. Ferreira-Mota,[1] M. A. Sussman,[2] V. M. Fowler[1]; [1]Cell Biology, The Scripps Research Institute, La Jolla, CA, [2]Biology, San Diego State University, San Diego, CA

Tropomodulin1 (Tmod1) caps the pointed ends of actin filaments in striated muscle sarcomeres and in the erythrocyte membrane skeleton, and is first expressed at E7.5 of embryogenesis in myocytes of the developing heart tube and in blood islands of the yolk sac. Targeted deletion of the Tmod1 gene in mice leads to abnormal cardiac development, and defective vasculogenesis and hematopoesis in the yolk sac, followed by embryonic lethality between E9.5-10. We rescued the embryonic lethality of the Tmod1 knockout mouse by crossing with a TOT mouse that expresses a Tmod1 transgene in the heart under the control of the α-myosin heavy chain promoter. Genotyping of litters from crosses of Tmod1-/+;TOT+ mice with Tmod1+/- mice demonstrates that embryos with no endogenous Tmod1 but expressing the Tmod1 transgene (Tmod1-/-;TOT+) develop to term and that pups are viable and fertile. Western blotting and immunofluorescence staining demonstrates that Tmod1 protein is present only in the heart but not the blood cells of Tmod1-/-;TOT+ rescued embryos. In contrast to Tmod1 null embryos, which fail to undergo normal looping morphogenesis of the heart tube and have defective yolk sac vasculogenesis, the cardiac and yolk sac morphology of Tmod1-/-;TOT+ embryos are similar to wild type embryos. Immunofluorescence staining and confocal microscopy of hearts of E8-9.5 embryos demonstrates that myofibril assembly is grossly defective in the absence of Tmod1 but normal in Tmod1-/-;TOT+ embryos. We conclude that 1) Tmod1 expression in blood cells is not required for embryonic development or viability, 2) the absence of Tmod1 in blood cells does not lead to cardiac defects, 3) Tmod1 function in cardiac myocytes is directly required for cardiac development and function, 4) yolk sac defects are secondary to defects in cardiac development.

2373

**The Role of the Serine Rich Linker Regions of Nebulette and Nebulin in Myofibril Assembly**

Z. Panaviene,[1] K. J. Doane,[2] C. L. Moncman[1]; [1]Biochem, University of Kentucky, Lexington, KY, [2]Anatomy, Northeastern Ohio Universities College of Medicine, Rootstown, OH

Nebulette and nebulin are large modular proteins associated with the thin filament-Z-line complex of striated myofibrils. Both proteins contain an acidic N-terminal region, a large central repeat domain, a serine rich linker region and a C-terminal SH3 domain. We have previously demonstrated using nested deletions of GFP tagged nebulette constructs that the linker region was necessary for proper targeting of the repeat domain to the Z-lines. These data suggest that the linker region plays an important role in the assembly and stability of nebulette with the Z-lines. The recent

identification of the focal adhesion splice variant LIM-nebulette, that lacks the majority of the linker region supports this hypothesis. Expression of a nebulette cDNA containing the C-terminal splice variant of the LIM-nebulette or a nebulette cDNA completely lacking the linker region result in a membrane skeleton distribution of the recombinant protein. We have extended these studies by examining the ability of the nebulin and LASP1 linker regions to perform similar targeting functions in muscle and nonmuscle cells and have found that both linker regions perform targeting functions in their perspective cell types. These data further support an essential role for the linker regions of these proteins in their assembly and function. We are currently performing a yeast two hybrid screen to identify interacting proteins for the linker region.

2374

**The N-terminal Domain of the Cardiac Muscle Protein Nebulette Interacts with a Number of Different Proteins**

W. B. Holmes, C. L. Moncman; Biochemistry, University of Kentucky, Lexington, KY

Nebulette is a member of the nebulin family of proteins found only in cardiac muscle. Nebulette has the same domain layout as nebulin along with ~ 70% sequence homology. However, nebulette is much smaller than nebulin, ~ 110 kD for nebulette vs. 600 - 900 kD for nebulin. The N-terminal domains of nebulette and nebulin are highly acidic with pIs of 3.9 and 4.9 respectively. The N-terminal domains of both proteins are well conserved in animals. Tropomodulin interacts with repeat modules at the N-terminal end of nebulin however no function has been identified for the acidic N-terminal domain of nebulin or nebulette. The smaller size of nebulette indicates that interaction with tropomodulin is unlikely. To evaluate the functions of the nebulette N-terminal domain we have used the yeast two-hybrid system to screen a human heart cDNA library using a.a. residues 1-80 as bait. We have identified 15 unique interactions using the two-hybrid system, among these are: myosin binding protein-c, cyclin I, filamin, lin-7 and a number of proteins with unknown function that are present in the EST database from striated muscle. These results suggest a role for the N-terminal domain of nebulette in mediating nebulette interactions with many other proteins.

2375

**A Frequency of Calcium Oscillation Determines a Rate of Sarcomere Assembly in C2C12 Myotubes**

H. Fujita, T. Nedachi, M. Kanzaki; TUBERO, Tohoku University, Sendai, Japan

The assembly of sarcomere, the smallest contractile unit in striated muscle, is a complex and highly coordinated process that relies on spatial organization of numerous sarcomeric proteins. Recent finding has indicated that spontaneous $Ca^{2+}$ transient is important for sarcomere development, but the precise mechanism underlying this event is still unknown. In order to investigate relationship between $Ca^{2+}$ transients and sarcomere assembly, we took advantage of electrical pulse stimulation (EPS) that allows us to control the frequency of $Ca^{2+}$ transients through depolarizing the membrane potential. At 6 days after inducing differentiation of C2C12 myoblasts, they formed myotubes and expressed whole set of sarcomeric proteins required for $Ca^{2+}$-induced contraction, but they did not display any contractile activity in response to EPS because sarcomere architecture was not yet developed. However, EPS-induced repetitive $Ca^{2+}$ transients (1 Hz) for 2 hrs induced a marked increase in their contractile activity that occurred in concurrent with the development of sarcomere structure. Application of low frequency of EPS (0.1 Hz) required much longer period until the immobile myotubes acquire contractile activity. A persistent increase in intracellular $Ca^{2+}$ (not oscillatory) by high frequency of EPS (10 Hz) was incapable of inducing sarcomere assembly. We have also found that EPS-induced $Ca^{2+}$ transients increased calpain-mediated proteolysis of talin and its prevention by calpain inhibitor abrogated the EPS-facilitated assembly of functional sarcomere. In addition, modulation of integrin signals by adding collagen or RGD-peptide significantly affected the EPS-induced acquisition of contractile activity. Together, these results indicate that a period required for the development of functionally active sarcomere structure is dependent on a frequency of $Ca^{2+}$ oscillation. Our results also suggest an importance of the reorganization of the integrins/talin /α-actinin complex mediated through the calpain-induced talin cleavage.

**Viability in Cells with an Activated Dicentric Chromosome Requires the Central Spindle and Kar3p**

J. N. Molk, J. Haase, E. D. Salmon, K. Bloom; Biology, University of North Carolina, Chapel Hill, NC

Dicentric chromosomes undergo a breakage-fusion-bridge cycle *in vivo.* In budding yeast, activation of a conditional dicentric chromosome is lethal in the absence of the DNA repair gene *RAD52*. Defects in proteins that weaken kinetochore-microtubule attachments partially suppress the *rad52* lethality in strains that contain activated dicentric chromosomes. We investigated if the central spindle contributes to breakage and/or resolution of the dicentric chromosome. To weaken the central spindle, we used *ase1Δ* mutants. Ase1p localizes to the spindle midzone and is required for spindle integrity during anaphase. Unexpectedly, the viability of cells with an activated dicentric chromosome in *ase1Δ* was decreased and was similar to deletion of *RAD52*. Therefore, central spindle function is required for cells to survive following activation of the dicentric chromosome and is separable from kinetochore function. In support of this hypothesis, the loss of several microtubule plus-end binding proteins (Bik1p, Slk19p, Cik1p, and Kar3p) resulted in low viability in cells with an activated dicentric chromosome. Bik1p and Slk19p have been implicated in maintaining spindle integrity where microtubule plus-ends overlap. To determine if Kar3p could act in a similar manner, we imaged Kar3p-GFP and found that Kar3p localizes to the mitotic spindle in early to mid-anaphase. We propose Kar3p, associated with Cik1p, functions at the plus-ends of overlapping microtubules in the spindle midzone to provide structural support during anaphase. In the presence of an activated dicentric chromosome, inward forces pulling the spindle poles together promotes spindle disassembly. Kar3p and other proteins at the plus-end in the central spindle may resist this force to allow recovery from the dicentric arrest.

2377

**Kar3 Dimerization with Cik1 Enhances Motor Velocity**

H. M. Annie Chu,[1] M. Yun,[2] D. E. Anderson,[1] H. Sage,[3] H. W. Park,[2] S. A. Endow[1]; [1]Cell Biology, Duke University, Durham, NC, [2]Structural Biology, St. Jude Children's Research Hospital, Memphis, TN, [3]Biochemistry, Duke University, Durham, NC

Kar3, a Kinesin-14 microtubule motor of *S. cerevisiae* required for mitosis and karyogamy, or nuclear fusion after mating, reportedly interacts *in vivo* with Cik1, a nonmotor protein, through its central, predicted coiled-coil domain. Although other workers have reported that neither Kar3 nor

Cik1 forms homodimers *in vivo*, we show here that purified Kar3 is a dimer *in vitro*, as assayed by sedimentation equilibrium ultracentrifugation. The protein appears as paired particles by rotary shadow electron microscopy (EM) and circular dichroism (CD) spectroscopy of the Kar3 stalk shows helical characteristics, indicating that dimerization of the protein probably occurs by coiled coil formation. CD analysis of the nonmotor region of purified Kar3/Cik1 protein indicates even higher helicity than observed for the Kar3 stalk, and, strikingly, rotary shadow EM reveals a large single or two smaller particles attached to a stalk, which is not visible in Kar3. Analytical ultracentrifugation shows that Kar3/Cik1 is a dimer at low concentration (2.58 μM). The Kar3/Cik1 motor moves on microtubules at a velocity of 2-2.4 μm/min, 2-5 fold faster than Kar3, and destabilizes microtubules at the lagging ends. Thus, structural changes in Kar3 occur upon dimerization with the Cik1 nonmotor protein that convert it into a faster motor. These changes are likely to regulate Kar3 motor activity *in vivo.*

2378

**Kidins220/ARMS-Containing Vesicles are Transported to the Central Region of Growth Cones through Complexes with KIF3A, KIF3C and KAP3A**

Y. H. Liao, W. W. Liu, S. M. Hsu, P. H. Huang; Graduate Institute of Pathology, National Taiwan University College of Medicine, Taipei, Taiwan Republic of China

In polarized neurons, kinesin superfamily proteins (KIFs) are the motors responsible for targeting membranous or non-membranous cargos to axons and dendrites. Among them, KIF3C, when associated with KIF3A, is proposed as a membranous vesicle-associated motor. However, the cargos for the KIF3A/3C complex have not been identified. Kidins220 (kinase D-interacting substrate of 220kD), also known as ARMS (ankyrin repeat-rich membrane spanning), accumulates at the tips of growing axons in cultured neurons and those of NGF-treated PC12 cells, but the molecular mechanism for such specific localization remains unknown. Here, we demonstrate a direct interaction of Kidins220 with KIF3C, KIF3A, and KAP3A in neurons, but not with KIF3B. Using yeast two-hybrid screening and co-immunoprecipitation assay, we identify that the C-terminal region of Kidins220 is essential for the interactions. By using in vitro cultured neuronal cells and in vivo sciatic nerve ligation experiments, we show that Kidins220 is anterogradely transported along axons and is focally enriched in the central region of growth cones. Moreover, by RNAi approach against KIF3 complex and the expression of dominant-negative KIF3A/KIF3C, the targeting of Kidins220 to the tips of neurite is inhibited. Furthermore, the expression of Kidins220ΔC construct that disrupts Kidins220-KIF3 binding interferes with the localization of Kidins220 at the tips of neurite in PC12 cells. The above evidence indicates that the targeting of Kidins220 to the tips of neurites depends exclusively on its C-terminal region and partially on the presence of KIF3A, KIF3C and KAP3A. By electron microscopy, Kidins220 is associated with 100 to 220 nm, electron-lucent, membranous vesicles. Taken together, our studies indicate that Kidins220 resides in membranous vesicles and targets to the tips of neurites through interaction with KIF3A/KIF3C/KAP3A complex.

**The KIF3 Motor Transports N-cadherin and Organizes the Developing Neuroepithelium**

J. Teng,[1] T. Rai,[1] Y. Tanaka,[1] Y. Takei,[1] T. Nakata,[1] M. Hirasawa,[2] A. B. Kulkarni,[2] N. Hirokawa[1]; [1]Department of Cell Biology and Anatomy, University of Tokyo Graduate School of Medicine, Tokyo, Japan, [2]Functional Genomics Section, Craniofacial Developmental Biology and Regeneration Branch, National Institute of Dental and Craniofacial Research, National Institutes of Health, Bethesda, MD

In the developing brain, the organization of the neuroepithelium is maintained by a critical balance between proliferation and cell−cell adhesion of neural progenitor cells. The molecular mechanisms that underlie this are still largely unknown. Here, through analysis of a conditional knockout mouse for the *Kap3* gene, we show that post-Golgi transport of N-cadherin by the KIF3 molecular motor complex is crucial for maintaining this balance. N-cadherin and beta-catenin associate with the KIF3 complex by co-immunoprecipitation, and colocalize with KIF3 in cells. Furthermore, in KAP3-deficient cells, the subcellular localization of N-cadherin was disrupted. Taken together, these results suggest a potential tumour-suppressing activity for this molecular motor.

**Functional Coordination of Intraflagellar Transport Motors in *C elegans* Neurons**

G. Ou,[1] O. E. Blacque,[2] J. J. Snow,[1] M. R. Leroux,[2] J. M. Scholey[1]; [1]Center for Genetics and Development, Section of Molecular & Cellular Biology, University of California, Davis, Davis, CA, [2]Department of Molecular Biology and Biochemistry, Simon Fraser University, Burnaby, BC, Canada

Cilia play diverse roles in motility and sensory reception, and defects in their functions contribute to ciliary diseases. Intraflagellar transport (IFT) motors assemble and maintain cilia by transporting ciliary precursors, bound to protein complexes called IFT particles, from the base of the cilium to their site of incorporation into ciliary structures. In *Caenorhabditis elegans,* this is accomplished by two IFT-motors, kinesin-II and OSM-3 kinesin, which are both members of the kinesin-2 family. These motors cooperate to form two sequential anterograde IFT pathways, the “middle” and “distal” segment pathways, that build distinct parts of cilia. By watching fluorescent IFT-motors and IFT-particles move along the cilia of numerous ciliary mutants, we identified three ciliary proteins that mediate the functional coordination of these motors. The Bardet-Biedl Syndrome (BBS) proteins, BBS-7 and BBS-8 are required to stabilize complexes of IFT-particles containing both IFT-motors because in *bbs-7 and bbs-8* mutants, IFT-particles break down into two subcomplexes, A and B, which are moved separately by kinesin-II and OSM-3-kinesin, respectively. A novel, conserved ciliary protein, DYF-1, is specifically required for OSM-3-kinesin to dock onto and move IFT-particles, since in *dyf-1* mutants, OSM-3-kinesin is inactive and intact IFT-particles are moved by kinesin-II alone. These findings implicate BBS ciliary disease proteins and a novel kinesin-2 activator in the formation of two IFT pathways that build functional cilia. Similar screens of ciliary mutants are being used to identify cargo molecules as well as additional regulatory proteins that mediate the functional coordination of these IFT-motors.

**The Roles of Kinesin Motor Proteins in Spermatid Differentiation in *Marsilea vestita***

F. Deeb, S. M. Wolniak; Cell Biology and Molecular Genetics, University of Maryland, College Park, MD

The microspore of the water fern *Marsilea vestita* contains a single cell that undergoes a series of nine successive mitotic divisions to produce 32 spermatids, six sterile jacket cells and one prothallial cell. After the dry microspore is placed into water, cytoplasm reorganization precedes the first

division; certain proteins and mRNAs aggregate into zones that later become the spermatogenous initials of the gametophyte. Our results indicate that some proteins and some mRNAs become redistributed by kinesin-driven movements along cytoplasmic microtubules. Gametophyte development relies on the translation of stored mRNAs, and we developed RNAi strategies to target the degradation of specific mRNAs to arrest development. These published studies show that the temporal and spatial patterns of translation in the gametophyte are precisely ordered. Centrin translation occurs exclusively in spermatogenous cells and is required for the *de novo* formation of basal bodies. Various tubulin isoforms become localized in the spermatogenous cells and are essential for nuclear shaping and ciliogegnesis. We are studying how different kinesins affect development, cell fate, and differentiation during spermiogenesis. dsRNA probes were made from cDNAs encoding seven different kinesin isoforms isolated from our gametophyte library. The dsRNAs were added to populations of developing gametophytes to assess the time and stage of development at which each transcript becomes limiting. Two kinesin knockdowns show no effects on development while the others alter division patterns at specific developmental stages. The disruption of the pattern of cell divisions in the gametophyte predicts changes in cell fate that are manifested by changes in centrin translation and β-tubulin localization patterns. The loss of kinesin-based movements at particular times during gametophyte development effectively results in changes in cell fate determination. (Supported by NSF grant MCB-0234423 to SMW).

### A Truncated *Leishmania* K39 Kinesin Protein Binds Along Cortical Microtubules in an ATP-Dependant Manner and Accumulates at the Tip of the Cell

N. J. Gerald, D. M. Dwyer; Lab of Parasitic Diseases, NIAID, NIH, Bethesda, MD

Kinesins are a superfamily of microtubule motor proteins with diverse functions that include trafficking, signal transport and microtubule reorganization in eukaryotic cells. Patients with the parasitic disease visceral leishmaniasis mount a strong immune response against the *Leishmania* kinesin K39, indicating that parasites produce this protein during the course of infection. However, the role of K39 in the cell biology of *Leishmania* remains unknown. To investigate the function of this kinesin in L. donovani, we expressed GFP fusions to different K39 domains in promastigote cells. The motor domain (HEAD) localized diffusely throughout the cytoplasm, while the coiled-coil C-terminus (TAIL) localized to the anterior and posterior ends the cell. The motor domain combined with 65% of the coiled-coil tail (HCC) accumulated in a bolus at the posterior end of the cell near the tips of cortical microtubules. To test the association of these proteins with microtubules, cells were extracted with detergent to isolate the insoluble microtubule cytoskeletons. Western blots demonstrated that native K39, HEAD, TAIL, and HCC proteins were all largely solubilized with detergent. When ATP was depleted prior to detergent extraction, native K39 and HCC protein showed increased binding to microtubule cytoskeletons. The HEAD and TAIL proteins remained soluble after ATP-depletion. Microscopy of ATP-depleted cytoskeletons revealed that HCC was loaded prominently along the lengths of cortical microtubules leading to the posterior end of the cell. Microtubule associated HCC was released back into the supernatant with the addition of fresh ATP. These results are consistent with an ATP dependent kinesin motor that traffics along cortical microtubules to their tips at the posterior end of the cell.

### K-165: An Organelle Motor in the Squid Giant Axon

J. A. DeGiorgis, P. E. Gallant, T. S. Reese, J. A. Galbraith; Laboratory of Neurobiology, National Institutes of Health, Bethesda, MD

Conventional kinesin, the founding member of a diverse and functionally important group of molecular motor proteins, was discovered in the North Atlantic Squid, *Loligo pealei*. While its role was attributed to moving vesicles along microtubules, little evidence links the motor activity of conventional kinesin to vesicle translocation. Here, we identify a second kinesin in squid by analysis of a nucleotide sequence from a new Expressed Sequence Tag (EST) database representing RNAs expressed in the squid stellate ganglia. A peptide polyclonal antibody raised against this new kinesin identified seven clones in an optic lobe expression library, each of which overlapped with the kinesin EST sequence. This antibody recognized an ~165-kDa band in immunoblots while anti-conventional kinesin antibodies recognize a band at 110 kDa. Mass spectroscopic analyses of the ~165 kDa (K-165) and 110 kDa (K-110) bands yielded peptides that matched the predicted amino acid sequence of the new kinesin and conventional kinesin respectively. Thus, this new kinesin (K-165) and conventional kinesin (K-110) are products of different genes and antibodies raised against these two kinesins are specific to their respective gene products. Further immunoblot analyses demonstrated that the K-165 protein is highly enriched in sucrose density gradient fractions of KI-washed axoplasmic organelles. The K-165 antibody also decorates axoplasmic organelles in extruded axoplasm by immuno-gold electron microscopy. These data demonstrate that there are at least two kinesins in the giant axon, that K-165 is tightly associated with organelles, and is a candidate to be an organelle motor.

2384

### $PIP_3$ Transport by GAKIN, a Kinesin 3 Family Protein, Regulates Neuronal Polarity

K. Horiguchi, T. Hanada, A. H. Chishti; Department of Pharmacology and UIC Cancer Center, University of Illinois, College of Medicine, Chicago, IL

Phosphatidylinositol 3,4,5-trisphosphate (PIP3), a product of PI 3-kinase, is an important second messenger implicated in signal transduction and membrane transport pathways. In hippocampal neurons, the accumulation of PIP3 at the tip of axon regulates the axon-dendrite specification and neuronal polarity formation. Here, we show that a kinesin-like protein GAKIN/KIF13B directly interacts with a PIP3-interacting protein, PIP3BP/Centaurin-alpha, and mediates the transport of PIP3-containing vesicles. The FHA domain of GAKIN mediates the interaction with PIP3BP. The interaction is specific for GAKIN; since human KIF13A, the closest homologue of GAKIN, does not bind to PIP3BP. Recombinant GAKIN and PIP3BP form a complex on synthetic liposomes containing PIP3, and supports the motility of the liposomes along microtubules *in vitro*. In differentiating PC12 cells, both GAKIN and PIP3BP localized at the tip of the growing neurites. PIP3, as monitored by GFP-PH domain of AKT (GFP-AKT-PH), was also found at the tip of the neurites. Overexpression of DN-GAKIN, which is the motor domain deleted construct, significantly reduced the accumulation of PIP3 at the neurite tips. In cultured hippocampal neurons obtained from mouse embryo, PIP3 accumulation was observed at the tip of axons. Overexpression of DN-GAKIN inhibited the accumulation of PIP3. Importantly, heterologous expression of DN-GAKIN in hippocampal neurons induced morphological changes with highly branched dendrites, and resulted in the loss of axonally differentiated neurites as determined by tau-1 monoclonal antibody staining. Together, these results suggest that GAKIN- PIP3BP complex mediates the transport of PIP3 containing vesicles in neuronal cells and contributes to the accumulation of PIP3 at the axon tip, which in

turn regulates the axon-dendrite specification and neuronal polarity formation *in vivo*.

**Localization and Expression of Kinesin Motor Proteins in Cancer Cells**

K. M. Bartoli, W. S. Saunders; Biochemistry and Molecular Genetics, University of Pittsburgh, School of Medicine, Pittsburgh, PA

Kinesin motor proteins play an important role in transportation of specific intracellular cargoes along microtubules. Some kinesins have been implicated in mitosis and are important for proper cell division. Recent studies suggest that some motor proteins are mislocalized as well as overexpressed in cancer cells leading to mitotic defects. This led us to systematically compare the expression and distribution of mitotic kinesin motor proteins in untransformed primary and tumor cells. We found striking differences for kinesin-like DNA binding protein (KID), involved in chromosome orientation during mitosis, and kinesin 5- Eg5, involved in bipolar spindle formation and microtubule sliding. Both proteins have previously been demonstrated to localize diffusely throughout the nucleus in some cell types. In this present study, we show that during interphase these motors each localize to the nucleolus of primary cells. However, in most tested cancer cell lines the nucleolar localization was not observed but the motors were instead diffusely localized in the nucleus. We are currently testing a model whereby mitotic motors are normally sequestered, and perhaps inactivated, in the nucleolus during interphase. Loss of the sequestration in cancer cells may promote a return to mitosis or be a consequence of abnormal cell cycle regulation in malignant cells.

**Characterization of Mouse Kif26a, a Putative Vab-8 Orthologue**

E. Cid,[1] C. Zhan,[1] P. Höök,[2] R. Vallee,[2] M. Hatten[1]; [1]The Rockefeller University, New York, NY, [2]Pathology and Cell Biology, Columbia University, New York, NY

The aim of this study is to characterize KIF26A, a member of the N-11 kinesin family. Vab-8 is a *C. elegans* kinesin involved in neuroblast posterior migration and axon extension. Sequence comparisons between VAB-8 and mouse proteins resulted in the identification of KIF26A as a putative orthologue. It has a long N-terminal region before its kinesin motor domain, a neck region, and a short coiled coil segment at the carboxyl end. *Mm*KIF26A was cloned using RT-PCR and granule neuron phage library screening. Its expression pattern was determined by Northern Blot, RT-PCR and in situ hybridization. It is mainly restricted to the nervous system during embryogenesis. At E14.5 is localized in the cortex ventricular zone and cortical plate, in the spinal cord and sympathetic ganglia among other regions. In postnatal day 6 is present in the rostral migratory stream and olfactory bulb. In order to study the protein distribution a polyclonal antibody was raised against KIF26A. Immunolocalization in transfected COS7 cells showed a speckled pattern for KIF26A. The motor domain was overexpressed in bacteria as a GST fusion protein and its basal ATPase activity measured (188.1±14.6 nmol $P_i \cdot min^{-1} \cdot mg$ at 37°C). Two-hybrid analyses were also carried to assay a possible interaction between the kinase Unc51.1 and KIF26A. This interaction as has been described between their *C. elegans* counterparts UNC-51 and VAB-8. Correspondingly, the C-terminal half of the kinase interacts weakly with the central domain of KIF26A. In conclusion, KIF26A has been localized in the nervous system and is present in regions undergoing cell movements and axon extension. It also shares structural and functional characteristics with VAB-8 suggesting that it is a truly orthologue. More functional assay will clarify the role of KIF26A in neuroblast migration and axon extension in the mouse model.

**Exposure of the Auxiliary Microtubule Binding Site in the Tail of Kinesin-1 Increases Processivity**

D. D. Hackney; Department of Biol. Sciences, Carnegie Mellon Univ., Pittsburgh, PA

Conventional kinesin-1 contains an auxiliary MT binding site (ABS) in the tail that is masked in folded full length DKH975, exposed in weakly folded DKH945 and DKH937 and lost in DKH894 (Nature Cell Biol. 2, 257 (2000)). Fusions between gelsolin and C-terminal truncations of kinesin have now been generated so that the influence of the ABS on processive movement can be monitored at the single molecule level by the method of Yajima et al (Curr.Biol. 12, 301 (2002)) that utilizes the ability of gelsolin to cap short fluorescently-labeled actin filaments. In agreement with the results of Yajima et al on short kinesin constructs lacking the ABS, DKH412GS moves in short runs along axonemes adsorbed to glass. Complexes of DKH941GS with F-actin, however, usually continue all the way to the end of an axoneme without dissociation. Thus exposure of the auxiliary MT binding site in DKH941GS significantly increases motile processivity. Furthermore, the sliding velocity of DKH941GS is not significantly decreased compared to DKH412GS and thus the ABS increases net MT affinity without binding so tightly as to impose a load that slows the rate of movement. DKH941GS also tends to remain attached on reaching the end of the axoneme and it accumulates in a bright fluorescence clump at the plus end. When the axonemes or microtubules are free in solution, they rapidly aggregate into asters with clumps of fluorescently-labeled DKH941GS at the foci. Thus even conventional kinesin-1 is capable of producing an accumulation of cargo molecules (F-actin in this model) at the plus ends of microtubules when its auxiliary MT binding site is exposed. The assistance of M. Parepally in cloning is gratefully acknowledged.

**What Backstepping Tells Us About Kinesin Head Coordination**

N. R. Guydosh,[1] S. M. Block[2]; [1]Biophysics, Stanford University, Stanford, CA, [2]Biological Sciences and Applied Physics, Stanford University, Stanford, CA

The kinesin motor utilizes energy from ATP hydrolysis by both of its head domains to power processive motion over long distances. To maintain this processivity, the kinetic cycles of the two heads must be maintained out of phase (‘gated’) to ensure that at least one head remains tightly bound to the microtubule track at all times. Two broad classes of models explain this gating by invoking the effect of intermolecular strain that is generated at the point in the cycle when both heads are bound to the microtubule. In one class of models, rearward strain inhibits the front head until the back head catches up. In the other class, forward strain releases the back head before the front head proceeds prematurely. We tested these alternatives at the single-molecule level by probing the kinesin kinetic cycle using analogs of ATP and inorganic phosphate. Steps taken by native squid kinesin molecules bound to beads in an optical trap under force-clamped conditions were scored in the presence of ATP and beryllium fluoride ($BeF_x$). Binding of $BeF_x$ interrupts normal stepping by inducing long pauses. These events occur most often at high hindering loads or low

[ATP]. Our data are consistent with $BeF_x$ binding to the rear head before ATP can bind to the front head to trigger a normal forward step. During long pause events, we were able to resolve numerous short-lived backsteps of 8 nm. We found that normal forward stepping only resumed after a final, obligatory backstep, during which $BeF_x$ was presumably released from the front head. We conclude that the affinity of the front head for $BeF_x$ is reduced by strain while the back head remains unaffected, supporting models where strain leads to processivity by inhibiting the front head from productive nucleotide binding.

2389

**Force Generation by Ncd *in vitro* and in the Spindle**

S. A. Endow,[1] C. D. Yankel,[1] S. S. Rosenfeld[2]; [1]Cell Biology, Duke University, Durham, NC, [2]Neurology, Columbia University, New York City, NY

*Drosophila* Ncd is a nonprocessive minus-end Kinesin-14 spindle motor with a tail, coiled-coil stalk and C-terminal motor domain. We recently reported a new crystal structure of the dimeric motor showing a large displacement of the stalk compared to previous structures, indicating that the stalk can rotate and may act like a lever arm. FRET experiments now show a rapid movement of the stalk towards the microtubule after motor binding and away from the microtubule after hydrolysis, prior to motor release from the microtubule, identifying the steps at which the Ncd stalk moves and could amplify force. Analysis of live null-mutant oocytes and embryos expressing HeadlessNcdVenus and TaillessNcdVenus fluorescent proteins show that the Ncd tail is essential for binding to spindle microtubules and centrosomes. Fluorescence photobleaching experiments indicate that Ncd binding to meiotic spindles is primarily by the tail. The abnormal meiotic spindles of HeadlessNcd oocytes show that binding by both the Ncd head and tail to spindle microtubules is needed for spindle assembly. Mitotic spindles of HeadlessNcd embryos appear almost normal, suggesting that the role of Ncd in mitosis may be to crosslink microtubules to one another and attach chromosomes to the spindle, rather than to produce force for microtubule or chromosome movement.

2390

**High-Resolution Cryo-electron Microscopy on KIF1A-Microtubule Complex**

M. Kikkawa,[1] N. Hirokawa[2]; [1]Cell Biology, Univ. of Texas, Southwestern, Dallas, TX, [2]Cell Biology & Anatomy, Univ. of Tokyo, Graduate School of Medicine, Tokyo, Japan

Kinesin is a microtubule-based motor using ATP as the energy source. To understand how the chemical energy derived from ATP hydrolysis is converted to mechanical energy, we have been studying the structures of kinesin. Although previous X-ray crystallographic studies reveal two key conformations of the kinesin motor domain, the lack of high-resolution structures of the kinesin-microtubule complex prevents unambiguous correlation between a particular conformation and the nucleotide state. i.e. In the absence of microtubules, presumed ATP-like structures were observed even when ADP was bound, and a presumed ADP structure was observed with an ATP analogue. To clarify this and other issues, here, we used high-resolution cryo-electron microscopy and helical image analysis to obtain 10 Å resolution structures of the monomeric kinesin KIF1A-microtubule complex. By comparing the ADP- and the AMPPNP-state structures, we visualized most of the nucleotide-dependent conformational changes in the complex, including the switch II cluster, the neck linker, and the core rotation. These conformational changes are tightly coupled to the nucleotide-state. We also observed that the nucleotide-binding pocket is open in the ADP state, while the pocket is closed in the AMPPNP state. These structures are not observed in X-ray crystallographic structures, suggesting that the open/closed states of the nucleotide-binding pocket depend mainly on microtubules. Based on the new result, we propose a novel universal force generating mechanism, namely, “random diffusion & biased capture model”, which can explain asymmetric hand-over-hand movement of the dimeric kinesin as well as single-headed kinesin movement.

2391

**Stalk Region of Kinesin-related Protein Unc104 Has Moderate Ability to Form Coiled Coil Dimer**

Y. Shimizu,[1] H. Morii,[2] T. Shimizu,[2] F. Arisaka,[3] M. Tanokura[1]; [1]Grad. Sch. Agricult. Life Sci., Univ. Tokyo, Bunkyo-ku, Tokyo, Japan, [2]Inst. Biol. Resourc. Funct., Natl. Inst. Adv. Indust. Sci. Technol., Tsukuba, Japan, [3]Grad. Sch. Biosci. Biotechnol., Tokyo Inst. Technol., Yokohama, Japan

Unc104/KIF1A, a kinesin family member, is reported to be monomeric in solution, though its polypeptide has regions that potentially form coiled coils. It is also reported to carry synaptic vesicles along microtubules in nerve cells at a speed of 1.2 μm/s and that the movement is likely to be processive. The ‘hand-over-hand’ mechanism is proposed for processive movement of certain molecular motors, but for such a mechanism, dimerization of the protein would be necessary. To better understand the mechanism underlying Unc104/KIF1A’s motility, therefore, it is important to evaluate its dimerization ability. Thus, we have analyzed the stalk region of Unc104 from *C. elegans* by our program Amphisearch to confirm that several regions would have potential to form coiled coils. Based on this analysis, more than 20 peptides were synthesized. The CD measurements for those fragments indicated that the peptides having a common region (N358-K379) showed spectra characteristic to α-helix, while the peptides covering the other regions were likely to be random coils. Dimerization of the peptides described above by coiled coil formation was confirmed by analytical ultracentrifugation. From the concentration dependence of the CD spectra, the monomer-dimer dissociation constant Kd was estimated to be about 5 μM (slightly less than 1 mg prot./ml), considerably higher than that of the corresponding segment of human kinesin (62 nM). Though its dimerization ability is moderate, Unc104/KIF1A could nonetheless dimerize and, therefore, could move by the same mechanism as human kinesin when its concentration would get high. This further suggests that the motility of Unc104/KIF1A is controlled by the protein concentration.

2392

**Structure-Function Relationships of the Kinesin Superfamily Proteins (KIFs)**

H. Miki, Y. Okada, N. Hirokawa; Cell Biology and Anatomy, University of Tokyo, Bunkyo-ku, Japan

Kinesin superfamily proteins (KIFs) play fundamental roles in the intracellular transport system, which is essential for cellular function and morphology. KIFs are molecular motors which have been shown to transport organelles, protein complexes, and mRNAs to specific destinations along microtubules while hydrolyzing ATP for energy. KIFs also participate in chromosomal and spindle movements during mitosis and meiosis. It

is the first large protein family in mammals whose constituents have been completely identified and confirmed both *in silico* and *in vivo*. Numerous studies have revealed the structures and functions of individual family members, however the relationships between members or a perspective of the whole superfamily structure remain elusive. Here we present a comprehensive perspective based on a large, systematic phylogenetic analysis of the kinesin superfamily. All available sequences in public databases were analyzed to yield the most complete phylogenic kinesin tree thus far, comprised of 623 KIF sequences from all four biological kingdoms, animalia, plantae, fungi and protista. Over 98% of these KIFs are affiliated with 14 families. The clustering of KIFs to form groups that constitute subfamilies leading to the formation of families reveal the structural features that enlighten the cellular function of respective families. This comprehensive classification builds on the standardized nomenclature for kinesins and allows systematic analysis of the structural and functional relationships within the kinesin superfamily. Our full tree, viewable at our homepage (http://cb.m.u-tokyo.ac.jp/) is mainly comprised of uncharacterized KIFs, as the precise cellular function of relatively few have been elucidated. We hope this tree will aid in navigation through the unmapped areas of intracellular trafficking.

## Cilia & Flagella II (2393-2419)

2393

### Tissue Homeostasis is Regulated by the Primary Cilium in Fibroblasts

L. Schneider,[1] G. Pazour,[2] E. K. Hoffmann,[1] P. Satir,[3] S. T. Christensen[1]; [1]Department of Biochemistry, IMBP, The August Krogh Building, University of Copenhagen, Copenhagen, Denmark, [2]Program in Molecular Medicine, University of Massachusetts Medical School, Worchester, Copenhagen, MA, [3]Department of Anatomy and Structural Biology, Albert Einstein College of Medicine of Yeshiva University, Bronx, NY

We recently showed that the growth-arrest specific receptor tyrosine kinase, PDGFRα, is targeted to the primary cilium during growth arrest in NIH3T3 cells and primary cultures of mouse embryonic fibroblasts, MEFs [Schneider et al. (2005) Submitted]. PDGF-AA-induced activation of PDGFRαα in the cilium is followed by activation of the mitogenic Akt and the Mek1/2-Erk1/2 pathways and cell cycle entrance. Quiescent MEFs derived from *Tg737*$^{orpk}$ mutants fail to up-regulate PDGFRα, to form normal cilia and to activate Mek1/2-Erk1/2 and re-enter the cell cycle after stimulation with PDGF-AA. Here we investigated the role of the primary cilium in tissue homeostasis, in which MEFs were serum starved for 48 h to induce growth arrest. In wt cells, growth arrest was associated with activation of p53 by phosphorylation on serine in position 15. Wt cells remained viable and showed p53 phosphorylation for at least 144 h of serum starvation. In contrast, *Tg737*$^{orpk}$ mutants had a low level of phospho-p53 and after 96 h of serum starvation cells began to die by formation of apoptotic bodies and activation of caspase 3 such that all cells were dead after 144 h of starvation. Incubation with PDGF-AA or PDGF-BB could not compensate for this starvation-induced death. These results indicate that the primary cilium is required for activation of p53 to maintain cell quiescence and prevent cells from entering the apoptotic mode of programmed cell death. The ciliary signalling pathways regulating cell survival are presently unknown, although β1 integrin is shown to localize specifically to the primary cilium, indicative of the cilium signalling the interaction with the connective tissue and controlling tissue homeostasis. Thus the primary cilium in fibroblasts coordinates several fundamental cellular events in cell growth, survival, and potentially in migration supporting tissue homeostasis of connective tissues.

### Mechanism of Nodal Flow: A Conserved Symmetry Breaking Event in Left-Right Axis Determination

Y. Okada, S. Takeda, Y. Tanaka, N. Hirokawa; Dept Cell Biol & Anatomy, Univ Tokyo, Grad Sch Med, Tokyo, Japan

The leftward flow in extra-embryonic fluid is critical for the initial determination of the left-right axis of mouse embryos. It is unclear if this is a conserved mechanism among other vertebrates and how the directionality of the flow arises from the motion of cilia. In this paper, we show that rabbit and medakafish embryos also exhibit a leftward fluid flow in their ventral nodes. In all cases, primary monocilia present a clockwise rotational-like motion. Observations of defective ciliary dynamics in mutant mouse embryos support the idea that the posterior tilt of the cilia during rotational-like beating can explain the leftward fluid flow. Moreover, we show that this leftward flow may produce asymmetric distribution of exogenously introduced proteins suggesting morphogen gradients as a subsequent mechanism of left-right axis determination. Finally, we experimentally and theoretically characterize under which conditions a morphogen gradient can arise from the flow.

2395

### Flagellar Motility as an Essential Function for Bloodstream African Trypanosomes

S. Griffiths, N. Portman, M. Shaw, S. Gordon, K. Gull; Sir William Dunn School of Pathology, University of Oxford, Oxford, United Kingdom

Inducible RNAi is a useful tool for analysing gene function in the African trypanosome, *Trypanosoma brucei.* This organism is the etiological agent of African sleeping sickness, infecting the bloodstream of man and animals and being spread by the tsetse fly. The first RNAi motility mutants in trypanosomes (Bastin et al (1998) Nature **391**, 548) showed that one could produce viable but paralysed trypanosomes. Such a phenotype has subsequently been revealed for many flagellar RNAi mutants in trypanosomes. These phenotypes were obtained using strains of procyclic trypanosomes that represent the insect midgut form of the parasite. We have now made a direct comparison of a number of these RNAi mutants using the same constructs expressed in the bloodstream form parasites. In each case, expression of RNAi against the flagellar protein resulted in an impaired motility but viable phenotype in procyclic parasites, but an aberrant flagellum and death phenotype in bloodstream cells. Even though we employed RNAi knockdown of a diverse range of structural and regulatory proteins we found a similar aspect to the phenotype. Bloodstream cells produced a large flagellar pocket indicative of aberrant secretion/uptake traffic, flagellar and cell morphogenesis defects, and ultimate production of monstrous cells. Our results indicate the flagellum as having a critically important pathogenecity function in bloodstream trypanosomes and hence reveal motility as a therapeutic target.

2396

### Development of an Immortalized PCK Cholangiocyte Cell Line to Study ARPKD in vitro

T. Masyuk, M. Muff, B. Huang, P. Splinter, V. Torres, N. LaRusso; Internal Medicine, Mayo Clinic College of Medicine, Rochester, MN

ARPKD is caused by mutations in PKHD1, the gene that encodes the protein, fibrocystin (FC). The formation of liver cysts in the PCK rat (a rodent model of ARPKD resulting from a mutation in Pkhd1) is associated with morphological abnormalities of cholangiocyte cilia (they become

shorter and malformed) and alterations in the FC intracellular location (it disappears from cilia but is expressed in the cytoplasm; Gastroenterology 2003, 125:1303). However, the relationships among mutations in FC, malformed cholangiocyte cilia, FC topographical alterations, and hepatic cystogenesis remain unclear. To continue to clarify these relationships, we developed a spontaneously immortalized PCK-derived cholangiocyte cell line (PCK-CCL). These cells were maintained in culture for one year over twenty passages. They continue to express cholangiocyte markers cytokeratins 7 and 19, and GGT, but were essentially devoid of desmin and vimentin, non-epithelial cell markers. The cells showed typical cholangiocyte morphology: large, notched nuclei, numerous microvilli on the apical surface, and tight junctions. Compared to a normal rat cholangiocyte cell line (NRC), the PCK-CCL exhibits higher electrical resistance (2200 ohmscm2 vs 1500 ohmscm2), and possesses short, malformed cilia (1.29±0.08um vs 7.64±1.7um), abnormalities similar to what we observed in PCK cholangiocytes in vivo. Moreover, the PCK-CCL forms spherical cysts in a 3D collagen matrix and the number of cystic structures, rate of cyst formation and the cystic area are significantly greater in the PCK-CCL than in NRC. Finally, the PCK-CCL expresses FC in the cytoplasm and plasma membrane and not in the cilia. In conclusion, we have developed and characterized a non-malignant, spontaneously immortalized cholangiocyte cell line from the PCK rat to allow further studies on the mechanisms involved in hepatic cyst formation, expansion and progression and to test treatment approaches for inherited cystic liver disease.

### Primary Cilia in Fibrosis Associated with Two Models of Polycystic Kidney Disease

S. R. McGlashan,[1] C. A. Poole,[2] C. Stayner,[3] A. C. Johnstone,[4] M. R. Eccles,[3] C. G. Jensen[1]; [1]Dept. of Anatomy with Radiology, University of Auckland, Auckland, New Zealand, [2]Section of Orthopaedic Surgery, Dept. of Medical and Surgical Sciences, University of Otago, Dunedin, New Zealand, [3]Dept. of Pathology, Dunedin School of Medicine, University of Otago, Dunedin, New Zealand, [4]Pathobiology Section, Institute of Veterinary, Animal and Biomedical Sciences, Massey University, Palmerston North, New Zealand

The two characteristics of polycystic kidney disease (PKD) are the development of cysts and fibrosis. Fibrosis, a common cause of renal failure, results from excessive interstitial fibroblast proliferation and extracellular matrix production. Although previous studies of PKD have concentrated on primary cilia defects of cyst epithelia, we hypothesize that abnormalities in fibroblast primary cilia lead to fibrosis. Our study aimed to characterize interstitial fibrosis and fibroblast primary cilia expression in two separate models of PKD - an autosomal dominant PKD mouse ($Pkd1^{del34/del34}$) and a recently-described) autosomal recessive PKD in sheep (Johnstone *et al*., 2005, NZVJ). Kidneys from E18.5 $Pkd1^{(del34/del34)}$ and wild-type mice, and from newborn wild-type and mutant lambs were fixed, wax-embedded and sections were stained using H&E or Masson's Trichrome. Indicators of fibrosis were the mean percentage area and cell count of the interstitium. Primary cilia were labeled using an acteylated α-tubulin antibody. Moderate-to-severe fibrosis surrounded cysts in both the mutant kidneys with an increase in fibroblast numbers. Primary cilia were present on tubular epithelia and interstitial cells in both wild-type mouse and lamb kidneys. In Pkd1 kidneys, primary cilia were associated with both unaffected epithelia and cyst epithelia and there was no difference in length between epithelial cilia of the cysts and those of wild-type tubules. However, only a small proportion of Pkd1 fibroblasts expressed primary cilia. In contrast, in the lamb, the majority of cyst epithelia did not express primary cilia and interstitial cells expressed only stunted cilia. This is the first study to describe fibrosis in two models of cilia-related PKD. The presence of primary cilia in cyst epithelia confirms reports that the Pkd1 mutation results in a functional ciliary defect; in the lamb, the absence of primary cilia suggests a structural abnormality.

### The Cytoplasmic Tail of Fibrocystin/Polyduction Contains A Ciliary Targeting Sequence

L. Li, J. Follit, E. Luna, G. Pazour; Molecular Medicine, University of Massachusetts Medical School, Worcester, MA

The human autosomal recessive polycystic kidney disease gene (PKHD1) encodes an ~450 kD protein called fibrocystin or polyductin that is predicted to be almost entirely extracellular with a short 192 amino acid cytoplasmic tail (Ward et al., Nat Genet. 30(3):259-69; Onuchic et al., Am J Hum Genet. 70(5):1305-17). Fibrocystin localizes to cilia and centrosomes in cultured mammalian cells (Ward et al., Hum. Mol. Genet. 12(20):2703-10; Wang et al., JASN 15(3):592-602) and it is likely that the cytoplasmic tail plays a role in targeting to these organelles. To test this idea, the cytoplasmic tail of mouse fibrocystin was fused to GFP and expressed in kidney cells. In non-ciliated cells, the tagged protein localizes around centrosomes; in ciliated cells the protein is found predominately in the cilia. Dissection of the cytoplasmic tail sequence identified an 18 amino acid peptide that is sufficient to target GFP to cilia. This sequence is highly conserved in vertebrates and contains cysteine residues that are likely to be palmitoylated. Mutation of these cysteines to alanine or treatment of the cells with 2-bromopalmitate, an inhibitor of palmitoylation, abolish the ability of this peptide to target to the cilium. Certain point mutations within the ciliary targeting sequence prevent ciliary targeting but instead cause the protein to accumulate in small punctate spots on the plasma membrane. These spots also label with cholera toxin B, which binds GM1 and is a marker for lipid rafts. Palmitoylation can target proteins to lipid rafts, thus we propose that the ciliary targeting event is a two step process whereby the protein is first targeted to GM1-rich regions of the plasma membrane and then to the ciliary membrane.

### A Homologue of Polycystic Kidney Disease Protein Polycystin-2 is Present in Chlamydomonas Flagellar Membranes

K. Huang,[1] G. J. Pazour,[2] G. B. Witman,[3] M. Hippler,[4] J. L. Rosenbaum[1]; [1]MCDB Department, Yale University, New Haven, CT, [2]Program in Molecular Medicine, University of Massachusetts Medical School, Worcester, MA, [3]Department of Cell Biology, University of Massachusetts Medical School, Worcester, MA, [4]Department of Biology, University of Pennsylvania, Philadelphia, PA

The proteins encoded by most polycystic kidney disease (PKD) genes are found, in part, on cilia, and defects in ciliary assembly in vertebrates cause PKD. These observations led to the "ciliary hypothesis of PKD". Several PKD gene homologues are found in the Chlamydomonas flagellar proteomic database, including polycystin-2 (PKD2) (C_590099), polyductin/fibrocystin (C_420012) and qilin (C_10017). We cloned the Chlamydomonas PKD2 gene; it has 12 exons that encode a protein of 180 kD, which contains 4 putative leucine zipper pattern domains, an EF-hand domain, and six transmembrane domains, which are characteristic of PKD2 family members. Using antibodies generated against either the first extracellular loop or a small peptide from the C-terminus, two polypeptides (180 kD and 120 kD) were detected in the cell body by immunoblotting. The smaller of these was the predominant flagellar form, and was enriched in a flagella membrane fraction. PKD2 could be visualized in the flagella by immunofluorescence microscopy. When the temperature-sensitive mutant *fla10*, which harbors a defective subunit of

the anterograde intraflagellar transport (IFT) motor Kinesin-2, was shifted to the restrictive temperature, the amount of PKD2 in the flagella increased. These data suggest that IFT is involved in the turnover of PKD2 in flagella. A PKD2-GFP fusion construct and an RNA interference construct have been made and transformed into Chlamydomonas. We are screening and analyzing the transformants to determine the dynamics and function of Chlamydomonas PKD2 in the flagellum. Supported by NIH grants GM14642 to JLR and GM30626 to GBW.

**Cell Cycle Regulation of Primary Cilium Biogenesis in Mammalian Cells**

C. T. Anderson, T. Stearns; Biological Sciences, Stanford University, Stanford, CA

In mammalian cells, primary cilia normally grow from mother centrioles during early G1 phase, but the regulatory mechanisms by which cells control primary cilium biogenesis are poorly understood. We tested whether cells require specific cell cycle events and regulators in order to generate primary cilia. Cells arrested in mitosis by expression of non-degradable cyclin B do not generate primary cilia, while cells that are $p53^{-/-}$ or $pRb^{-/-}/p107^{-/-}/p130^{-/-}$, cells that fail cytokinesis after treatment with the actin inhibitor cytochalasin B or the myosin II inhibitor blebbistatin, cells arrested in S phase by hydroxyurea or aphidicolin treatment, and cells arrested in G2 by etoposide treatment are able to generate new primary cilia. Thus, primary cilium biogenesis requires cyclin B degradation, but not completion of cytokinesis or the pRb family or p53 regulatory proteins. In addition, primary cilium biogenesis can occur during S or G2 arrest, indicating that the maturation process by which centrioles become competent to form primary cilia, and the growth of primary cilia themselves, may be independent of normal cell cycle progression.

2401

**Testing Models of Flagellar Length Control**

K. A. Wemmer, W. F. Marshall; Biochemistry & Biophysics, University of California, San Francisco, San Francisco, CA

Cilia and flagella are organelles that serve a diverse set of functions in a wide range of organisms. Despite the importance of these structures, the mechanisms driving assembly of the axoneme and maintenance of its length are poorly understood. It is possible to study these mechanisms in the flagellated unicellular green alga *Chlamydomonas reinhardtii*, as cilia and flagella have a high degree of structural conservation across species. Here, we focus on how length is tightly and precisely controlled. It is known that the distal tips of flagella are unstable and undergoing continuous turnover, thus the precise length of the flagella must be maintained by balancing assembly and disassembly at the tip of each flagellum. Several models have been proposed to explain the mechanism responsible for this balance. We would like to test these models by examining flagellar length mutants using a combination of genetics and microscopy to test predictions derived from these models of length control.

2402

**Phosphoinositides are Required for Spermatid Elongation in *Drosophila***

H. Wei; Developmental Biology, The Hospital for Sick Children, Toronto, ON, Canada

During sperm tail formation, cellular membranes undergo dramatic remodeling, concomitant with assembly of a microtubule-based axoneme. The mechanisms that coordinate these membrane and cytoskeletal changes in *Drosophila* spermatogenesis are unknown, although genes required for spermatid elongation have been identified. Two such genes, *syx5* and *fws*, encode proteins involved in membrane trafficking, suggesting that an intact secretory pathway is critical for membrane remodeling during sperm tail formation. Phosphatidylinositol phospholipids (PIPs) modulate membrane trafficking, actin cytoskeletal organization and signal transduction. To deplete PIPs and determine if these key regulatory phospholipids affect sperm tail formation, we expressed the *Salmonella* PIP phosphatase, SigD, in developing male germ cells. SigD depleted $PI(4,5)P_2$ from the plasma membrane and caused profound defects in spermatid elongation. These defects were largely rescued by co-expression of PIP 5-kinase, confirming that PIPs are needed for normal spermatid differentiation. Septins typically localize to stable intercellular bridges and to punctate structures that lie along the length of elongating axonemes. In contrast, SigD-expressing testes exhibit abnormal septin filaments and few, if any, axonemes. We determined that *Drosophila* septins, like their mammalian homologs, bind PIPs *in vitro*, suggesting PIPs may modulate septin polymerization. In addition, centrosomin and γ-tubulin, basal body proteins that are not thought to bind PIPs directly, were mislocalized in postmeiotic spermatids from PIP-depleted testes. We speculate that PIPs promote sperm tail formation by influencing membrane trafficking, septin organization, as well as localization and/or activation of basal body proteins required for axoneme assembly.

2403

**PDGF-AA Induced Activation of the Mitogenic Erk1/2-Mek1/2 Pathway Localizes to the Primary Cilium and the Ciliary Basal Body in NIH3T3 Fibroblasts**

C. A. Clement,[1] L. Schneider,[1] S. C. Teilmann,[1] P. Satir,[2] S. T. Christensen[1]; [1]Department of Biochemistry, IMBP, The August Krogh Building, University of Copenhagen, Copenhagen, Denmark, [2]Department of Anatomy and Structural Biology, Albert Einstein College of Medicine of Yeshiva University, Bronx, NY

Primary cilia are present in most quiescent tissue cells in our body as solitary organelles that emerge from the mother centriole that has become a basal body. Our research focuses on the function of the primary cilium in connective tissues in tissue homeostasis, growth control and migration in wound healing. We previously showed that PDGFRαα-mediated transition from growth arrest to cell cycle entrance is initiated through activation of the receptor homodimer in the primary cilium of quiescent fibroblasts followed by activation of the mitogenic Mek1/2-Erk1/2 pathways [Schneider et al. (2005) Curr. Biol., Submitted]. Here we investigated the subcellular position of the signal transduction cascades initiated by ligand-dependent activation of ciliary PDGFRαα through phosphorylation of the receptor docking site for Shp/Grb2 that leads to activation of Mek1/2 through the Ras-Raf pathway in NIH3T3 fibroblasts. Co-localization studies with anti-acetylated α-tubulin and anti-pericentrin show that PDGF-AA increases the level of phospho-Mek1/2 (c-Raf-dependent Mek1/2 phosphorylation in the activation loop on serines in positions 217 and 221 that activates Erk1/2) along the cilium and at the base of the cilium, i.e. to the mother centriole, and not to the daughter centriole. Further, Mek1 is phosphorylated in the cilium on serine in position 298, which is executed by p21-activated protein kinase, PAK, and which is a convergence point for integrating growth factor signaling via the MAPK pathway. We also demonstrate feed back inhibition of Mek2 by Erk-mediated phosphorylation of threonine on position 394 in the primary cilium, supporting the conclusion that Raf-dependent activation of Mek1/2 is assisted by PAK in the cilium, and that the primary cilium contains the signalling machinery from PDGFRαα activation to Mek1/2 through the

Ras-Raf pathway.

**Activated Disassembly of the Axoneme and Increased Trafficking of IFT Particles during Shortening of Eukaryotic Flagella**

J. Pan, W. J. Snell; Cell Biology, UT Southwestern Medical Center, Dallas, TX

Cells possess mechanisms not only to assemble and maintain cilia/flagella but also to shorten them. We are using *Chlamydomonas* to study the mechanisms that regulate the flagellar shortening that is induced by environmental and developmental cues. Previously, we showed that the aurora protein kinase CALK plays a central role in the regulation of flagellar shortening. When cells receive cues to shorten, CALK is phosphorylated and its protein kinase activity is stimulated. Moreover, RNAi knockdown of CALK inhibits shortening. Here we report on studies of the cellular mechanisms of flagellar shortening. Phosphopeptide analysis of CALK shows that triggers for shortening lead to phosphorylation of CALK on several sites, suggesting that it is regulated by more than one protein kinase. In studies on events downstream of CALK, we found that the flagellar shortening pathway is independent of the Lf4 protein, which is essential for the transient shortening that enforces flagellar length. Studies on the rates of shortening in wild type cells and mutants with a conditional lesion in the anterograde intraflagellar transport (IFT) motor, kinesin 2, immunoblot analysis of the amounts of IFT particle proteins and motors in steady state and shortening flagella, and analysis of anterograde and retrograde cargo in steady state and shortening flagella have led to the following model for shortening. When triggered to shorten their flagella, cells stimulate disassembly of the axoneme at the tip over the basal rate, they increase by 4-fold trafficking of IFT particle proteins in the flagella, and the newly entering IFT particles are empty of cargo. Thus, during flagellar shortening cells increase the rate of entry of empty IFT particles into the flagella to pick up the disassembled flagellar components generated by active disassembly. Supported by NIH.

**Adenylate Kinases in the Eukaryotic Flagellum: Protein Targeting, Energy Metabolism, and a Novel Related Gene Family Required for Motility**

E. Barnwell, K. Gull, M. Ginger; Sir William Dunn School of Pathology, University of Oxford, Oxford, United Kingdom

Three novel adenylate kinases in the flagellar proteome of the protozoan parasite *Trypanosoma brucei* (causal agent of African sleeping sickness) provide prime examples of metabolic enzymes which are anchored within the trypanosome's flagellar architecture. These enzymes differ from ubiquitous cytoplasmic and mitochondrial adenylate kinase isoforms by the presence of N-terminal extensions of approximately fifty amino acids, which are both necessary and sufficient for flagellar targeting. Intriguingly, using a bioinformatics approach, these flagellar targeting sequences are sufficient to identify unusual tandem adenylate kinases in the genomes of other eukaryotic flagellates, including nematodes, humans, and the ciliate *Tetrahymena thermophila.* The *T. brucei* flagellar proteome also contains two examples of larger proteins (m.w. >120kDa) that contain the pfam adenylate kinase domain. However, the primary sequence homology with adenylate kinase is disrupted in several places by insertions of unrelated amino acid sequences. We refer to these novel polypeptides as adenylate kinase-related proteins, and find examples of this "split adenylate kinase" theme in all eukaryotic flagellates for which complete or extensive genome coverage is available. Significantly, we do not find examples of unusual adenylate kinases or adenylate kinase-related proteins in the genomes of eukaryotes which do not build a cilium or flagellum. We show by epitope-tagging that both trypanosome adenylate kinase-related proteins are present in the axoneme. We speculate that our characterisation of the *T. brucei* flagellar adenylate kinases provides evidence for a flagellar energy generating capacity that is determined by the specific niche environment occupied by trypanosome parasites. RNA interference-mediated gene silencing demonstrates that an absence of the adenylate kinase-related proteins results in motility defects in cultured parasites.

**The *Chlamydomonas* Flagellar Axoneme Contains a cGMP-dependent Protein Kinase (PKG) that Regulates Axonemal Motility**

B. Verhalen, A. R. Gaillard; Biological Sciences, Sam Houston State University, Huntsville, TX

Studies of cilia and flagella in various systems have revealed a role for cGMP and cGMP-dependent kinase (PKG) in the regulation of axonemal motility. To determine whether the *Chlamydomonas* axoneme contains a PKG that is involved in the regulation of axonemal motility, we performed both pharmacological and biochemical experiments using *Chlamydomonas* axonemes. We first performed studies of reactivated cell motility using demembranated cell models. These studies revealed that the percentage of motile cells decreases when reactivation of wild-type cells is performed in the presence of the PKG inhibitor Rp-8-pCPT-cGMPS, indicating that PKG is a regulator of axonemal motility. We then performed Western blot analysis of axonemal protein from wild-type cells using a peptide antibody to a putative *Chlamydomonas* PKG, revealing the presence of two protein bands of approximately 110 and 120 kD. The sizes of these protein bands are consistent with the predicted size of 105 kD for the product of genie 214.2, a putative *Chlamydomonas* PKG gene. Studies of axonemal protein samples from various structural mutants have demonstrated that the 110 and 120 kD proteins are not exclusively localized to the radial spokes, central pair apparatus, dynein regulatory complex, I1 inner dynein arm, or the outer dynein arms. The 110 and 120 kD proteins are extractable with 0.6 M NaCl, and sucrose gradient fractionation of 0.6 M NaCl extracts has shown that the 110 kD protein sediments at approximately 10S, while the 120 kD protein sediments at around 12S. These results suggest that *Chlamydomonas* axonemal PKG may exist as part of one or more protein complexes.

2407

**Intracellular Ca2+ and cAMP Signaling Pathways Are Involved in Mechanosensory Function of Primary Cilia in Biliary Epithelia**

A. I. Masyuk, T. V. Masyuk, P. L. Splinter, B. Q. Huang, A. J. Stroope, N. F. LaRusso; Internal Medicine, Mayo Clinic College of Medicine, Rochester, MN

Cholangiocytes, the epithelial cells lining intrahepatic bile ducts, contain primary cilia extending into the ductal lumen. The functions of cholangiocyte cilia are unknown. Studies on primary cilia in renal epithelia suggest that these organelles function as mechanosensors. In present study, we tested the hypothesis that cholangiocyte cilia are mechanosensory organelles that detect and transmit luminal bile flow stimuli into intracellular signaling responses. Scanning and transmission electron and immunofluorescent confocal microscopy of rat isolated intrahepatic bile duct units (IBDUs) were employed to assess cholangiocyte cilia. Changes in cholangiocyte [Ca2+]i and [cAMP]i in response to luminal perfusate flow in microperfused IBDUs were measured by epifluorescence microscopy and a fluorescence assay, respectively. We found that each

cholangiocyte in IBDUs contains a primary cilium on its apical plasma membrane. Cholangiocyte cilia express a mechanoreceptor, polycystin-1 (PC-1), a Ca2+ channel, polycystin-2 (PC-2) and the Ca2+-inhibitable adenylyl cyclase isoform 6 (AC6). Perfusion of IBDUs at flow rates of sufficient magnitude to bend cilia resulted in a 40 % increase in [Ca2+]i and a four-fold decrease of forskolin-stimulated [cAMP]i levels. The flow-induced changes in [Ca2+]i and [cAMP]i were significantly reduced or abolished when cholangiocyte cilia were removed by chloral hydrate or when PC-1, PC-2 and AC6 were individually down-regulated by siRNAs. In conclusion, cholangiocyte cilia contain PC-1, PC-2 and AC6 through which luminal flow stimuli affect both the [Ca2+]i and cAMP signaling pathways, two pathways known to be involved in regulation of ductal bile secretion.

2408

**Evidence That $Ca^{2+}$ Selectively Affects Dyneins on Certain Microtubule Pairs in the Mouse Sperm Axoneme**

K. C. Ponichter, K. A. Lesich, C. B. Lindemann; Biological Sciences, Oakland University, Rochester, MI

Mouse sperm were induced to undergo sliding disintegration of the axoneme by a two step method. First, epididymal sperm were detergent extracted with 0.1% Triton X-100 in a potassium glutamate based reactivation buffer in the presence of 0.3mM Mg-ATP at pH 7.8 as described in Lindemann and Goltz, 1988 (Cell Motil. Cytoskeleton, 10:420-431). A high percentage (~90%) of sperm exhibited a coiled “curlicue” shape if 1mM $Ca^{2+}$ was also added to the mixture. Second, the cells were stripped of their mitochondrial sheath by transferring 0.5 ml of the reactivated cells to 4.5 ml of an extraction buffer that contained 0.1 M potassium glutamate, 2mM DTT, 0.02M Tris-HCl, 5mM $MgCl_2$, 0.5mM EGTA, 1mMATP and 0.5% Triton X-100 at pH 9.5 and incubating at 34ºC for 5 min. After incubation in the extraction buffer, phase microscopy revealed disintegrated axonemes with extruded outer dense fibers and microtubules. The polarity of the disintegration patterns was analyzed with respect to the reference provided by the pointed asymmetric sperm head. In the absence of $Ca^{2+}$ most cells had emergent fibers that came from the side of the axoneme opposite to the head point (47% vs. 14%). This ratio was shifted to almost equal numbers in the samples treated with $Ca^{2+}$ (28% vs. 27%). There were also significantly more cells showing fibers ejected from both sides of the axoneme in the $Ca^{2+}$ treated samples (6% control; 12% with $Ca^{2+}$; $p < 0.05$). These results suggest that the dyneins on doublets #1 and #2 are more likely to actively initiate sliding in the presence of $Ca^{2+}$.

**The Evolution of Flagellar Length Control: Novel IFT Kinesin Function in the Basal Eukaryote Giardia Intestinalis**

S. C. Dawson, M. S. Sagolla, W. Z. Cande; MCB, UC-Berkeley, Berkeley, CA

*Giardia* intestinalis belongs to the most basal group of eukaryotes, and is a model for cytoskeletal evolution. Control of flagellar length is an important question in biology, as links exist between proper flagellar function and human disease. Intraflagellar transport (IFT) is the process responsible for flagellar assembly and maintenance in *Chlamydomonas*, yet this mechanism has not been studied in *Giardia*. Many components of anterograde and retrograde IFT, and two kinesin-2 homologs, are present in the *Giardia* genome. We are unable to find cytoplasmic dynein, a component essential for retrograde IFT in other eukaryotes. Using GFP-tagging, we show that conserved IFT proteins (kinesin-2, EB1, IFT-81) show conserved localization to extracellular regions, docking sites, and flagellar tips of all axonemes. Further, the overexpression of a dominant negative kinesin-2 inhibits the growth of only external axonemes. Interestingly, the MT depolymerizing kinesin-13 homolog has a novel localization to flagellar tips, and flagellar growth appears to be affected by the overexpression of a dominant negative. Unique intracellular regions characterize the four pairs of giardial axonemes. Several novel giardial kinesins also localize only to intracellular axonemes. Finally, unlike *Chlamydomonas*, flagellar length in *Giardia* is affected by the microtubule-stablilizing drug taxol and destablizing drug nocodazole. Anterior and ventral flagellar pairs have a greater sensitivity to nocodazole than other flagellar pairs. These data support the balance point model for regulation of flagellar length and suggest a novel mechanism of regulation for the internal versus external axonemes. IFT is largely a conserved process in *Giardia*, despite the novel role for a depolymerizing kinesin in flagellar disassembly. Although we propose an ancient origin of anterograde IFT (likely present in ancestral eukaryotes), we speculate that *Giardia* diverged before the evolution of “conventional” retrograde IFT.

2410

**Intraflagellar Transport Particles Participate Directly in Signal Transduction During Cilium-generated Signaling in *Chlamydomonas***

Q. Wang, W. Snell; Cell Biology, UT Southwestern Medical Center, Dallas, TX

Cilia are widely used as sensory transducers in both unicellular and multicellular organisms. Several previously poorly understood human disorders are now known to be cilia-related disorders. The most common inherited disease in humans, polycystic kidney disease, is due to a failure of cilium-generated signaling in kidney epithelial cells. And Bardet-Biedl Syndrome, characterized by obesity, mental retardation, and diabetes, is due to defects in cilia genes. The intraflagellar transport (IFT) machinery, powered by anterograde motor kinesin-II and retrograde motor cytoplasmic Dynein 1b transports proteins between the cell body and the cilium. Here we show that IFT is essential not only for cilia/flagella assembly and maintenance, but also for modulation of cilium-based sensory processes. In studies on the biflagellate alga, *Chlamydomonas* we find that IFT is essential for maintaining a high concentration of a soluble signaling protein, cGMP-dependent protein kinase (PKG), in the flagella. During fertilization, flagellar adhesion between gametes of opposite sex activates a signal transduction pathway leading to gamete activation and cell fusion. RNA interference and pharmacological experiments indicate that the PKG is involved in this pathway and is essential for fertilization. Analysis using immunopurification and mass spectrometry shows that the PKG is activated and tyrosine phosphorylated by a protein tyrosine kinase, which is activated by flagellar adhesion. Moreover, biochemical fractionation of flagella isolated from non-adhering and adhering gametes indicates that adhesion causes the PKG to become part of a multiprotein signaling complex that includes IFT particles; generation of signaling requires kinesin-II. Thus, in addition to its role in transporting flagellar structural components between the flagella and the cell body, IFT plays a direct role in cilium-generated signaling. Supported by NIH GM25661

2411

**Signaling in *Tetrahymena* Cilia: Evolution of Ciliary Signaling for Mammalian Growth Control Regulation**

C. F. Guerra,[1] A. J. Bell,[1] A. Awan,[1] S. T. Christensen,[2] P. Satir[1]; [1]Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, [2]Institute of Molecular Biology, University of Copenhagen, Copenhagen, Denmark

Environmental sensing and cell signaling by ciliary membrane proteins are especially significant for single celled ciliated organisms, e.g. *Tetrahymena*, not only for rapid behavioral responses, but also for longer term responses leading to fission or mating. Recently we have reported on a ciliary membrane bound protein with a proposed receptor tyrosine kinase function (TtPTK1, Christensen et al ,2003), which has sequence motifs homologous to insulin-like growth factor (IGF) receptors. We have searched the *Tetrahymena* database for other molecules to complete this growth control signaling pathway. SH2-domain containing proteins, tyrosine phosphatases and MAP kinases are all present. *Tetrahymena* database protein #16928 is homologous to *C.elegans* EMB-5, an SH2 domain protein, which interacts with a transmembrane receptor. Rad 51 has been identified in *Tetrahymena* (Campbell and Romero,1998) and reportedly interacts with IRS-1 (Trojanek et al, 2003). We have designed probes based on database sequences for these and similar potential ciliary signaling proteins in *Tetrahymena* to test for mRNA upregulation during ciliogenesis. Upregulation is taken to be a sign that the protein is expressed in connection with the cilium, and could be part of the signaling system. TtPtk1, Gef1, Rad51 and PI3K are upregulated by 2.87, 4.37, 8.16 and 15.47 fold respectively, while control proteins are not upregulated**.** These findings are consistent with other reports of ciliary proteomics (Pazour et al 2005, Smith et al 2005) identifying several signaling proteins within the cilium. We conclude that growth factor signaling pathways starting in the ciliary membrane, which influence and directly control cell survival, chemotaxis and division, are present in *Tetrahymena*, which suggests that such pathways arise early in eukaryotic cell evolution and are retained.

### Protein Tyrosine Kinase Activation and Cilium-Generated Signaling in *Chlamydomonas*

Q. Wang, W. Snell; Cell Biology, UT Southwestern Medical Center, Dallas, TX

Fertilization in the biflagellated green alga *Chlamydomonas* is initiated by flagellar adhesion between mt+ and mt- gametes. Recently, we showed that activation of a flagellar protein tyrosine kinase (PTK) is an early event during this cilium-generated signaling process. In order to identify protein tyrosine kinases in *Chlamydomonas* , we performed bioinformatics screening of the *Chlamydomonas* JGI v.2 genome database. We identified three predicted proteins as putative PTK's, which represent less than 0.15% of the total predicted proteins in *Chlamydomonas* (~20,000). This percentage is much less than that in Metazoan (~2%), but is larger than that in *Arabidopsis* and rice, which contain no predicted PTKs. It is possible that the PTK's are related to cilia, since higher plants do not contain these organelles. According to Clustal W analysis, the *Chlamydomonas* PTK's have about 30% identity in the catalytic domains with known protein tyrosine kinases, including high similarity in the PTK active site (VIb) signature (prosite number PS00109). However, all three lack the tyrosine residue around the DFG motif, suggesting that they may not be regulated by tyrosine phosphorylation. We cloned two of the putative PTK genes and have generated anti-peptide antibodies. Experiments are in progress to identify and characterize the proteins. Supported by NIH GM25661.

### Another Chlamydomonas NIMA-related Kinase with a Flagellar Function

J. D. K. Parker, L. M. Quarmby; MBB, Simon Fraser University, Burnaby, BC, Canada

NIMA-related kinases (Neks) are best known in mammals as cell cycle regulators, but the Chlamydomonas Neks Cnk2p and Fa2p have flagellar functions in addition to cell cycle roles. Over- and under-expression of Cnk2p leads to defects in flagellar length (Bradley & Quarmby, 2005), while fa2 mutants have defects in flagellar disassembly (Mahjoub et al., 2002; Parker & Quarmby, 2003). Additionally, studies in Tetrahymena have implicated the Nek family as regulators of flagellar length (Wloga et al., 2004). The genes for several Chlamydomonas long flagella (lf) mutants have been cloned, but the identities of the genes mutated in short flagella (shf) mutants have not yet been reported. As the shf1 mutation maps near to the CNK3 gene, we are testing the hypothesis that CNK3 carries the shf1mutation. Expression of the wild-type CNK3 cDNA rescues shf1 mutants, while stable CNK3[RNAi] lines have short flagella. At this writing, we are sequencing the CNK3 gene from shf1 mutants. Cnk3p is the closest Chlamydomonas homologue of mouse Nek1 (54% identity in the kinase domains). Because Nek1 is the causative gene in the kat murine model of the ciliopathy autosomal recessive polycystic kidney disease, we thus speculate that Nek1 may have a ciliary function.

### Ciliary Waveform Analysis of Human Airway Epithelium Using High Speed Differential Interference Contrast Video Microscopy

P. R. Sears, C. Davis; Cystic Fibrosis Center, University of North Carolina at Chapel Hill, Chapel Hill, NC

The shape of a cilium depends on the activation of dynein motors and viscous drag. Our preparation allows precise measurements of this shape and inferences of activation. A 1 cm wide culture is wrapped around the edge of a square 18x18 mm #1 coverglass and placed on a 55x25 mm #1 coverglass. A second 18x18 coverglass is placed on top and overhangs the cells by 3 mm. Silicone grease secures the assembly and circumscribes the medium (DMEM-F12). The cells are observed using a 40x or 60x oil objective (NA $\geq$ 1.3) and up to 3x post-objective magnification. A Megaplus ES-310T camera is used at 125-250 frames per second. The cilium was divided into two 3.5 µm regions. The base region assumes maximum positive and negative curvatures at the beginning of the reverse and forward strokes and the two motions are identical relative to their respective starting positions and durations. For the tip region, the magnitude of the curvature is greater during the reverse stroke than the forward stroke. The beginning of the forward stroke is marked by a highly curved configuration while the beginning of the reverse stroke has low curvature. The base region curvatures and standard errors corresponding to the beginning of the forward and reverse strokes are ($\mu m^{-1}$) -0.52 ± 0.06 and 0.55 ± 0.04, respectively. For the tip region they are 0.85 ± 0.06 and 0.14 ± 0.1. n = 3. The base region may not be activated differentially during the forward and reverse strokes except for the subset of motors activated. The tip region motion can be explained by either differential activation or asymmetrical structures.

### Theoretical Analysis of Balance-point Model for Flagellar Length Control System

W. Marshall; Biochemistry, UCSF, San Francisco, CA

Flagella are an excellent model system for studying the mechanism of organelle size control, because their size can be specified by a single number - the flagellar lenght. We have previously presented a balance-point model for flagellar length control, based on our analysis of flagellar microtubule turnover and intraflagellar transport. Here we analyze the behavior of this model as a function of individual parameters, and indicate how flagellar length distribution are predicted to change in mutants affecting specific aspects of turnover and IFT. We investigate the system

requirements for this model to work in order to formulate the most general possible version of the model. We explore the noise-resistance of the proposed length control system and the ability of the system to equalize flagellar lengths in response to transient alterations in length. We also indicate how similar models can account for size control in microvilli and other organelles.

**Estimation of Ciliary Waveform Changes in Axonemal Dynein Mutants of Tetrahymena by Ciliary Beat Angle Quantitations**

D. Y. Kim,[1] D. G. Pennock,[2] T. M. Hennessey[1]; [1]Department of Biological Sciences, University at Buffalo, Amherst, NY, [2]Department of Zoology, Miami University, Oxford, OH

Swimming speed in *Paramecium* and *Tetrahymena* is governed by both the ciliary beat frequency and ciliary waveform of somatic cilia. It has been suggested that outer arm dyneins (OADs) of the ciliary axoneme are necessary for beat frequency changes and that inner arm dyneins (IADs) determine waveform. Ciliary waveform affects the direction of ciliary beating and the direction of the powerstroke. In *Paramecium*, it has been shown that depolarizing stimuli cause an increase in intracellular Ca++, a counter-clockwise shift of the powerstroke and a wider helical path due to the cilia beating more across the body than anterior-posterior. This decreases forward motion and swim speed. Threshold depolarizations produce Ca++-based action potentials, ciliary reversal and backward swimming. Detergent-permeabilized, reactivated *Paramecium* "models" have been used to show that such ciliary waveform changes are Ca++-dependent by correlating ciliary beat angles with changes in free Ca++. However, it is not know what role(s) individual OAD and IAD pathways play in these responses. Our objective is to adapt these procedures to *Tetrahymena* so that we can analyze the effects of a number of IAD and OAD mutants on Ca++-dependent waveform changes. Our results show that the beat angles of wild type *Tetrahymena* "models" also change reliably with free Ca++. Furthermore, an under-responsive IAD gene-disruption mutant called KO6 (which cannot show ciliary reversals) shows no such changes in beat angle within the physiological range of Ca++ concentrations tested while over-responsive mutants do. Our conclusion is that this procedure, along with the many IAD gene disruption mutants currently available and under construction, can be used to help understand the functions of the many different IADs in the axoneme. Supported by NSF grant MCB-0445362 to T.M.H. and NIH grant GM-59855 to D.G.P.

**Young's Modulus of Primary Cilia Measured with Optical Tweezers**

Y. Harada,[1] T. Ota,[2] P. Dai,[1] H. Tanaka,[1] M. Oyamada,[1] S. Kawata,[2] T. Takamatsu[1]; [1]Department of Pathology and Cell Regulation, Kyoto Prefectural University of Medicine, Kyoto, Japan, [2]Department of Applied Physics, Graduate School of Engineering, Osaka University, Osaka, Japan

Most mammalian kidney epithelial cells express solitary nonmotile primary (so-called 9+0) cilia that project into the renal tubular lumen, where they are exposed to urinary flow. The primary cilium of renal epithelia has been hypothesized to be mechanically sensitive to urinary flow. However, the mechanical properties of the primary cilium of an individual cell are not well understood. In this study, we successfully manipulated micron-sized primary cilia of MDCK cells, a widely used cell line derived from the collecting duct of canine kidney, by using optical tweezers. Optical tweezers employ the radiation pressure from a focused laser beam to trap and manipulate small objects, and forces on the objects in the trap can be measured. The primary cilia of MDCK cells, cultured on thin flexible Formvar membranes, could be clearly visualized from the side by video microscopy. Using optical tweezers, we demonstrated that we could apply forces in the piconewton range to a polystyrene bead attached to the tip of the primary cilium; thereby the primary cilium could be bent, stretched, and even snapped. We plan to report the modulus of elasticity and Young's modulus of each primary cilium, analyzed by measuring the displacement of the laser-trapped bead.

**The Counterbend Response of Mouse Sperm: Evidence That the Nexin Links Have an Elastic Limit**

K. A. Lesich, C. B. Lindemann; Biological Sciences, Oakland University, Rochester, MI

Mammalian sperm demembranated with Triton X-100 and inhibited with 50 µM $NaVO_3$ in the presence of 0.1 mM ATP are immotile and flaccid. When the proximal portion of the flagellum of these sperm is manipulated into a bend with a glass microprobe, the distal flagellum develops a bend in the direction opposite the imposed bend. This is the counterbend response. An analysis of this phenomenon in rat sperm (Lindemann et al., 2005, Biophys. J. Vol. 89:1150-1164) concluded that the counterbend can best be explained by the presence of inter-doublet elastic elements in the axoneme, most likely the nexin links. Mouse sperm also exhibit the counterbend response. In addition, mouse sperm are unique in their exaggerated response to calcium. Reactivated mouse sperm respond to the addition of 1 mM $CaCl_2$ by going into a coiled shape best described as a "curlicue". The curlicue shape can generate a shear angle at the flagellar tip as large as 16 radians. This amount of shear will produce an interdoublet sliding of 800 nm between doublets pairs 2-3, 3-4, 7, 8 and 8-9 in the distal flagellum. We hypothesized that stretching the interdoublet linkages this much would likely exceed the elastic limit and result in breakage. When reactivated mouse sperm were induced into the curlicue configuration with $Ca^{2+}$, we subsequently found that they would not show a normal counterbend response after $NaVO_3$ treatment. This confirmed the hypothesis that the interdoublet elastic linkages have an elastic limit and will break if this limit is exceeded. Supported by NSF grant MCB-0110024.

**A Flagellar Oscillation Driven by Mechanical Feedback**

D. M. Woolley; Physiology, University of Bristol, Bristol, United Kingdom

Eukaryotic flagella typically generate bends that alternate in direction. The mechanism of this oscillation is unknown. Here, the behaviour of quail spermatozoa in viscous media has been analysed. The flagellum of this cell has the advantages of great length, simple '9+2' structure and positional markers. When the sperm head attaches to glass, the normal 3-D flagellar motion is converted to torsion-free planar bending. Because of the high viscous resistance, fully-formed bends do not propagate in relation to an external reference-frame; instead, the flagellum is driven forward through essentially static bends. The flagellar velocity is closely correlated with the oscillation frequency. The bend-initiation-site is gradually displaced proximally, showing that all regions can act as oscillators. A meander-wave develops. Eventually the oscillation pauses. The timing of the pause is contingent on the position of the last-antecedent bend. A new bend cannot form if the direction of the thrust generated by the last bend is too

oblique. A new phase of oscillation and meander formation can be initiated by the arrival of one or more apparently spontaneously-formed, sigmoid bends from the flagellar base. Such bends decelerate as they propagate; only when they reach full development does the new oscillation begin. Sometimes, when the meander bends escape compression by slipping alongside one another (figure-of-8 mode), the oscillation continues without long pauses. These facts indicate that the last-formed bend times and regulates the oscillation by applying a bending force to the region of flagellum proximal to it. This mode of oscillation and bend propagation, dependent on a longitudinal force directed along the axonemal axis, has a close parallel in the published accounts of the behaviour of axoplasmic microtubules translocating over a glass substrate.

### DH-domain Mutation in Bcr-Abl Reveals a Synergistic Mechanism between GEFs

J. Chasseriau,[1] A. El Ali,[1] J. Rivet,[2] B. Constantin,[1] A. Kitzis,[1,2] N. Bourmeyster[1,2]; [1]Institut de Physiologie et Biologie Cellulaires UMR 6187, CNRS, Poitiers, France, [2]Laboratoire de Génétique Cellulaire et Moléculaire, CHU de Poitiers, Poitiers, France

Bcr-Abl is a chimeric oncogene found in several hematological diseases. The most frequent form is $p210^{bcr-abl}$ responsible for chronic myelogenous leukemia. Less frequent, $p190^{bcr-abl}$ is associated with acute lymphoid leukemia. The only structural difference between $p190^{bcr-abl}$ and $p210^{bcr-abl}$ resides in the absence in p190 of a DH/PH domain able to activate Rho family GTPases. In a previous work, we showed that Rho GTPases are differentially activated by both forms of Bcr-Abl. $p210^{bcr-abl}$ activates RhoA, Rac1 and Cdc42, while $p190^{bcr-abl}$, although devoid of a DH domain activates only Rac1 and Cdc42, but not RhoA. We showed that $p95^{vav}$ is present in an activated state in complex with Bcr-Abl. Our results also show that Bcr is a GEF for RhoA only, and Vav a GEF for Rac1 only. We investigated the regulation of GEF activities in the Bcr-Abl complex. Different mutants of Vav (dominant positive-DP and negative-DN mutant for GEF activity) were constructed and stably transfected in Bcr-Abl expressing Ba/F3 cells. A DH domain mutant of $p210^{bcr-abl}$ was constructed and stably expressed in Ba/F3 cells. Mobility in 3D matrigel was observed by videomicroscopy along within Boyden chamber, and GEF activity measurements were conducted. VavDN mutant inhibits pseudopodia production and Rac1 activation, suggesting that Vav is the unique vector of Bcr-Abl-induced Rac1 activation. Interestingly, in $p210^{bcr-abl}$/VavDN expressing cells, RhoA activity is lowered and amoeboid movements slow down. VavDP mutant enhances pseudopodia production and raises the level of activated Rac1. In parallel, amoeboid movements are accelerated and the level of activated RhoA is enhanced. Mutation of DH domain of $p210^{bcr-abl}$ totally inhibited the amoeboid movements, and abolished RhoA activation. A decrease in Rac1 activation was observed in these cells. A synergistic mechanism between GEF activities linked to Bcr-Abl is revealed by these experiments.

### A Small GTPase Rap1 is Activated by IGF-I in Breast Cancer

W. S. Y. Lee, M. A. Guvakova; University of Pennsylvania, Philadelphia, PA

In this pilot study, we investigated a mechanism by which Rap1, a Ras family GTPase and an essential regulator for normal and some pathological cellular functions is controlled in the mammary cells. We report high levels of the Rap1 protein expression in human nontumorigenic MCF-10A cells and a number of human breast cancer cell lines, including MCF-7, T47D, BT-20, MDA-MB-231. Insulin-like growth factor I (IGF-I), a peptide known to play a role in cancer cell migration, induces an acute, but transitory increase in GTP-loading of Rap1, as we show by a Rap1 pull-down assay. The tyrosine kinase activity of the cell surface IGF-I receptor (IGF-IR) is required for Rap1 activation by IGF-I, because there was no increase in GTP-loading of Rap1 in IGF-I-treated cells expressing a dominant negative IGF-IR (IGF-IR/YF3). We then used a novel *in vivo* tool, which was generated by fusing the enhanced green fluorescent protein (EGFP) to the Rap1 binding domain of RalGDS (RBD-RalGDS), and which is recruited specifically to sites of the increased Rap1 activity in live cells. By confocal laser scanning microscopy, we monitored dynamics of EGFP-RBD-RalGDS and found accumulation of the activated Rap1 in ruffling lamellipodia of MCF-7 cells within 5 minutes of IGF-I exposure. This suggests a potential role for Rap1 in IGF-I-stimulated cell migration. Although the specific effector mechanism used by the IGF-IR to control Rap1 remains unknown, our results strongly suggest the involvement of a putative IGF-IR kinase-dependent Rap1 guanine exchange factor (GEF) acting at the plasma membrane.

### Nek3 Kinase Regulation of Vav2 and Paxillin During Prolactin-mediated Breast Cancer Motility

S. L. MIller,[1] C. V. Clevenger[2]; [1]Cell and Molecular Biology, Unniversity Of Pennsylvania Medical School, Philadelphia, PA, [2]Department of Pathology, Northwestern University, Chicago, IL

Our lab has demonstrated a role for the serine/threonine kinase activity of Nek3 in the regulation of the Vav2 guanine nucleotide exchange factor during prolactin (PRL) receptor signaling. In breast cancer cell lines, PRL stimulates the generation of membrane ruffles, stress fibers and the formation of focal adhesions Given these actions of PRL and Nek3, we hypothesized that Nek3 may contribute to PRL-mediated pathogenesis and motility of human breast cancer. Initial studies using breast tissue microarrays have demonstrated a significant up-regulation of Nek3 expression in malignant versus normal specimens. Overexpression of Nek3 in CHO transfectants potentiated cytoskeletal re-organization in response to PRL. In contrast, down-regulation of Nek3 expression by small-interfering-RNA (siRNA) attenuated PRL-mediated cytoskeletal re-organization, activation of GTPase Rac1, and cell migration of the well-differentiated T47D, but not of the poorly differentiated MDA-MB-231 cells. In addition, PRL stimulation induced an interaction between Nek3 and paxillin and led to a significant increase in paxillin serine phosphorylation. Correspondingly, Nek3 siRNA transfected cells showed a marked reduction in paxillin phosphorylation. Taken together, these data suggest that Nek3 contributes to PRL-mediated breast cancer motility through mechanisms involving Rac1 activation and paxillin serine phosphorylation.

### Role of the Rac Small Gtpase in Rheumatoid Arthritis

A. Chan,[1] M. Akhtar,[2] Y. Zheng,[3] P. Gulko,[4] M. Symons[1]; [1]Oncology and Cell Biology, Institute for Medical Research at North Shore-LIJ, Manhasset, NY, [2]Department of Pharmaceutical Sciences, St. John's University, Queens, NY, [3]Division of Experimental Hematology, Children's Hospital Research Foundation, Cincinati, OH, [4]Center for Genomics and Human Genetics, Institute for Medical Research at North Shore-LIJ,

Manhasset, NY
Rheumatoid arthritis (RA) is characterized by synovial hyperplasia and joint destruction. Activated fibroblast-like synoviocytes (FLS) play a critical role in RA pathogenesis. The signaling mechanisms that are responsible for the activated phenotype of RA-FLS to a large extent remain to be elucidated. Our previous work has demonstrated that the Rac small GTPase plays an important role in fibroblast invasion, proliferation and survival. We therefore hypothesized that Rac contributes to RA by stimulating the invasive and proliferative properties of FLS. We inhibited Rac function in primary FLS cultures obtained from RA patients using two independent methods, transient transfection of Rac1-directed small interfering RNA or treatment with a Rac-specific small molecule inhibitor (PNAS 101: 7618-23). Both methods yielded similar results. We showed that inhibiting Rac causes a significant inhibition in RA-FLS proliferation, without affecting cell survival. Targeting Rac also inhibited RA-FLS invasion through reconstituted extracellular matrix. Together, these results indicate that Rac contributes to the aggressive behavior of fibroblast-like synoviocytes in rheumatoid arthritis. This work was supported by an Innovative Research Grant from the Arthritis Foundation, Long Island chapter.

**S100A4/Mts1 Mediated PhosphoERK and BMP2 Induced Chloride Intracellular Channel 4 (CLIC4) Produce Co-dependent Migration of Human Pulmonary Artery Smooth Muscle Cells (hPASMCs)**

E. Spiekerkoetter,[1] L. Wang,[1] N. Ambartsumian,[2] A. Schmidt,[3] M. Rabinovitch[1]; [1]Stanford University Medical School, Stanford, CA, [2]Danish Cancer Society, Copenhagen, Denmark, [3]Department of Physiology, Medicine and Surgery, Columbia University, New York, NY

Mutations in bone morphogenetic protein receptor (BMPR)-II are linked to pulmonary hypertension (PH). Our previous studies showed that migration of hPASMCs, a key feature in PH, was induced by BMP2 (a ligand for BMPR-II) and S100A4/Mts1 (the ligand for the receptor for advanced glycation end products (RAGE)) in an interdependent manner. That is, migration of hPASMCs induced by Mts1 or BMP2 was inhibited by either anti-RAGE or BMPR-II siRNA. Further characterization of this interdependency is important in understanding the link between the mutation and the disease. We therefore investigated the signaling pathways and gene expression that require input from RAGE and BMPR-II after stimulation with Mts1 or BMP2. We treated hPASMCs with recombinant (r)Mts1 (500 ng/ml) or BMP2 (10 ng/ml) ± preincubation with a RAGE blocking antibody ± BMPR-II siRNA. Migration was quantified in a modified Boyden chamber. Activation of signaling pathways was evaluated by western immunoblot and changes in gene expression by cDNA microarray analysis and quantitative RT-PCR, followed by siRNA. Phosphorylation of ERK (phosphoERK), induced by both ligands, was blocked by anti-RAGE but not by BMPR-II siRNA ($n=3$, $p < 0.001$) suggesting phosphoERK is necessary but not sufficient to induce migration. BMPR-II siRNA (70% knock-down), but not anti-RAGE led to downregulation of CLIC4 gene expression to < 40% ($n=3$, $p < 0.001$). Knocking down CLIC4 by siRNA (80% knock-down) abrogated Mts1 and BMP2 induced migration ($p < 0.001$, $n=4$). We conclude that migration of hPASMCs with either Mts1 or BMP2 requires ERK activation via RAGE and CLIC4 expression via BMPR-II. We speculate that when there is BMPR-II loss of function, another stimulus is necessary to de-repress CLIC4 permitting smooth muscle cell migration associated with PH pathology.

2425

**Paxillin-associated ARF-GAP Activity Mediates Slit2-Robo4 Induced Chemorepulsion**

N. Nishiya,[1] C. A. Jones,[2] W. B. Kiosses,[3] J. Han,[1] D. Y. Li,[2] M. H. Ginsberg[1]; [1]Medicine, University of California San Diego, La Jolla, CA, [2]Program in Human Molecular Biology and Genetics, University of Utah, Salt Lake City, UT, [3]The Scripps Research Institute, La Jolla, CA

Attractive and repulsive guidance cues orchestrate pathfinding events in the developing nervous, vascular, and other systems. Directional cell migration requires inhibition of Rac activation at the trailing edge to maintain cell polarity. In the present study, we establish a general mechanism by which membrane receptors attenuate Rac activation, thereby resulting in repulsion. Previously, we found (Nature Cell Biol. vol 7, pg 343, 2005) that the alpha4 integrin subunit recruits paxillin-binding ARF-GAPs to the rear of a migrating cell, leading to local inhibition of Rac activation and suppression of membrane protrusive activity. We now report that this pathway mediates chemorepulsion involved in vascular patterning. Robo family chemorepulsive receptors are transmembrane receptors that regulate pathfinding events. Among the family, Robo4 is specifically expressed in endothelial cells and controls the trajectory of inter somitic angiogenesis . Robo4 inhibits endothelial cell migration through binding of a chemorepulsive ligand, Slit2. We report that paxillin and its paralogue, HIC-5, bind to the cytoplasmic domain of Robo4. Paxillin binding to Robo4 leads to recruitment of an ARF-GAP and consequent inhibition of Rac activation and cell protrusion in response to Slit2. These data establish the generality of this novel pathway for regulating Rac activity and show that the signaling pathway can mediate developmental chemorepulsion in addition to contributing to the polarization of migrating cells.

2426

**A New Positive Role for Raf Kinase Inhibitor Protein in Epithelial Cell Migration**

S. Zhu, K. T. Mc Henry, G. Fenteany; Chemistry, University of Illinois, Chicago, IL

Raf kinase inhibitor protein (RKIP) is a modulator of cell signaling that functions as an endogenous inhibitor of multiple kinases. Here we demonstrate a new positive role for RKIP in the regulation of cell locomotion. We discovered that RKIP is the relevant cellular target of locostatin, a novel cell migration inhibitor. Locostatin abrogates RKIP's ability to bind and inhibit Raf-1 kinase, making it the first known inhibitor of RKIP, one that acts by disrupting a protein-protein interaction, an uncommon mode of action for a small molecule. Small interfering RNA-mediated silencing of RKIP expression also reduces cell migration rate. Overexpression of RKIP converts epithelial cells to a highly migratory fibroblast-like phenotype, with dramatic reduction in the sensitivity of cells to locostatin. RKIP is therefore the compound's valid target and a key regulator of cell motility.

2427

**Targeting and Activation of Rac1 are Mediated by the Exchange Factor β-Pix**

P. L. Hordijk, J. ten Klooster; Experimental Immunohematology, Sanquin Research, Amsterdam, The Netherlands

Rho GTPases are critical regulators of cytoskeletal dynamics and control complex functions such as cell adhesion, spreading, migration and cell division. It is generally accepted that localized GTPase activation is required for proper initiation of downstream signalling events, although the

molecular mechanisms that control intracellular targeting of Rho GTPases are unknown. Rho GTPases carry a C-terminal lipid anchor for membrane association, but likely also require protein domain(s) for specific, subcellular targeting. Here we show that the Rho GTPase Rac1, via a proline stretch in its C-terminus, binds to the SH3 domain of the Cdc42/Rac activator β-Pix. This interaction with endogenous β-Pix is necessary and sufficient for Rac1 recruitment to the plasma membrane and to focal adhesions and for Rac1 activation by β-Pix. Moreover, we show that Rac1 and Pak1, are competitive interactors for β-PIX. Finally, activated CDC42 was found to promote the β-PIX-mediated recruitment of Rac1 to the membrane, possibly by activating PAK1, which leads to its dissociation from β-PIX.. These data provide a model for the intracellular targeting and localized activation of Rac1 through a Cdc42-Pak-β-Pix axis.

2428

**Components of Sema3A Receptor Complex Implicated in the Migration of Glioma Cells**

C. Pinaudeau (Nasarre), M. Perraut, D. Aunis, D. Bagnard; Centre de Neurochimie, INSERM U575, Strasbourg, France

Recent studies showed that semaphorins may play critical roles in cancer cells migration, and may act in the migration of glial cells. Here, using co-culture assays, we investigated the biological effects of a secreted class 3 semaphorin (Sema3A) on the migration of C6 glioma cells, a model of the major human brain tumour cells. Our results demonstrated that Sema3A had no effect on the migration on C6 cells after 24 hours co-culture. However, a significant chemorepulsive effect occurred after 48 hours, and the effect increased with time, indicating that the expression of neuropilin-1 (NRP1), the ligand-binding subunit of semaphorin receptor complex, might be long-term up regulated by the presence of Sema3A. Indeed, the expression of NRP1 was weak in C6 cells; however, by the presence of Sema3A, the NRP1 expression increased. The expression of NRP2 (a potential binding subunit of Sema3A), and the expression of Plexine-A1 (Plex-A1; the functional receptor of Sema3A), were not modified by the presence of Sema3A. Gain of function experiments in which NRP1 was over-expressed in C6 cells also showed a significant chemorepulsive effect of Sema3A. These results suggested that the repulsive effect of Sema3A was dependant of NRP1. Then, using blocking antibodies against NRP1 or Plexine-A1, we showed that the chemorepulsive effect of Sema3A wasn't only lost, but strikingly, was switched into a chemoattractive one. With a blocking antibody against NRP2, NRP1+NRP2, NRP2+Plex-A1 or NRP1+NRP2+Plex-A1, the repulsive effect was abolished. These results confirmed that the repulsion mediated by Sema3A in the C6 cell migration required a receptor complex composed of at least 3 subunits NRP1/NRP2/Plex-A1, in which NRP2 might be a modulator. Indeed, in C6 cells overexpressing NRP2, Sema3A had a chemoattractive effect.

**Mechanisms of Regulation of GIT1 Activation by PIX Required for Cell Migration**

L. Za, S. Paris, A. Totaro, I. de Curtis; San Raffaele Scientific Institute, Milano, Italy

Cell migration requires the reorganization of the cytoskeleton and membrane trafficking for effective protrusion. The mechanisms coordinating these processes are poorly understood. GIT1/p95-APP1 is an ubiquitous ArfGAP that forms stable complexes with the Rac activator/effector complex PIX/PAK, and with paxillin. Studies in neuronal and non neuronal cells indicate an important role of this complex in the regulation of endocytosis and focal adhesion assembly in migrating cells. We have shown by time lapse analysis that motogenic factors induce the rapid accumulation of the GIT mutants at perinuclear endocytic structures, causing inhibition of lamellipodia formation and cell retraction. BetaPIX is required for the association of the GIT1 complex to transferrin receptor-positive endocytic structures. Both dimerization and a functional SH3 domain are necessary for this function of betaPIX. The interaction of betaPIX with GIT1 correlates with the release of an intramolecular interaction between the aminoterminal and carboxyterminal portions of GIT1, and with increased binding to paxillin, a protein implicated in the regulation of integrin-mediated adhesion. Immunofluorescence and cell fractionation were use to establish the tight association of about 30% of the endogenous complex to membranes. Moreover, studies with permeabilized cells show a correlation between the association of endogenous betaPIX to GIT1 and the association of the endogenous complex to membranes. Our data indicate that _etaPIX is an important regulator of the subcellular distribution and regulation of GIT1. BetaPIX-mediated relocalization of the complex allows the redistribution of factors important for the regulation of adhesion and actin dynamics during motility. Supported by Telethon-Italy, grant GGP02190.

**HGF-mediated Endothelial Cell Migration Requires c-Met Ligation, $S1P_1$ and EphA2 Receptor Transactivation, Dynamin2, Cortactin, PI3 kinase and Rac1**

P. A. Singleton, S. M. Dudek, J. G. N. Garcia; Medicine, University of Chicago, Chicago, IL

Therapeutic angiogenesis is an important goal in the treatment of atherosclerosis and ischemic heart failure. As hepatocyte growth factor (HGF) ligation of its receptor tyrosine kinase, c-Met, invokes a potent angiogenic response, we examined the mechanism(s) by which HGF promotes human endothelial cell (EC) migration, a key component of the angiogenic response. We observed that HGF (50 ng/ml, 5 min.) induced c-Met tyrosine phosphorylation, threonine phosphorylation of the sphingosine 1-phosphate receptor ($S1P_1$)and tyrosine phosphorylation of EphA2 receptor in caveolin-enriched EC microdomains (CEM, or lipid rafts). Further, HGF induced recruitment to CEMs of the vesicular regulatory molecule, dynamin II, the actin-regulatory molecule, cortactin, and the regulatory PI3 kinase subunit, p85α in concert with Rac1 activation. Reductions in c-Met or $S1P_1$ expression (siRNAs) blocked HGF-induced EphA2 tyrosine phosphorylation, activation of Rac1, and CEM recruitment,of dynamin II, cortactin, and p85α PI3 kinase. Reductions in EphA2 expression did not block HGF-induced c-Met or $S1P_1$ phosphorylation but attenuated p85α PI3 kinase CEM recruitment and Rac1 activation. Reductions in dynamin II, but not cortactin expression further attenuated HGF-induced Rac1 activation. Finally, attenuation of either lipid raft formation (via cholesterol depletion), actin cytoskeletal rearrangement (via cytochalasin D) or c-Met, $S1P_1$, EphA2, dynamin II, cortactin, p85α PI3 kinase or Rac1 expression all served to block HGF-induced EC migration. These results indicate that c-Met transactivation of $S1P_1$ receptor and EphA2 receptor in CEM is required for HGF-induced EC migration.

**Regulation of VASP Serine 157 Phosphorylation in Human Neutrophils Stimulated by Chemoattractants**

R. E. Eckert, Y. Sharief, S. L. Jones; Clinical Sciences, North Carolina State University, Raleigh, NC

Vasodilator-stimulated phosphoprotein (VASP) is a cAMP-dependent protein kinase (PKA) substrate that links cellular signaling to cytoskeletal organization and cellular movement. VASP is phosphorylated by PKA on serine 157, which is required for VASP function in platelet adhesion and fibroblast motility. Our hypothesis is that PKA regulates neutrophil migration through VASP Ser 157 phosphorylation. The objective of this study was to characterize VASP Ser157 phosphorylation in chemoattractant-stimulated neutrophils. Formylated Met-Leu-Phe (fMLF), IL8, leukotriene $B_4$ ($LTB_4$), or platelet-activating factor (PAF) stimulation resulted in an initial increase in VASP Ser 157 phosphorylation that was maximal by 30s, and was followed by a return to baseline Ser 157 phosphorylation by 10 min. In contrast, stimulation with the pro-inflammatory cytokine TNF alpha did not affect Ser 157 phosphorylation. FMLF-induced Ser 157 phosphorylation was abolished by pretreatment with the PKA-specific inhibitors H89 or KT5720, but was unaffected by the PKC inhibitor staurosporine or the PKG inhibitor Rp-8-pCPT-cGMP. Moreover, prolonging PKA activity by elevating cAMP with prostaglandin $E_2$ or the phosphodiesterase inhibitor IBMX did not increase initial VASP Ser 157 phosphorylation, but did reduce VASP dephosphorylation at later time points. Inhibition of adhesion with either EDTA or the anti-beta 2 integrin antibody IB4 did not alter fMLF-induced VASP phosphorylation or dephosphorylation. These data show that chemoattractant stimulation rapidly increases PKA-dependent VASP Ser 157 phosphorylation, followed by rapid dephosphorylation. Adhesion does not appear to be an important regulator of the state of VASP Ser 157 phosphorylation in chemoattractant-stimulated neutrophils.

### Regulation of Cell Migration by the Cofilin Phosphatase, Chronophin, in EGF-stimulated MTLn3 cells

C. DerMardirossian,[1] V. Delorme,[1] T. Huang,[1] G. M. Danuser,[2] C. M. Waterman-Storer[2]; [1]Immunology, The Scripps Research Institute, La Jolla, CA, [2]Cell Biology, The Scripps Research Institute, La Jolla, CA

Cell motility plays a crucial role in many basic biological processes, including development and wiring of the nervous system, wound healing, inflammation, and cancer metastasis. Motility of cells is dependent on a coordinated regulation of actin cytoskeletal dynamics, i.e. cycles of actin polymerization and depolymerization. As a crucial mediator of actin dynamics, cofilin is regulated by cycling between an active, unphosphorylated form that depolymerizes and/or severs actin, and an inactive, phosphorylated form. The inactivation of cofilin is mediated through its phosphorylation by LIM kinase and its activation results from its dephosphorylation through two unrelated phosphatases: slingshot (SSH) and a recently characterized phosphatase, chronophin (CIN). We examined the effects of this novel cofilin phosphatase, CIN, in actin cytoskeletal dynamics in the context of stimulated cell motility. We have found that in starved carcinoma cells (MTLn3), overexpressed CIN is mostly diffusely distributed in the cytosol. In response to epidermal growth factor (EGF) stimulation, a marked transient localization of overexpressed CIN wt at the leading edge of the lamellipodium occurs at 3 min. In contrast, overexpressed CIN dominant negative (D25N) remained distributed throughout the cytoplasm. Interestingly, EGF-stimulated MTLn3 does not induce SSH translocation to the leading edge. We next determined whether CIN regulates cell motility in response to growth factor. Analysis of cell speed, using phase-contrast microscopy revealed that MTLn3 injected with CIN wt migrated nearly twice as fast as cells controls. Consistent with these results, we observed marked effects of WT and DN CIN on actin dynamics at the leading edge, as determined by quantitative Fluorescence Speckle Microscopy. We are currently analyzing the mechanisms regulating CIN translocation and function.

### Rac1 and Rac2 Regulate Cell Morphology But Are Not Essential for Migration

A. P. Wheeler,[1] S. D. Smith,[2] C. M. Wells,[3] V. Tybulewicz,[4] A. J. Ridley[5]; [1]Cell Biology, The Scripps Research Institute, La Jolla, CA, [2]Ludwig Institute for Cancer Research, London, United Kingdom, [3]The Ludwig Institute for Cancer Research, London, United Kingdom, [4]The National Insitute for Medical Research, London, United Kingdom, [5]Cell and Molecular Biology, The Ludwig Institute for Cancer Research, London, United Kingdom

Rac proteins are Rho family GTPases involved in transducing signals from cell surface receptors to the cytoskeleton, cell-cell and cell-substratum adhesions and cell cycle . Mammals have three closely related Rac isoforms, Rac1, Rac2 and Rac3. Rac1-null mice die early in embryogenesis, whereas Rac2 is not essential for development or fertility. Rac2 is predominantly expressed in haematopoietic cells, and Rac2-null mice show defects in the function of several different haematopoeitic cell types. Using haematopoietic cell-specific knockout of Rac1, Rac1 and Rac2 have been shown to have differential roles in differentiation, motility, adhesion, phagocytosis and recruitment . We have previously shown that loss of Rac1 in macrophages affects cell shape but not migration speed. Rac3 is not expressed in macrophages, but it is possible that Rac2 compensates for loss of Rac1. Here we report that Rac2 deletion does not affect macrophage migration speed although it does induce loss of podosomes, integrin-based adhesion sites in myeloid cells, and affects cell adhesion. Deletion of Rac1 and Rac2 alters cell morphology but surprisingly does not prevent the migration of macrophages, although it alters their mode of migration.

2434

### Arf6 Acts as a Negative Regulator of Rac1 Activity in Membrane Ruffling Formation

M. Cotton,[1] T. Houndolo,[1] J. A. Pitcher,[2] A. Claing[1]; [1]Pharmacologie, Université de Montréal, Montréal, PQ, Canada, [2]MRC Laboratory for Molecular and Cellular Biology and Department of Pharmacology, University College of London, London, United Kingdom

The ADP-ribosylation factor 6 (ARF6) and Rac1 are small GTP-binding proteins that regulate several signaling events ranging from vesicle trafficking, to modification of membrane lipids and reorganization of the actin cytoskeleton. However, the molecular mechanisms by which ARF6 and Rac1 act in concert to control these different cellular process remain unclear. Here, we show that in HEK 293 cells, ARF6 and Rac1 can be found in complex upon stimulation of the angiotensin receptor. In vitro experiments indicate that these two small G proteins can directly interact together, and that ARF6 preferentially interacts with the GDP-bound form of Rac1. Depletion of ARF6 by RNA interference leads to a marked activation of Rac1 in cells independently of receptor stimulation. Conversely, overexpression of the ARF guanine-nucleotide exchange factor ARNO significantly reduces the angiotensin-stimulated activation of Rac1 while a dominant negative form of ARNO has no effect. Unregulated Rac1 activation induced by the depletion of ARF6 has important physiological consequences. First, angiotensin-stimulation of Rac1 leads to membrane ruffling. Interestingly, depletion of ARF6 also leads to similar membrane ruffling together with the formation of actin-rich protrusions, which can be prevented by expression of a dominant negative form of Rac1. Reorganization of the actin cytoskeleton induced by suppression of ARF6 expression also leads to cell migration. Taken together, these results demonstrate that ARF6 is a key regulator of Rac1 activity *in vivo.*

2435

**Synergistic Effect of Activated Cdc42 and Inactivated Rho via PI 3-kinase Is Required for Injury-induced Cell Migration in Corneal Endothelial Cells**

J. Lee,[1] E. P. Kay[1,2]; [1]Doheny Eye Institute, Los Angeles, CA, [2]Ophthalmology, USC Keck School of Medicine, Los Angeles, CA

Acquisition of elongated cells with prominent pseudopodia is observed in CECs simultaneously treated with FGF-2 and RhoA inhibitors. In the present study, we investigated whether these pseudopodia-containing elongated CECs were migratory phenotypes and whether Cdc42 activation and RhoA inactivation were involved in cell migration via phosphatidylinositol (PI) 3-kinase. Scratch-induced directional migration assay was employed in a 90% confluent CECs; wound healing and migratory rates were measured 24 h following wounding. FGF-2 stimulation alone resulted in a 43% recovery of the wound area, but recovery was completely blocked by the addition of LY294002. CECs treated with both FGF-2 and ROCK inhibitor achieved an 84% recovery of the wound area with a fast migratory speed (0.72 μm/min), and the synergistic effects of FGF-2 and ROCK inhibitor were completely blocked by LY294002. Under these conditions, significant PI 3-kinase and Cdc42 activation was also observed in migratory cells. We further confirmed the involvement of activated Cdc42 and inactivated Rho kinase in endothelial migration by transfecting CECs with constitutively active (ca) or dominant negative (dn) vectors (Rho, Rac, or Cdc42). CECs expressing caCdc42 demonstrated a very high migratory rate (0.52 μm/min), while those expressing caRho showed a complete inhibition of endothelial migration. When cells expressing caCdc42 were treated with FGF-2, migration reached the maximum rate (0.69 μm/min), similar to that observed in cells treated with FGF-2 and Y27632. These findings suggest that endothelial migration is induced by activated Cdc42 and inactivated Rho kinase via PI 3-kinase pathway in response to FGF-2 and that Cdc42 activation is crucial to CECs acquiring characteristic endothelial migration phenotypes.

2436

**A DDR1/Shp2 Signaling Complex Inhibits α2β1 Integrin-mediated Stat1/3 Activation and Cell Migration**

C. Wang,[1] H. Su,[1] Y. Hsu,[2] M. Shen,[3] M. Tang[2]; [1]Physiology, Institute of Basic Medical Sciences, National Cheng Kung University, Tainan, Taiwan Republic of China, [2]Physiology, National Cheng Kung University, Tainan, Taiwan Republic of China, [3]Pharmacology, National Cheng Kung University, Tainan, Taiwan Republic of China

Cell migration is one important factor that regulates branching tubule morphogenesis in collagen gel. Here we showed that discoidin domain receptor 1 (DDR1) inhibited collagen-induced tyrosine phosphorylation of Stat1 and Stat3 and cell migration triggered by α2β1 integrin. Overexpression of DDR1 increased the interaction of DDR1 with SHP-2 and upregulated the tyrosine phosphatase activity of SHP-2. We demonstrated that the SH2-SH2 and PTP domains of SHP-2 were responsible for interaction with DDR1, and that both tyrosine phosphorylation sites 703 and 796 of DDR1 were essential for it to bind with SHP-2. Mutation of tyrosine 703 or 796 of DDR1 abolished the ability of DDR1 to inhibit the tyrosine phosphorylation of Stat1 and Stat3, and restored collagen-induced cell migration and hepatocyte growth factor (HGF)-induced branching tubulogenesis in collagen gel. Taken together, these results demonstrate that SHP-2 is required for the DDR1-induced suppression of Stat1/3 tyrosine phosphorylation, cell migration, and branching tubulogenesis.

**Investigation of Centaurin β4 Arf-gap Isoforms in Human Melanoma Cell Lines**

R. K. Martin, T. Thody, T. R. Jackson; Dermatological Sciences, University of Newcastle, Newcastle-upon-Tyne, United Kingdom

PCR, sequencing and western blotting were used to look for evidence of alternate splicing over the C terminal proline rich regions and SH3 domain of centaurin β4. These domains are used for protein-protein interactions involving oncogenes and focal adhesion proteins. Western blotting using two different antiserum show multiple bands in melanoma cell line lysates. To determine whether these arise by alternate splicing we have performed PCR across the C terminal region known to show splicing in mouse. The total PCR mix containing bands of varying sizes were cloned and subjected to sequencing for each size band for each cell line in duplicate. Two splice forms present in all four melanoma cell lines screened are orthologous to those found in mouse. Three further novel splice variants were found in two melanoma lines. Our investigation of Centaurins in human melanoma cell lines has found several isoforms of Centaurin β4. Centaurins are ADP Ribosylation Factor (Arf) GTPase Activating Proteins (GAPs) that, together with Arf Guanine nucleotide Exchange Factors (Arf-GEFs), regulate cyclic activation of Arfs. Arf signalling is required for certain actin cytoskeletal responses and intracellular trafficking. Centaurin β4/ASAP1/DDEF1/PAG3/AMAP1, shows Arf-GAP activity towards Arf1 and Arf5 . It is the product of the DDEF1 gene locus which has recently been shown to be amplified and upregulated in different stages of uveal melanoma , breast and colon cancer . Ddef1 has also been reported to drive adipogenic differentiation . These novel human melanoma splice forms variously lack proline rich regions implicated in interactions with Src , Crk-L and cortactin , or an SH3 domain implicated with paxillin and FAK , POB1 and Pyk2 . These may therefore differ in their regulation of adhesion and therefore metastatic properties and/or cell growth.

2438

**Identification of Par3 as a Novel Substrate of Rho-kinase**

M. Nakayama,[1] T. Nishimura,[1] M. Sugimoto,[2] T. M. Goto,[1] S. Ohno,[3] M. Amano,[1] K. Kaibuchi[1]; [1]Cell Pharmacology, Nagoya University Graduate School of Medicine, Nagoya, Japan, [2]Vascular Surgery, Nagoya University Graduate School of Medicine, Nagoya, Japan, [3]Department of Molecular Biology, Yokohama City University School of Medicine, Yokohama, Japan

The Rho/Rho-kinase pathway plays important roles in various cell events including cell contraction, cell migration, and polarity establishment. Various substrates of Rho-kinase were already identified so far, such as myosin-binding subunit (MBS) of myosin phosphatase, myosin light chain (MLC), Adducin, Ezrin/Radixin/Moesin (ERM), Lim-kinase, Calponin, and Map2/Tau, which regulate the actin cytoskeleton and microtubules. However, the substrate which regulates cell polarity establishment has not yet been identified. To understand roles of the Rho/Rho-kinase pathway in establishment of cell polarity precisely, we searched for the other Rho-kinase substrates by in vitro kinase assay and identified Par3 as a novel substrate of Rho-kinase. Par3 forms the large protein complex with Par6, atypical protein kinase (aPKC), Cdc42, and so on. This complex functions in various cell-polarization events, including axon specification, asymmetric cell division, cell migration and cell morphology. We determined phosphorylation sites of Par3 by Rho-kinase and also found that interactions among Par complex components, Par3, Par6 and aPKC, were disrupted by phosphorylation of Par3 by Rho-kinase, which decreased the affinity of Par6 and aPKC to Par3. Our results suggest that Rho-kinase plays important roles in cell polarity formation through regulating Par complex.

2439

**Cdc42 is Required for EGF-Stimulated Protrusion and Motility in Carcinoma Cells**

M. El-Sibai,[1] P. Nalbant,[2] F. Macaluso,[3] M. Cammer,[3] M. Symons,[4] J. S. Condeelis,[5] K. M. Hahn,[6] J. M. Backer[1]; [1]Molecular Pharmacology, Albert Einstein College of Medicine, The Bronx, NY, [2]Immunology, Scripps Research Institute, La Jolla, CA, [3]Analytical Imaging Facility, Albert Einstein College of Medicine, The Bronx, NY, [4]Center for Oncology and Cell Biology, Institute for Medical Research at North Shore, Manhasset, NY, [5]Anatomy and Cell Biology, Albert Einstein College of Medicine, The Bronx, NY, [6]Pharmacology, University of North Carolina School of Medicine, Chapel Hill, NC

Cdc42 plays a central role in regulating the actin cytoskeleton and maintaining cell polarity. In this study, we have used a recently developed Cdc42 biosensor (MeroCBD) in order to monitor the activation of endogenous Cdc42 in single cells. When stimulated with EGF, carcinoma cells showed a rapid increase in activated Cdc42 that is primarily localized to the leading edge of the cells. Cdc42 activation is co-temporal with the actin polymerization transients at 1 and 3 min previously defined in MTLn3 cells. To identify the upstream regulator of Cdc42, we examined the effect of the PI3K inhibitor wortmannin on Cdc42 activity. PI3K inhibition led to a substantial decrease in Cdc42 activation. Surprisingly, siRNA-mediated knock-down of Cdc42 expression caused a decrease in EGF-stimulated PIP3 production, suggesting a positive feedback mechanism coordinately regulating Cdc42 and PI3K. We next looked at the effect of Cdc42 inhibition on cell protrusion and lamellopodia formation. Cells treated with Cdc42 siRNA duplexes showed a decrease in EGF-stimulated protrusion. This decrease correlated with a decrease in Arp2/3 localization at the cell edge. The loss of Arp2/3 recruitment in Cdc42 siRNA-treated cells was consistent with images obtained by rotary shadowing scanning electron microscopy, which showed a marked defect in actin filament branching. Finally, we found that the Cdc42 siRNA-treated cells show reduced motility in time-lapse studies. Our data show that the PI3K-kinase-dependent activation of Cdc42 at the leading edge is required for both protrusion and motility in carcinoma cells.

2440

**Role of Rac1 in Heregulin-Mediated Cell Invasion**

S. J. Coniglio,[1,2] S. R. Nanda,[3] M. H. Symons[1,2]; [1]Department of Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, [2]Institute for Medical Research at North Shore-LIJ, Manhasset, NY, [3]Department of Biology, St. Johns University, Queens, NY

The Rho-GTPase Rac1 has been shown by our laboratory to be critical for cell invasion in a panel of human tumor lines. The mechanism of Rac1 mediated invasion however is unclear. The purpose of this study is to investigate the molecular mechanism(s) responsible for invasion downstream of Rac1. Here we show Rac1 is required for the heregulin (Hrg)-stimulated lamellipodia and invasion of human breast carcinoma cell line T47D. Hrg potently activates many signaling pathways potentially involved in invasion and carcinogenesis including ERK, JNK, p38, and PI-3K/AKT. Using small interfering RNA (siRNA), we demonstrate that Rac1 is required for Hrg-mediated activation of JNK1 and JNK2, whereas activation of ERK and p38 are largely independent of Rac1. The mammalian group 1 Pak kinases (Pak 1-3) are direct effectors of Rac and Cdc42. Activation of both Pak1 and Pak2 by Hrg is mediated primarily by Rac1, with a minor contribution by Cdc42. Inhibition of either Pak1 or Pak2 using siRNA blocks Hrg-stimulated invasion. Furthermore, blockade of the JNK pathway with the pharmacological inhibitor SP600125 also inhibits invasion. In summary, we propose a model whereby Hrg stimulates cell invasion via Rac1, Pak1, Pak2 and JNK.

2441

**Live Visualization of RhoA Activity in Carcinoma Cells Reflects a Novel Role of the Rho/p160ROCK in Cell Motility**

M. El-Sibai,[1] O. Pertz,[2] M. Lorenz,[3] J. S. Condeelis,[3] K. M. Hahn,[4] J. M. Backer[1]; [1]Molecular Pharmacology, Albert Einstein College of Medicine, The Bronx, NY, [2]Immunology, Scripps Research Institute, La Jolla, CA, [3]Anatomy and Cell Biology, Albert Einstein College of Medicine, The Bronx, NY, [4]Pharmacology, University of North Carolina School of Medicine, Chapel Hill, NC

RhoA plays a central role in cell motility through the regulation of adhesion and actin/myosin contractility. Recently, RhoA has been found to localize to the leading edge of moving fibroblasts, suggesting a role of RhoA in lamellopodia formation. In this study, we use a FRET-based RhoA biosensor in order to examine the spatial and temporal activation of RhoA in EGF-stimulated carcinoma cells (MTLn3). We found that RhoA follows a biphasic activation profile with peaks at 1 and 3 min, coinciding with the dynamics of EGF-stimulated actin polymerization in MTLn3 cells. The activation of RhoA was localized to a 5 μm-wide zone at the leading edge of cells, suggesting that Rho helps to coordinate the regulation of actin nucleating proteins leading to lamellopodia formation. Inhibition of Rho by microinjection of cells with C3 exoenzyme led to a constitutive increase in cell area. In contrast, cells treated with the ROCK inhibitor Y27632 showed normal basal surface area, but showed an exaggerated extension of lamellopodia in response to EGF. Inhibition of Rho or ROCK also led to a change in Rac localization; instead of accumulating in a narrow band at the edge of control EGF-stimulated cells, Rac was localized in a broad 5 μm band in C3T- or Y27632 treated cells. Inhibition of Rho or ROCK caused a decrease in cell motility in serum that correlated with a decrease in myosin light chain phosphorylation and focal adhesion formation following EGF stimulation. Our study shows that the antagonistic effect of Rho on Rac at the leading edge is mediated through ROCK, and suggests that the RhoA/p160ROCK pathway regulates the formation of adhesive structures during EGF-stimulated protrusion.

2443

**Diacylglycerol Kinase-ζ Regulates Growth Factor-Induced Membrane Ruffling and Migration by Promoting Rac1-RhoGDI Dissociation and PAK1 Phosphorylation**

H. Abramovici,[1,2] R. Parks,[1,3] M. K. Topham,[4,5] X. P. Zhong,[6,7] G. A. Koretzky,[6,8] S. H. Gee[1,2]; [1]Center for Neuromuscular Disease, University of Ottawa, Ottawa, ON, Canada, [2]Cellular and Molecular Medicine, University of Ottawa, Ottawa, ON, Canada, [3]Biochemistry, Microbiology and Immunology, University of Ottawa, Ottawa, ON, Canada, [4]Huntsman Cancer Institute, University of Utah, Salt Lake City, UT, [5]Internal Medicine, University of Utah, Salt Lake City, UT, [6]Signal Transduction Program, Abramson Family Cancer Research Institute, Philadelphia, PA, [7]Cancer Biology, University of Pennsylvania, Philadelphia, PA, [8]Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA

Growth factor-induced cell migration relies on the rapid reorganization of the actin cytoskeleton, a process regulated by the small Rho GTPases, Rac1, RhoA and Cdc42. Rac1 controls the formation of lamellipodia and membrane ruffles, specialized structures that promote cell movement. Although Rac1 associates with several signaling and scaffolding proteins, relatively little is known about how these proteins regulate its function. Here, we show that diacylglycerol kinase-ζ (DGK-ζ), an enzyme that phosphorylates diacylglycerol to yield phosphatidic acid, associates with

Rac1 and plays an important role in membrane ruffling and cell migration in mouse embryonic fibroblasts. DGK-ζ deficient (-/-) fibroblasts showed a three-fold decrease in platelet-derived growth factor (PDGF)- induced membrane ruffling. In addition, (-/-) fibroblasts displayed a 50% decrease in migration rate in both wound healing and three-dimensional migration assays. The decrease in ruffling and migration could be rescued by infecting DGK-ζ (-/-) fibroblasts with adenovirus containing wild-type DGK-ζ, suggesting DGK-ζ plays a role in regulating Rac1-dependent actin remodeling. Consistent with this interpretation, overexpression of a DGK-ζ mutant lacking the Rac1-binding C1AC1B domains decreased membrane ruffling in wild-type (+/+) fibroblasts. Compared to DGK-ζ (-/-) cells, PDGF-stimulated (+/+) fibroblasts had increased Rac1 activity and a decreased amount of Rac1 associated with the Rho guanine-nucleotide dissociation inhibitor (RhoGDI), which sequesters and inhibits Rac1. DGK-ζ (+/+) cells also had higher levels of phosphorylated PAK1, a Rac1-regulated serine/threonine kinase involved in membrane ruffling and migration. Taken together, these results suggest that DGK-ζ regulates Rac1-dependent actin remodeling by promoting the dissociation of Rac1 from RhoGDI and increasing the phosphorylation and activity of PAK1.

2444

**Serine 2 Phosphorylation Regulates Coronin 1B Activity and Affects Cell Migration**

L. Cai,[1,2] M. D. Schaller,[1,2] J. E. Bear[1,2]; [1]Cell and Developmental Biology, School of Medicine, UNC at Chapel Hill, Chapel Hill, NC, [2]Lineberger Comprehensive Cancer Center, Chapel Hill, NC

Coronin 1B, a conserved WD40 repeat-containing, actin binding protein, is ubiquitously expressed and co-localizes with the Arp2/3 complex at the leading edge of fibroblasts. Pharmacological experiments show that the interaction between Coronin 1B and the Arp2/3 complex is regulated through protein kinase C (PKC) phosphorylation. Using tryptic peptide mapping and site-direct mutagenesis, we show that Coronin 1B is phosphorylated at Serine 2 (Ser2) upon phorbol-12-myristate-13-acetate (PMA) stimulation *in vivo*. Rat2 fibroblasts expressing the Coronin 1B S2A mutant show enhanced ruffling in response to PMA and increased speed in single cell tracking assay, while the S2D mutant expression attenuates PMA-induced ruffling and slows cell speed. Expression of the S2A mutant partially protects cells from the inhibitory effects of PMA on cell speed. These data demonstrate that Coronin 1B regulates leading edge dynamics and cell motility in fibroblasts through Ser2 phosphorylation, and this phosphorylation is responsible for a measurable fraction of PMA's effects on motility. To elucidate the regulation of Coronin 1B function via Ser2 phosphorylation, we developed an assay for measuring dephosphorylation using a phosphor-specific antibody. Following termination of PMA treatment with PKC inhibitors, phosphorylated Coronin 1B undergoes a rapid, okadaic acid-insensitive dephosphorylation and returns to basal phosphorylation level within 10 min. RNAi-mediated knockdown of Coronin 1B leads to defects in both leading edge protrusion and cell motility, which can be rescued by over-expression extrinsic wild-type protein. While S2A and S2D mutants reciprocally enhance or suppress cell motility in the presence of wild-type protein, neither is capable of rescuing Coronin 1B knockdown phenotypes. These data are consistent with a model in which Coronin 1B undergoes cycles of phosphorylation and dephosphorylation *in vivo* in order to function properly.

**CSF-1-stimulated Wasp Activation is PI 3-kinase and Cdc42-dependent**

M. Cammer,[1] R. House,[2] M. Lorenz,[3] J. Condeelis,[1] D. Cox[1]; [1]Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, [2]Biochemistry, Albert Einstein College of Medicine, Bronx, NY, [3]Optical Technology Development, Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany

A role for WASP (Wiskott-Aldrich Syndrome Protein) in chemotaxis to various chemoattractants has been demonstrated in monocyte-derived macrophages, dendritic cells and osteoclasts, although it is unclear how WASP activity is regulated in vivo. To determine the temporal and spatial activation of WASP, we have constructed a WASP biosensor (WASPbs) that exhibits intramolecular fluorescence resonance energy transfer (FRET) in its autoinhibited conformation, similar to the N-WASP biosensor (Lorenz et al., Curr. Biol., 2004). Following transfection into COS-7 cells, the activation of WASPbs induced by constitutively-active Cdc42 (Q61L) was inhibited in the presence of the WASP inhibitor wiskostatin, indicating that changes in FRET observed accurately reported changes in WASPbs conformation and activity. WASPbs was expressed in the murine macrophage RAW/LR5 cell line and its activation was observed in response to multiple chemoattractants such as CSF-1, SDF-1 and fractalkine. In response to an upshift of CSF-1 concentration, WASPbs activation was detected globally as early as 30 sec and remained sustained in protrusive regions at later times. Confirmation that the WASPbs reflected activation of endogenous WASP was obtained using conformation-sensitive antibodies that only recognize the open (and therefore active) conformation of WASP and N-WASP. It has been speculated that following CSF-1 treatment PI 3-kinase activates guanine nucleotide exchange factors which in turn activate the Rho GTPases Rac and Cdc42. Since Cdc42 is a known activator of WASP, we determined whether PI 3-kinase and Cdc42 were required for CSF-1-stimulated WASP activation. WASPbs expressing RAW/LR5 cells either co-expressing a dominant-negative Cdc42 mutant (N17) or treated with the PI 3-kinase inhibitor wortmannin, showed reduced WASPbs activation following CSF-1 addition as compared to control cells. These results indicate that WASP activation downstream of the CSF-1R is PI 3-kinase and Cdc42 dependent.

**Rho and its Effector Diaphanous Regulate Adherens Junctions**

C. Homem, R. B. Hauser, M. Peifer; Department of Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

The coordinated tissue movements and cell shape changes that occur during morphogenesis require that cell-cell adhesion and its link to the actin cytoskeleton be very dynamic. In epithelial cells, cell-cell adhesion is mediated through Adherens Junctions (AJs), in which cadherins link cells by homophylic adhesion and in turn link to the actin cytoskeleton via α and β catenin. We are interested in molecules that may regulate the actin cytoskeleton at AJs. Recent findings suggest that formins are good candidates to be regulators of actin polymerization at sites of cell-cell adhesion. Previous studies in cultured mammalian cells have shown that formins interact with α-catenin and that formin function is important for the stability of cell contacts. Studies in *Drosophila* showed that Rho GTPase, a known regulator of Diaphanous, a *Drosophila* formin, is a regulator of AJs, although the mechanism of this regulation is not yet understood. To try to understand how are AJs dynamically regulated we are looking at how these actin regulators modify AJs during embryonic *Drosophila* development. Our hypothesis is that Rho regulates AJs through its effect on the actin cytoskeleton via Diaphanous (Dia). In our study we have found that *dia* co-localizes with AJs throughout much of *Drosophila* development. Further, we have seen that Dia interacts genetically with AJs components. To assess Dia's role during morphogenesis we are using a constitutive

active form of Dia. At dorsal closure two epithelial sheets migrate over the amnioserosal cells until both sheets meet and fuse. During this process the leading edge epithelium cells elongate and the amnioserosal cells constrict apically. Additional force is provided by actin-rich membrane protrusions. Initial results suggest that Dia activity has to be tightly regulated during dorsal closure in order for this each of these events to occur normally.

2447

### Function and Regulation of Fascin in Human Colonic Epithelial Cells

Y. Hashimoto, D. W. Loftis, J. C. Adams; Cell Biology, Lerner Research Institute, Cleveland Clinic, Cleveland, OH

Fascin is an actin-bundling protein with roles in the assembly of cell protrusions that function in cell motility. Fascin is low or absent in normal epithelial cells, but is strongly expressed in human carcinomas from multiple tissues, where it is associated with poor prognosis (reviewed in Int. J. Biochem. Cell Biol. 37, 1787-1804). We hypothesise that fascin contributes to tumor cell migration through actin-bundling and through complexing of S39-phosphorylated fascin with protein kinase C (PKC) (see IJBCB 37, 1787-1804). A second objective is to understand how fascin becomes up-regulated in carcinoma cells. GFP-fascin and two point mutants, GFP-fascinS39A and GFP-fascinS39D, were over-expressed in human colonic epithelial SW1222 cells that lack endogenous fascin and clonal cell lines derived. All lines attached to collagen IV, fibronectin and laminin, but the wildtype or S39A-fascin-expressing lines were morphologically distinct with thick actin protrusions. Proliferation in tissue culture was equivalent in all lines. The major conventional PKC in colon epithelial cells is PKCgamma and we have demonstrated fascin binding to the C1 region of the regulatory domain. Human fascin promoter activity was compared in SW1222 and SW480 (a fascin-positive human colon carcinoma line), using a luciferase reporter assay. A 3.1kb genomic region upstream of the transcriptional start site significantly activated reporter expression in SW480 cells but had negligible activity in SW1222 cells. In contrast, a 1. 6kb genomic region upstream of the transcriptional start site (also negligible in SW1222 cells) had twice the activity of 3.1kb in SW480 cells. We conclude that the mechanism of fascin up-regulation in colon carcinoma cells may involve release from transcriptional repression that acts in the region -3.1kb to -1.6kb and that, once up-regulated, fascin contributes to altered tumor cell signaling and migration.

2448

### Involvement of PI(4,5)P2 in the Initial Activation of Cofilin During Carcinoma Cell Motility and Chemotaxis

X. Song, X. Chen, G. Mouneimne, J. S. Condeelis, R. J. Eddy; Department of Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

The formation of cellular protrusions such as lamellipodia and invadopodia in response to EGF stimulation of mammary carcinoma cells involves the spatial and temporal control of actin dynamics. Cofilin, an actin severing protein, has been implicated in the initial steps leading to lamellipod protrusion and directional migration. In contrast to neutrophils, cofilin is initially activated following EGF stimulation of carcinoma cells by a mechanism that does not involve serine 3 dephosphorylation. The lipid second messenger PI(4,5)P2 has been proposed to integrate actin and membrane dynamics by regulating several actin-modulating proteins including cofilin. Furthermore, the initial peak of cofilin-dependent actin nucleation activity is diminished in the presence of the PLC inhibitor, U-73122. Although previous studies demonstrated that purified cofilin binds to PI(4,5)P2 micelles resulting in an inhibition of its actin severing activity, little is know about the interaction of cofilin with PI(4,5)P2 in cells. We observed that while the activites of cofilin and PLC increase within 60 sec after EGF stimulation, membrane-associated PI(4,5)P2 levels measured by GFP-PH(PLCdelta1) or a PI(4,5)P2-specific antibody decreases by half. This decrease in PI(4,5)P2 is accompanied by a reduction cofilin-PI(4,5)P2 colocalization at the membrane. Since PI(4,5)P2 is concentrated in cholesterol-dependent lipid microdomains (rafts), we investigated the association of cofilin with PI(4,5)P2 in rafts by TX-100 extraction followed by density gradient centrifugation. A fraction of the total cellular cofilin co-purified with lipid rafts. Preincubation of cells with methyl-beta-cyclodextrin prior to raft isolation reduced the levels of raft-associated cofilin significantly. Based on these observations, we propose the initial activation of cofilin may involve the release of a pool of raft-associated cofilin through activation of PLC during EGF-elicited protrusive events resulting in the first transient of action polymerization that determines the cell direction during chemotaxis.

## Cytoskeletal Organization II (2449-2472)

### Analysis of the *Caenorhabditis Elegans* Septin Complex Indicates that Septin Filaments Have No Polarity

C. M. John,[1] D. J. Fitzgerald,[2] M. Faty,[1] H. Jawhari,[3] F. K. Winkler,[3] Y. Barral,[1] M. O. Steinmetz[3]; [1]Institute of Biochemistry, Swiss Federal Institute of Technology, Zuerich, Switzerland, [2]Institute of Molecular Biology and Biophysics, Swiss Federal Institute of Technology, Zuerich, Switzerland, [3]Structural Biology, Paul-Scherrer-Institute, Villigen PSI, Switzerland

Septins are conserved GTPases involved in cytokinesis and cell polarity. In budding yeast, where they were first discovered, septins form a ring at the bud neck. At the ultrastructural level, this ring is formed of the so-called 10 nm neck filaments, which are closely associated with the plasma membrane. The results of many studies indicate that the neck filaments are formed by polymerization of septin subunits into ordered arrays. Whether septin filaments have any polarity is not known. We investigated the molecular organization of septin complexes to determine whether septin filaments show any polarity. We chose to study the *Caenorhabditis elegans* septins Unc59 and Unc61 since they form the simplest septin system currently known. Unc59 and Unc61 both share the three conserved septin domains: a phospholipid binding domain directly N-terminal of a GTPase domain which is followed by a predicted coiled-coil region. To reconstitute a soluble and functional *C.elegans* septin complex, Unc59 and Unc61 were co-expressed in *E.coli* and insect cells and affinity purified. By biochemical and biophysical means we show that Unc59 and Unc61 form a heterodimer that assembles tail-to-tail into a dumbbell shaped heterotetramer. Septin coiled-coil domains both stabilize the heterodimer and participate in the assembly of the heterotetramer. The heterotetramer forms the polymerization-competent subunit of septin filaments. Filaments elongate along the long axis of the tetramer, while lateral interactions mediate the formation of filament bundles and sheets. The tail-to-tail architecture of the tetramer suggests that Unc59 and Unc61 form a non-polar complex. This architecture is consistent with that of core septin complexes of yeast. Our data provide a first model to understand the formation of more elaborate septin complexes, and suggest that septin filaments in general have no polarity.

**Rhotekin, a Small GTPase Rho Effector, Regulates Septin Filament Structures in Rat REF52 Cells**

K. Nagata,[1] H. Ito,[1] I. Iwamoto,[1] R. Morishita,[1] Y. Nozawa,[2] S. Narumiya,[3] T. Asano[1]; [1]Molecular Neurobiology, Institute for Developmental Research, Aichi Human Service Center, Kasugai, Japan, [2]Gifu International Institute of Biotechnology, Gifu, Japan, [3]Pharmacology, Kyoto University Faculty of Medicine, Kyoto, Japan

There is growing evidence for cross-talk between septin filaments and actin cytoskeleton which is regulated by Rho family of GTPases. Here we show that active Rho disrupted septin filament structures in REF52 fibroblast cells. Among Rho effector molecules tested, Rhotekin showed morphological changes of septin filaments similar to those by activated Rho. The center region of Rhotekin was sufficient for the septin reorganization in the cells, and likely to interact indirectly with the C-terminal half of Sept9v3, where a GTPase domain is located. Rhotekin and Sept9v3 are co-localized in perinuclear regions in serum-starved REF52 cells while they redistributed along with actin stress fibers upon stimulation with lysophosphatidic acid (LPA). In neuroblastoma Nuero2a cells, Rhotekin and Sept9v3 were enriched in the tip of neurites, a location where cortical actin reorganization is induced upon stimulation with LPA. Taken together, we propose that Rhotekin is a novel regulator organizing mammalian septin structures and provide a new link between the septin and Rho-signaling.

**The Structural Dynamics of the Yeast Septin Polymer Determined by *in vivo* FRET Microscopy**

K. S. Thorn, M. Sheff; Bauer Center for Genomics Research, Harvard University, Cambridge, MA

The septins are a group of proteins, conserved from yeast to humans, that play important roles in cytokinesis, membrane compartmentalization, and exocytosis. These functions depend on their polymerization into filaments; however, the structure of these filaments is currently unknown. Here, we use fluorescence resonance energy transfer (FRET) microscopy to measure the distances between individual components of the septin filament in live *S. cerevisiae*, in both G1 and metaphase cells and in cells deleted for known regulators of septin function. To make these measurements, the five vegetative yeast septins (Cdc3, Cdc10, Cdc11, Cdc12, and Shs1) were tagged at their C-termini with CFP or YFP. These measurements identify a number of structural changes in the septin complex that occur between G1 and metaphase. Deletion of the kinases Cla4 or Gin4, or the septin Shs1, blocks one of these structural changes, a shortening of the distance between Cdc10 and Cdc11 in metaphase, but introduces a number of constitutive changes to the structure of the septin complex. These data uniquely determine a structural model of the monomeric septin complex and of the interfaces involved in septin polymerization. In this model the long axis of the septin complex is spanned by a heterodimer of Cdc3 and Cdc12 homodimers. Cdc10 and Cdc11 bind to the globular ends of Cdc3 and Cdc12, which interact with adjacent monomers in the end-to-end polymer. This model is supported by biochemical data on the septin complex. Our data further suggest that in G1 cells the septin complex is primarily present as individual linear polymers, and that the structural changes in the septins that are known to occur after bud-emergence result from side-to-side binding of these filaments.

2452

**Characterisation of SEPT9_v1 Protein Expression in Human Epithelial Cells**

P. L. Hyland, P. A. Hall, H. Russell; Centre for Cancer Research & Cell Biology, Queens Univesity Belfast, Belfast, United Kingdom

The expression of SEPT9, one of 13 known human septins, is perturbed in human neoplasia. While mutations have not been found, alterations in the level of SEPT9 transcripts are seen. In particular, changes in the levels of SEPT9_v1, v4 and v4* transcripts have been observed. Furthermore, we have shown that SEPT9_v4 can promote altered motility, perturb polarity and promote resistance to microtubule acting drugs. Our attention has therefore turned to the properties of SEPT9_v1 and we have constructed a model system that mimics the over-expression of this transcript in epithelial neoplasia. To this end we have over-expressed SEPT9_v1 in MCF7 cells both transiently and stably. We have also expressed point mutants that represent both gain of function (G308V) and dominant negative (loss of function; S312N) forms. Immunofluorescence showed both cytoplasmic and nuclear localization for wild-type SEPT9_v1 ranging from filamentous to particulate in nature, similar to that seen with endogenous SEPT9_v1 protein. In contrast, neither mutant was associated with filaments. Biochemical fractionation studies showed that both endogenous SEPT9_v1 and epitope-tagged wild-type SEPT9_v1 was present in cytosol, membrane, cytoskeleton and nuclear fractions. The latter observation is supported by the presence of a bipartite-NLS in the N-terminus of SEPT9-v1. In contrast, epitope-tagged mutant SEPT9_v1 (G308V and S312N) protein was not detected in nuclear fractions. Expression of SEPT9_v1 S312N induced prominent microtubule containing neurite-like extensions, not seen in the wild type or G308V expressing cells. We observe that the expression of SEPT9_v1 alters the adhesive properties of epithelial cells paralleling these morphological changes. Moreover the growth of SEPT9_v1 S312N expressing cells differ from that of other cells with a propensity to form multilayered colonies. These studies provide possible insights into the role of deregulated SEPT9_v1 expression in neoplasia.

2453

**Characterisation of the Functional Domains of SEPT9**

N. L. Pentland, P. L. Hyland, C. J. Scott, H. Russell, P. A. Hall; Centre for Cancer Research & Cell Biology, Queens University Belfast, Belfast, United Kingdom

Altered expression of SEPT9 is a common occurrence in neoplasia and recent data from our group indicates that over-expression of SEPT9_v4 promotes cell motility, perturbs polarity and can induce resistance to microtubule interacting drugs. We wish to understand the domains of SEPT9 that can confer such properties and determine the functional elements that contribute to SEPT9 interactions both with itself and other proteins. In addition to all wild type forms of SEPT9 (v1,v2,v3,v4 & v5), we have generated a complex series of nested deletion mutants as epitope tagged constructs, including: the N terminal variants (v1 residue 1-164; v2 residue 1-157; v3 residue 1-146); the unique region of SEPT9_v1 (residue 1-25); the common region of the N terminal forms (v1 residue 26-164); the N terminus of SEPT9_v4 (v4 residue 1-87); the GTP binding moiety, with (v5 residue1-220) and without the polybasic region (v5 residue 51-220); the GTP binding region plus the septin unique region (v5 residue 51-335) and the septin unique region (v5 residue 221-335). We have employed these constructs to examine homotypic and heterotypic interactions of the various domains in cell based assays by immunoprecipitation as well as confirming interactions using purified proteins. We observe evidence for homotypic interaction of SEPT9_v1 and this appears to be mediated by sequences in both the GTP binding domain as well as via sequences in

the N terminus. SEPT9_v2 and v3 are almost identical to SEPT9_v1, yet do not appear to show an interaction with SEPT9_v1 mediated by the N terminal moieties. Other immunoprecipitation experiments show that SEPT9_v5 can participate in homotypic interactions. In other experiments we are investigating the localisation of the various transgene encoded proteins and examining their functional consequences. Based upon this we can propose a model of how SEPT9 complexes can be formed.

**Role of Lipids in the Assembly of the Central Spindle and Actin Ring during Cytokinesis**

I. E. Szafer-Glusman, M. Fuller; Developmental Biology, Stanford School of Medicine, Stanford, CA

Although it has long been recognized that a contractile actin ring positioned at the equator of dividing cells, and an equatorial bundle of antiparallel microtubules (central spindle) actively participate in cytokinesis, the mechanisms that regulate and mediate assembly of these critical structures, as well as their inter-relationship remain largely unknown. In a large genetic screen for cytokinesis defects in Drosophila male germ cells, mutations that affect cytokinesis in meiosis were identified (Giansanti et al., 2004). One of these mutant genes, *bond*, fails to assemble a central spindle and the actin ring during early anaphase, but allows for the correct localization of myosin and anillin to the cell equator. Molecular cloning and sequencing analysis of *bond* alleles revealed mutations in a novel gene that belongs to the family of Elovl genes conserved from yeast to mammals. Elovl proteins are involved in the elongation of very long chain fatty acids, precursors of complex membrane sphingolipids. In accordance with these findings, inhibition of sphingolipid synthesis in cultured S2 cells induced cytokinesis failure, suggesting that *bond* and *bond*-dependent lipid domains may function in the assembly and organization of cortical F-actin and/or microtubules during cytokinesis. Perhaps these putative lipid domains serve as scaffolds for the recruitment of factors that may function in the regulation or assembly of microtubules or F-actin to the membranes.

2455

**Role of Microtubules and Tea1p in the Regulation of Cell Polarity in *Schizosaccharomyces pombe***

R. Basu,[1] D. Khodjakov,[2,3] S. G. Martin,[1] F. Chang[1,2]; [1]Microbiology, Columbia University, New York, NY, [2]Marine Biology Laboratory, Woods Hole, MA, [3]Columbia High School, East Greenbush, NY

Growth in the fission yeast *Schizosaccharomyces pombe* occurs by extension of the ends of its cylindrical structure. Microtubules have been implicated in establishing bipolar growth in a process known as new end take off (NETO). Direct observations show that microtubule plus ends transport the polarity factors tea1p and tea4p and deliver them to the cell tips. These factors subsequently recruit the formin-actin machinery responsible for cell growth. In this study we evaluate if microtubules are indeed necessary for the establishment of bipolar growth in fission yeast. FRAP studies using tea1-GFP showed that tea1p is delivered to the cell tips with a $t_{1/2}$ of about 5 mins. Interestingly, similar dynamics occurred even in cells treated with the microtubule-depolymerizing drug, MBC, showing that tea1p can dock in the absence of microtubules. We next monitored cellular growth patterns using time-lapse microscopy. In wildtype cells treated with MBC at the beginning of the cell cycle, most cells exhibited monopolar growth (NETO defective), but about 17% of the cells still grew in a bipolar fashion. In contrast, *tea1* mutant cells all exhibited monopolar growth both in the absence and presence of MBC. These data suggest that microtubules do contribute to NETO, but also that tea1p can dock and function even in the absence of microtubules. Current experiments focus on the contribution of other tea1-associated proteins on the microtubule-independent function of tea1p.

**Organization and Force Generation of Interphase Microtubules in Fission Yeast**

L. Krueger,[1] C. Pantoga,[1] D. Bhatt,[2] D. Foethke,[3,1] M. Dogterom,[4,1] F. Nedelec,[3,1] P. Tran,[2] M. Janson[2,1]; [1]Physiology Course, Marine Biological Laboratory, Woods Hole, MA, [2]Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA, [3]Cell Biology and Biophysics Program, EMBL, Heidelberg, Germany, [4]FOM Institute AMOLF, Amsterdam, The Netherlands

Interphase fission yeast cells organize 2 to 5 microtubule bundles that run along the long axis of cells. Each bundle contains two or more antiparallel microtubules that are overlapped and bound to the nuclear envelope at their minus ends, while the plus ends grow toward the cell ends. At the cell poles polymerization creates pushing forces that position the nucleus towards the cell middle. Microtubule bundles also deliver polarity factors to the cell cortex and thereby restrict cell growth to the cell poles. To perform these symmetry-maintaining roles it seems important that multiple bundles are well dispersed over the nuclear envelope and that the growth dynamics of microtubules is regulated at the cell cortex. This summer at the Woods Hole physiology course we investigated possible regulatory mechanisms. First, we observed that bundles in wild type cells are more regularly spaced over the nuclear envelope than would be expected by random placement. We used the software Cytosim to simulate the process of bundle formation and organization. We investigated whether a factor that selectively bundles anti-parallel microtubules could explain the observed bundle distribution. Second, we investigated how microtubule growth dynamics responds to forces generated in contact with the cell wall. We inferred growth velocities and forces from the buckling of single microtubules in contact with cell walls. For practical purposes we used round mutant cells (mor2-phenotype) that lacked the microtubule bundling protein ase1p. Our analysis shows that microtubule growth in yeast may be optimized for force generation as the growth velocity was decreased less by force than previously observed for microtubules polymerized from pure tubulin.

2457

**Coordination of Microtubule and Actin Functions is Essential for Rapid Hyphal Growth of *Aspergillus Nidulans***

T. Horio,[1] X. Dou,[2] S. A. Osmani,[2] B. R. Oakley[2]; [1]Institute of Health Biosciences, The University of Tokushima, Tokushima, Japan, [2]Department of Molecular Genetics, Ohio State University, Columbus, OH

Polarized growth is observed in many organisms and cell types. Cytoskeletal components are known to play important roles in this process. Tip growth of filamentous fungi serves as a model for polarized growth. Previously, we have reported that microtubules play an essential role in rapid hyphal growth of *A. nidulans* (MBC, 2005, 16, 918-926). The actin cytoskeleton is known to localize near the tip of the cell and play an essential role in the deposition of wall materials at the growing tip. To investigate the coordination of actin and microtubules in this process, we observed rapidly growing hyphae of a strain expressing GFP-labeled actin by time-lapse microscopy. In rapidly growing hyphae, actin localized to the

subapical region in a ring of plaques. The ring moved forward following the tip growth keeping even spacing from the tip. Treating hyphae with the anti-microtubule agent benomyl resulted in a vast reduction of the growth rate. The actin plaques dispersed through the cytoplasm as growth slowed. In about 40% of the hyphae, actin plaques failed to reorganize to any specific region throughout the observation period. However, in other hyphae, actin plaques re-accumulated either at the tip or in a medial region of the hyphal wall and slow growth resumed at the site of actin accumulation. After washing out benomyl, rapid tip growth resumed prior to the reorganization of acting plaques. The actin plaques became reorganized as the tip growth rate accelerated. Our results reconfirm the idea that functional actin is essential for the tip growth of filamentous fungi and indicate that coordination of actin and microtubules is required for organization of subapical actin plaques that is required for rapid and steady hyphal tip growth.

**Contribution of Actin-Binding Protein Filamin A to the Process of Stress Fiber Formation in Nonmuscle Cells**

K. Kato,[1] H. Haga,[1] K. Ohashi,[2] T. Ito,[3] K. Kawabata[1]; [1]Division of Biological Sciences, Graduate School of Science, Hokkaido University, Sapporo, Japan, [2]Department of Biology, Faculty of Science, Chiba University, Chiba, Japan, [3]Division of Biological Sciences, Graduate School of Science, Kyoto University, Kyoto, Japan

Filamin A (FLNa) is one of the actin-binding proteins that cross-links actin filaments and makes 3D actin networks at lamellipodia and cell cortices. FLNa is also expressed strongly at stress fibers in nonmuscle cells, indicating FLNa might contribute to some functions of stress fibers. We found previously that expression of FLNa led to an increase of intracellular tension resulted from the formation of stress fibers at dorsal cortex. In this study, to clarify the process of FLNa-dependent stress fiber formation, we observed spatial and temporal variations of stress fibers in FLNa-deficient human melanoma cells (M2 cells) and M2 derived cell-line expressing FLNa (A7 cells) by using immunofluorescent and GFP techniques. In mature A7 cells attaching to glass substrates, stress fibers were formed at the dorsal cortex, whereas stress fibers were not observed at the dorsal of M2 cells. To observe the process of the stress fiber formation, time-lapse imaging of GFP-tagged myosin regulatory light chain in spreading cells was performed using confocal laser scanning microscopy. In A7 cells, polygonal structures at basal and ring-like structures at approximately 4 μm above the base were observed at early stage of the stress fiber formation. Once cells elongated, the stress fibers at the dorsal cortex in A7 cells aligned with the axis of the cell elongation. We also examined the spatial distribution of FLNa in the stress fibers. FLNa was localized alternatively with myosin II in the stress fibers, as well as in the muscle fiber. All these results suggest that FLNa might control the spatial distribution of stress fibers.

**Shear-Induced Alterations in Cell Morphology and Stress Fiber Reorganization in Osteoblast and Osteocytes**

S. M. Ponik, J. Triplett, R. O'Riley, F. Pavalko; Cellular and Integrative Physiology, Indiana University School of Medicine, Indianapolis, IN

Cells subjected to fluid shear stress undergo significant architectural and biochemical changes. Our lab and others previously demonstrated increased actin stress fiber formation in osteoblasts subjected to unidirectional shear stress. To further evaluate the morphologic response of bone cells to different shear profiles, we analyzed changes in cell elongation, long axis alignment, and stress fiber organization in MC3T3 osteoblasts and MLO-Y4 osteocytes subjected to unidirectional and oscillatory shear stress. Unlike what has been reported for endothelial cells, we found that the shear-induced increase in actin stress fiber formation in MC3T3 osteoblasts was not accompanied by cellular realignment in the direction of flow, regardless of the type of shear stress. However, the percent of MC3T3 osteoblasts with significant elongation increased from 35% in static culture to 51% and 85% after 24 hours of oscillatory and unidirectional shear stress, respectively. Analysis of MLO osteocytes revealed that unlike osteoblasts neither cell elongation nor long axis alignment is altered in response to unidirectional or oscillatory shear stress for up to 24 hours. We did find differences in the temporal response of stress fiber formation in osteoblasts treated with either unidirectional or oscillatory shear. As reported previously, immunofluorescence analysis showed a dramatic reorganization of stress fibers in MC3T3 osteoblasts after just 1 hour of unidirectional shear. The same rearrangement of stress fibers did not occur in osteoblasts subjected to oscillatory shear until after 24 hours of stimulation. Additionally, only a modest reorganization of actin microfilaments was observed in MLO osteocytes after 24 hours of unidirectional flow. While shear stress is a potent stimulus for bone cell metabolism, these data suggest inherent differences in the architectural response of osteoblasts and osteocytes to unidirectional and oscillatory shear stress.

2460

**Mechanics and Shape Contributions of Single Stress Fibers in Living Cells**

S. Kumar,[1] I. Z. Maxwell,[2] A. Heisterkamp,[3] T. P. Lele,[4] T. R. Polte,[4] E. Mazur,[2] D. E. Ingber[4]; [1]Department of Bioengineering, University of California, Berkeley, Berkeley, CA, [2]Division of Engineering and Applied Sciences, Harvard University, Cambridge, MA, [3]Lazer Zentrum Hannover, Hannover, Germany, [4]Vascular Biology Program, Children's Hospital Boston and Harvard Medical School, Boston, MA

Cells change their form and function by assembling actin stress fibers at their base and exerting traction forces on their extracellular matrix (ECM) adhesions. It is widely assumed that individual stress fibers are actively tensed by the action of actomyosin motors and that they function as elastic cables that reinforce the basal portion of the cytoskeleton; however, these principles have not been directly tested in living cells, and their significance for overall cell shape control is poorly understood. Here we combine a femtosecond laser nanoscissor, traction force microscopy, and fluorescence photobleaching methods to show that each stress fiber in a living cell behaves as a viscoelastic cable that is both actively tensed by actomyosin motors and passively prestressed through ECM adhesions. By using femtosecond pulses, our nanoscissor is capable of *selectively incising and puncturing holes in individual stress fibers in living cells* with submicron precision and without compromising the plasma membrane. Surprisingly, stress fibers continue to support substantial tensile loads following inhibition of actomyosin contraction. Moreover, the degree to which a single stress fiber contributes to cell shape depends on the rigidity of the ECM. In cells cultured on rigid glass ECMs, disruption of multiple parallel fibers does not significantly alter cell shape. Conversely, in cells cultured on compliant ECM substrates, disruption of a single stress fiber transfers forces to multiple distant adhesion sites, induces cytoskeletal rearrangements many microns away from the site of incision, and changes the shape of the whole cell. In addition to revealing fundamental insight into the mechanical properties and cell-shape contributions of individual actomyosin stress fiber bundles, the technologies described here offer a novel experimental framework with which to spatially map the cytoskeletal mechanics of living cells on the nanoscale.

2461

**Self-organization and Computational Modeling of the Basal Microtubule Network in Polarized Epithelial Cells**

A. R. Reilein, S. Yamada, W. J. Nelson; Molecular and Cellular Physiology, Stanford University, Stanford, CA

Centrosome-derived microtubule arrays have been well-studied, but less is known about the formation and dynamics of non-centrosomal microtubule networks in cells. We examined microtubule networks on the basal cortex of polarized epithelial cells experimentally, and with a stochastic simulation. By examining microtubule dynamics in basal cytoplasts prepared from polarized cells, we found that unlike non-centrosomal networks that require microtubule treadmilling or microtubule motor proteins for organization, this network arises from microtubule-microtubule and microtubule-cell cortex interactions that include Adenomatous polyposis coli (APC). Clathrin-containing and LysoTracker Red-labeled vesicles move bi-directionally along the microtubules, indicating that the basal microtubules are functional in endocytosis. Although microtubules on the basal cortex have an apparently random orientation, the network is self-organized. Stochastic simulation of de novo network formation shows that without any stabilization points the microtubule network does not reach a steady-state configuration. However, in the presence of randomly-generated cortical attachment points (mimicking APC) and microtubule end-to-side interactions, both simulated by an increased microtubule rescue frequency, microtubules cluster over the cortical spots and reach a steady state pattern. Together, these results show a mechanism by which mixed-polarity microtubules can self-organize on the cell cortex to form a functional microtubule network.

**Polymer Physics of the Cytoskeleton**

B. D. Hoffman, K. A. Miranda, G. Massiera, J. C. Crocker; Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, PA

The importance of mechanics and force to biological processes is increasingly appreciated and affects behaviors as distinct as cell motility, morphogenesis, and differentiation. In this work we use four microrheological techniques to measure cellular mechanical properties in a variety of cell types. In combination, these techniques have the novel ability of probing cell mechanics over a wide range of frequency, length scale, geometry and driving (applied torques or innate thermal driving) in a single cell. We find a remarkably simple, but rich, consensus behaviour that, when interpreted with recent advances in polymer physics, shows for the first time that cells behave as a network of semi-flexible polymers, like actin or intermediate filaments, cross-linked by extensible proteins with unfoldable domains, like filamin or actinin. Furthermore a physical mechanism explaining the origins of these properties should help to identified mechanisms of mechanotransduction. Therefore we developed a model of cytoskeletal mechanics based on thermally activated, forced unfolding of protein cross-links in a stressed polymer gel. We find these unfolding events produce an emergent, nearly exponential distribution of cross-link tension. Such tension distributions readily reproduce the recently observed power-law form of cells' dynamic shear moduli as well as power-law creep response. Furthermore the primary determinant of the cellular mechanical response should be the strength of bonds holding together the cross-link domains. Unlike some existing mechanical models the model has a clear connection to cell signaling, as unfolded domains should be readily detectable biochemically. Interestingly, the number of unfolded domains in the simulations is a monotonic function of the strain and shows no hystersis. This leads to novel hypothetical mechanisms of cell shape sensing, compliance sensing, and mechanotransduction as the cell could "measure" the number of these domains to infer the strain in its local environment.

**Image-Based Identification of Small-Molecule Inhibitors of Yeast Pathogen Morphogenesis**

T. Lila,[1] P. Chua,[1] C. Vacin,[1] S. Collibee,[1] D. Clarke,[1] D. Roof,[1] B. Morgan,[1] M. Maxon,[2] D. Pierce,[1] J. Finer[1]; [1]Cytokinetics Inc., South San Francisco, CA, [2]Institute for Regenerative Medicine, San Francisco, CA

Yeast cells can respond to perturbation of the cell cycle or cytoskeleton with distinctive changes in extracellular and nuclear morphologies. To identify compounds that alter the morphology of *Candida albicans*, we conducted an automated fluorescence-microscopic screen of cells treated with a library of 6800 compounds known to be *C. albicans* growth inhibitors. 154 compounds causing diverse morphological phenotypes were identified, including one structural class that induces an isotropic growth phenotype characteristic of defects in polarization of the actin cytoskeleton. A survey of structual analogs in this class revealed members that lack appreciable human cell toxicity and have low micromolar morphogenesis-inhibitory potencies against *C. albicans, C. glabrata, and C. tropicalis* species. Inhibition of morphogenesis by compounds in the series is associated with protracted growth inhibition, making the compounds of interest as potential broad spectrum antifungal agents.

2464

**Interaction of *Plasmodium falciparum* Erythrocyte Membrane Protein 3 (PfEMP3) with Red Cell Membrane Skeleton**

X. Pei; Red Cell Physiology, New York Blood Center, New York, NY

*Plasmodium falciparum* erythrocyte membrane protein 3 (PfEMP3) is one of a large group of malaria proteins which are exported into red blood cytoplasm during parasite development. It has been previously shown that PfEMP3 contributes both to cytoadherence and to rigidity of malaria-infected red blood cells. Nonionic detergent solubility experiments strongly suggested a linkage between PfEMP3 and the red blood cell membrane skeleton. However the nature of interaction of PfEMP3 with red cell membrane skeletal proteins remains largely unknown. In the present study, we show that PfEMP3 binds to both spectrin and protein 4.1R. The binding sites in PfEMP3 for both spectrin and 4.1R were mapped to a 60 amino acid region (FIa1: residues 38 to 97). The FIa1 fragment bound only to one (α 17-C) of nine spectrin fragments which encompass the entire α and β spectrin molecules. The FIa1 binding site within the α 17-C fragment was further localized to repeat 18 and EF hands. Similarly, of the four structural domains of 4.1R, only the N-terminal 30 kDa membrane binding domain was shown to interact with PfEMP3. Furthermore, we documented that the interaction of either full length spectrin or 4.1R to PfEMP3 could be specifically inhibited by the α 17-C spectrin fragment and the 30 kDa membrane binding domain of 4.1R respectively. Detailed molecular characterization of interactions between malaria exported proteins with red cell membrane skeletal proteins should provide insights into mechanisms by which malarial proteins modify red blood cell membrane properties.

**New Cytoskeletal Structures Used to Build a Parasite**

K. Hu,[1] S. Suravajjala,[2] D. S. Roos,[2] J. M. Murray[3]; [1]Dept. of Cell Biology, Scripps Research Institute, La Jolla, CA, [2]Dept. of Biology, University of Pennsylvania, Philadelphia, PA, [3]Dept. of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

*Toxoplasma gondii* belongs to the phylum *Apicomplexa*, which includes 5,000 species of protozoan parasites, including many important human and veterinary pathogens with remarkable cytoskeletons. Central to both invasion and proliferation of *Toxoplasma* is the apical complex, a group of apical cytoskeletal and membrane-bound organelles built around the "conoid", an assembly of 14 spirally arranged novel tubulin polymers that is actively motile during invasion (Hu et al., 2002). In this study, we characterize the localization and dynamics of several apical complex components previously identified in a proteomics screen (Hu et al. 2005). These proteins are not only new markers to sub-compartments within the apical complex, but also define new compartments within the parasite scaffold. In particular, TgDynein Light Chain (TgDLC) concentrates at the ends of the conoid fibers and the anterior portion of the cortical microtubules. TgCentrinII, labels the centrioles , the pre-conoidal rings and 5-6 peripheral rings. Interestingly, the peripheral centrin rings occupy the border of the cap of GFP-TgDLC at the apical end of the parasite, indicating that the molecular composition of anterior and posterior cortical scaffold is distinct. TgMORN1 is a new component of the apical complex and the spindle pole, which in adult parasites also fills the basal gap of the IMC filament network. In dividing cells, TgMORN1 caps the ends of the growing daughter scaffolds. Using time-lapse microscopy, we established the sequence of recruitment of these proteins into the cytoskeleton during daughter scaffold formation. In addition, we studied the distribution of these proteins upon disrupting cell division using microtubule inhibitors to further understand the biogenesis of the new membrane/cytoskeletal compartments that these proteins have defined. Our results yield new insights into the roles of these apical complex components in the construction of the parasite membrane-cytoskeleton scaffold.

**Bacteria Mechanics: Defining the Role of the Cytoskeleton**

O. Esue,[1] Y. Tseng,[2] D. Wirtz[1]; [1]Chemical and Biomolecular Engineering, Johns hopkins University, Baltimore, MD, [2]Chemical Engineering, University of Florida, Gainesville, FL

MreB, FtsZ, and crescentin are highly homologous to eukaryotic actin, tubulin, and intermediate filaments respectively. Depletion of genes coding for MreB and FtsZ cause defects in cell morphology, division, and chromosome segregation, while depletion of crescentin causes *Caulobacter Crescentus* to loose its crescent shape. These results imply both biochemical and mechanical roles for these eukaryotic cytoskeleton protein homologs in bacteria. We use a cone and plate strain controlled rheometer and electron microscopy to study the gelation, structural, and rheological properties of these proteins and establish their structural significance in the cell. We find that MreB, crescentin, and FtsZ form filaments that gel extremely rapidly, with highly elastic networks within physiological time scales (~ minutes), much faster than other major dynamic cytoskeletal filaments in eukaryotic cells, including microtubules, actin and, vimentin. These findings suggest a mechanical role for MreB in cell shape, chromosome segregation, and possible intracellular transport; and crescentin filaments in shaping *C. Crescentus* cells; while FtsZ filaments have the toughness to provide strong mechanical support for the maintenance and circumferential constriction of the bacterial Z-ring. These studies may form a molecular basis for the development of the new generation of antibiotics.

**EhPAK2, a Novel p21-activated Kinase, is Required for Cytokinesis, Capping and Collagen Invasion in *Entamoeba histolytica***

L. E. Arias-Romero, M. J. Almaraz-Barrera, J. D. Diaz-Valencia, M. A. Vargas-Mejia; Biomedicina Molecular, CINVESTAV-IPN, Mexico City, Mexico

Rho GTPases are a family of molecular switches that control fundamental cellular processes in eukaryotic cells and they are known principally for their role in regulating the actin cytoskeleton. Rho GTPases are low-molecular weight proteins that cycle between two conformational states: an inactive GDP-bound form and an active GTP-bound form. Binding of GTP activates Rho GTPases by inducing structural shifts that support association of effector molecules that transmit downstream signals. The p21-activated kinases (PAKs) were the first GTPases-regulated kinases to be identified. They are serine/threonine kinases that serve as important mediators of Rac and Cdc42 GTPases. The kinase activity of PAK has been implicated in proliferative signaling by growth factor receptor tyrosine kinases, as well as in morphogenic processes that control cell polarity and actin cytoskeleton organisation. Recently, a putative PAK has been described in *E. histolytica* and plays a role in the amoeba polarity, motility and phagocytosis of human red blood cells. The aim of this study is to describe the function of a novel p21-activated kinase, EhPAK2. Our results have shown that the CRIB domain of EhPAK2 was able to bind *in vitro* to the *E. histolytica* GTPases EhRacA, EhRacG and EhRho1, whereas the over expression of C-terminal kinase domain of EhPAK2 in amoeba trophozoites, caused severe defects in capping and cytokinesis as well as a significant reduction in amoeboid collagen invasion, suggesting an involvement of EhPAK2 in these cellular processes.

**Simultaneous Analysis of Actin and Myosin II Reveals Three Modes of Contraction-Based Actin Organization in Migrating Epithelial Cells**

J. I. Lim, L. Ji, C. M. Waterman-Storer, G. Danuser; Cell Biology, The Scripps Research Institute, La Jolla, CA

Cells move by coupling forces generated by myosin II-based contraction in the actin cytoskeleton to the extracellular matrix. We previously used quantitative fluorescent speckle microscopy (qFSM) to define kinetically, kinematically and molecularly distinct actin-based modules mediating epithelial cell migration: the lamellipodium being the protrusive module and the lamella being the adhesive/contractile module. In the lamella, retrograde flow of actin powered by myosin II meets a myosin II- powered anterograde actin flow from the cell center in a region we termed the convergence zone. As hypothesized in the solation-contraction coupling model, contraction forces driving actin motion may promote the disassembly of actin filaments in the convergence zone. To test this hypothesis, we co-injected labeled actin with GFP-tagged myosin regulatory light chain (mRLC-eGFP) in PtK1 epithelial cells and imaged them by multispectral spinning disk confocal microscopy to investigate the role of actin and myosin in the convergence zone. qFSM image analysis tools have allowed us to generate spatiotemporal maps of actin polymerization and depolymerization and mRLC assembly and disassembly. We have additionally developed tools that allow correlation of the direction and speed of actin and mRLC-eGFP speckles. Using these tools we find that the flow of actin and mRLC are coupled in the lamella, whereas the absence of

mRLC (and hence, decoupling with actin) at the cell edge supports the actin-polymerization induced retrograde flow model in the lamellipodia. Our investigation of actin flow in the convergence zone provides evidence for three distinct modes of contraction-based actin organization associated with mRLC-eGFP : 1. “Compression” in which actin meshwork convergence is coupled to actin depolymerization; 2. Shear - in which contraction induces anti-parallel actin filament motion; 3. Bundling in which contraction induces actin bundle formation.

**Abl Interactor 1 is Required for Bcr-Abl to Induce Actin Cytoskeleton Remodeling and Integrin Clustering in Hematopoietic Cells**

Y. Li, N. Clough, Z. Dai; Medicine/Medical Oncology, University of Colorado Health Sciences Center, Aurora, CO

The hematopoietic cells isolated from patients with Bcr-Abl-positive leukemia exhibit multiple abnormalities of cytoskeletal function. The molecular events leading to these abnormalities are not fully understood. Here we show that the expression of $p185^{Bcr\text{-}Abl}$ in hematopoietic cells induces tyrosine phosphorylation of Abl interactor (Abi) 1 and the membrane translocation of Abi 1/WAVE 2 complex. This correlates with a striking actin cytoskeleton remodeling; particularly, the induction of an actin-enriched structure located in membrane protrusion. Abi 1, Bcr-Abl, and WAVE 2 were found to co-localize with this abnormal F-actin structure. The proteins involved in cell adhesion, such as integrin, paxillin, and vinculin were also found in association with this actin-enriched structure. Blockade of the signal transduction from Bcr-Abl to Abi 1 by disrupting the interaction between the two proteins not only abolished the tyrosine phosphorylation of Abi 1 and membrane translocation of Abi-1/WAVE 2, but also abrogated the ability of $p185^{Bcr\text{-}Abl}$ to induce abnormal F-actin reorganization and integrin clustering. Moreover, expression of a mutant Abi 1 defective in binding to $p185^{Bcr\text{-}Abl}$ inhibited the Bcr-Abl-induced abnormal actin cytoskeleton remodeling and integrin clustering. These studies define Abi-1/WAVE 2 as a downstream pathway utilized by $p185^{Bcr\text{-}Abl}$ to induce abnormal interaction between integrin and cytoskeleton, and may help to explain how Bcr-Abl induces abnormal adhesion, migration, and homing of leukemic cells.

**Regulation of Cell Migration and Spreading by the Ring Finger E3 Ligase Rnf5**

A. Delaunay, C. Didier, A. Bhoumik, K. Nakayama, Z. Ronai; Signal Transduction Program, The Burnham Institute, La Jolla, CA

RNF5 is a membrane anchored E3 ubiquitin ligase conserved from *C elegans* to Human. In the nematode, RNF-5 regulates the stability of a LIM domain protein involved in the formation of dense bodies and muscle attachment sites, structures that can be compared to mammalian focal adhesion (Broday et al., JCB 2004). In Mammals, one of RNF5 targets is the focal adhesion protein, paxillin, which coordinates cytoskeletal organization during cell migration and spreading. RNF5 overexpression leads to the ubiquitination-dependent exclusion of paxillin from focal adhesion and is associated with an inhibition of cell migration (Didier et al., Mol Cell Biol, 2003). To elucidate the physiological role of RNF5 in the control of paxillin dynamics and cell motility, we first monitored the endogenous localization of RNF5 in normal fibroblasts. RNF5 was found within the leading edge of migrating cells, as well as in specialized, ring shape Spreading Initiation Centers involved in the maturation of focal adhesion (de Hoog et al., Cell 2004). In both cases, RNF5 co-localized with a disorganized fraction of paxillin while in spread and/or static cells, where paxillin is fully organized in mature focal adhesions, RNF5 staining was rather low and diffuse. Consistent with these findings, MEFs obtained from *RNF5-/-* mice exhibited a delay in cell adhesion and spreading which is associated with a delay in the formation of focal adhesion. Impaired cytoskeleton organization was also found in *RNF5-/-* cells that were subjected to stress. These results suggest that RNF5 plays an important role in the control of focal adhesion maturation and/or turnover, as well as in cytoskeleton remodeling. Importantly, both RNF5 E3 ligase activity and membrane anchoring are required for RNF5’s function in cell adhesion and motility.

**Dip Regulates mDia2-mediated Membrane Remodeling at the Leading Edge of Migrating Cells**

K. M. Eisenmann,[1] S. M. Kitchen,[1] H. A. Holman,[1] E. S. Harris,[2] H. N. Higgs,[2] A. S. Alberts[1]; [1]Laboratory of Cell Structure and Signal Integration, Van Andel Research Institute, Grand Rapids, MI, [2]Dartmouth University, Hanover, NH

WASP/N-WASp, which promote branched-nucleation of actin via Arp2/3, and the mammalian Diaphanous-related (mDia; mDia1-3) formins, which nucleate and elongate non-branched actin filaments, participate in the assembly of structures promoting leading-edge extention of migrating cells. Despite recent advances, little is known relative to how these two classes of actin nucleators collaborate at the leading edge. We have tested the idea that GTPase-activated actin assembly mediated by WASp and mDia proteins is coordinated by factors that either modify their activities or bridge the two proteins within cells. One potential 'bridging' factor was Diaphanous-interacting protein (DIP)- also known as WASp-interacting SH3 protein (WISH). DIP binds to both WASp or the related N-WASp and mDia1-2 proteins. The interaction with mDia2 was mediated by a conserved C-terminal leucine-rich domain that bound to the C-terminus of mDia2 bearing the FH2 domain, the critical region of the formin necessary for actin nucleation. DIP also interacts with the respective proline-rich regions of both mDia proteins and WASp. Through a series of approaches, including fluorescence resonance energy transfer (FRET), mDia2 binds to DIP at the leading edge of motile cells and bridges a complex containing both mDia and WASp proteins. Functional experiments show that mDia, WASp and N-WASp collectively regulate actin-membrane dynamics: live cell confocal microscopy demonstrated that similar to the expression of dominant negative mDia, DIP induced profound non-apoptotic membrane blebbing when co-expressed with Cdc42V12 (an activator of mDia2 and N-WASp) in a panel of adherent and non-adherent cells. Collectively, these data suggest that the direct interaction of DIP with either WASp or mDia2 spatially regulate the actin cytoskeleton in profoundly different manners and point towards a fundamental role for DIP as a regulator of mDia2-mediated membrane remodeling at the leading edge of the cell.

**Exploring Rab-regulated Cytoskeleton Remodeling in Drosophila Development**

J. Zhang, M. Scott; Departments of Developmental Biology, Genetics, and Bioengineering, Howard Hughes Medical Institute, Stanford University School of Medicine, Stanford, CA

The F-actin cytoskeleton of most eukaryotic cells is dynamically assembled to provide the force for cell morphology change, cell movement and cytokinesis, which are all critical steps for the organism's normal development, growth, survival, and cellular functions. Rab proteins form the largest subfamily of Ras-like GTPases with more than 70 mammalian members and are previously identified as critical regulators of vesicle and

membrane trafficking. Recent data suggest Rabs may play much broader roles, such as mediating intracellular signal transduction. In this study, we identified a previously uncharacterized Drosophila Rab protein, dRab35, as an essential regulator of cytoskeleton remodeling during Drosophila development. Transgenic flies with dominant negative (DN) but not wild-type (WT) dRab35 introduced into flies caused a striking defect in bristle morphology, probably due to inappropriate actin and/or microtubule organization. Dramatic cell morphology changes were observed when yellow fluorescent protein (YFP)-labeled WT, DN, and CA forms of dRab35 were introduced into Drosophila S2R+ cultured cells. A detailed study of how dRab35 regulates actin remodeling is being conducted.

## Centrosomes II (2473-2491)

2473

### A Novel Role for Beta-Catenin in Centrosome Duplication

S. Bahmanyar, W. J. Nelson, A. I. M. Barth; Molecular and Cellular Physiology, Stanford School of Medicine, Stanford, CA

Centrosomes are comprised of a pair of centrioles that duplicate once per cell cycle to give rise to bipolar spindles required for correct segregation of chromosomes in mitosis. Hyperamplified centrosomes are common to many types of cancers and are thought to give rise to multipolar spindles that contribute to genomic instability. How hyperamplification of centrosomes arises in cancer is not known. Here, we show that wild type β-catenin is an integral component of normal centrosomes in interphase cells and the Armadillo repeat domain mediates β-catenin localization to centrosomes. Depletion of β-catenin inhibits centrosome reduplication in hydroxyurea treated U2OS cells indicating a physiological role for β-catenin at centrosomes. Accumulation of a stabilized form of β-catenin, found in many cancers, induces increased centriole splitting in G1/S phase and formation of extra γ-tubulin structures that are initially defective in microtubule (MT) nucleation. Cells that accumulate stabilized β-catenin with extra γ-tubulin structures progress through the cell cycle and gradually acquire greater than two MT-nucleating centrosomes leading to mitotic cells with multipolar spindles. A transcriptionally inactive form of stabilized β-catenin also gives rise to extra γ-tubulin structures indicating that β-catenin is acting structurally rather than transcriptionally to affect centrosome organization. We suggest that there is a threshold level of β-catenin at centrosomes for normal function. Increasing that level results in prolonged centriole separation in G1/S phase and increased centrosome duplication. Mature extra γ-tubulin structures result in spindle defects that could contribute cell transformation by promoting genomic instability.

### When does DNA Damage-induced Centrosome Amplification Occur in Human Cells?

H. Dodson, L. J. Jeffers, C. Morrison; Department of Biochemistry and NCBES, National University of Ireland - Galway, Galway, Ireland

Aberrant centrosome numbers are commonly observed in cancers and in cells with defective DNA repair. Our recent work revealed that centrosome amplification occurs in response to DNA damage caused by ionising radiation or depletion of the Rad51 recombinase (Dodson *et al*., 2004, EMBO J. 23:3864-73). Initial cell cycle analysis showed that this DNA damage-induced centrosome amplfication occurs without an additional round of DNA replication or failed cytokinesis. Therefore, we hypothesised that the centrosome amplification occurs during a prolonged G2 phase after DNA damage. In order to test this idea and to define the cell cycle stage at which centrosomes duplicate after irradiation, we are examining DNA damage-induced centrosome amplification in live cells. In response to gamma-irradiation, the human U2OS cell line shows increased numbers of centrosomes, as visualised by immunofluorescence microscopy of gamma tubulin in fixed cells. We have generated U2OS clones that stably express GFP-cyclin B1, cyclin E-GFP, and GFP-PCNA, which can serve as temporal markers of the cell cycle in live cells. To visualise centrosomes, we have generated centrin-GFP-expressing clones and are optimising the expression of centrin tagged with monomeric RFP (mRFP). The cell cycle markers may also be tagged with mRFP. Using these tools we propose to follow live cells after ionising radiation and to define centrosome amplification with respect to cell cycle stage using PCNA, cyclin B, cyclin E and possibly cyclin A. These experiments will define the relationship between the chromosome and centrosome cycles under conditions where they become decoupled after DNA damage.

2475

### Cell Cycle Control of Centrosome Duplication

M. Tsou, T. Stearns; Biological Sciences, Stanford University, Stanford, CA

The centrosome duplicates once per cell cycle following a stereotyped series of steps. During G1/S, new centrioles form closely juxtaposed to each of the two original centrioles. The new centrioles remain in a tightly opposed orthogonal configuration during S, G2, and early M phase. These centrioles become disengaged at the end of mitosis or early G1, losing their strict orthogonal configuration, but still joined by an uncharacterized flexible linker. Recent results indicate that there is a centrosome-intrinsic block to reduplication of centrosomes during a single cell cycle. These experiments used cell fusion between combinations of G1, S, and G2 phase cells to show that centrosome duplication only occurs when the fusion products contained previously unduplicated G1 centrosomes. The simplest model to account for this block is that there is a difference between unduplicated G1 centrosomes and duplicated G2 centrosomes such that centrosomes that have already duplicated are not competent to duplicate again within a single cell cycle. To understand this difference, we are using Xenopus egg extract to develop an in vitro system for centrosome duplication that recapitulates this control. By manipulating the duplication potential of centrosomes within the extract, we seek to identify factors that are required for the block to reduplication.

### A Novel Role for TGF-β in Regulating Centrosomal Amplification in Non-malignant Human Mammary Epithelial Cells

C. A. Maxwell, R. Gupta, A. Erickson, M. H. Barcellos-Hoff; Cancer Biology, Lawrence Berkeley National Laboratory, Berkeley, CA

Ionizing radiation (IR) induces genomic instability that may be offset by concomitant TGF-β activation. Centrosome abnormalities (CA) are implicated in the origin of chromosomal instability and are frequently present in cancer cells and premalignant lesions. Here, we investigate whether IR induces CA in non-malignant, p53-competent, human mammary epithelial cells (HMEC) and determine the influence of TGF-β. Following irradiation at graded doses (10-500cGy), either S1 or MCF10A HMEC grown in serum-free conditions were supplemented (+/-TGF-β; 400pg/ml) at 48 hour intervals and CA were quantified one week post-IR. Surprisingly, both HMEC are extremely sensitive to IR-induced CA (IRCA). IRCA occurs at low dose (10cGy), is dose dependent and is significantly inhibited by addition of TGF-β. In cancer cells, IRCA occur

during G2 growth arrest and are thought to precede mitotic catastrophe as another defense against genetic damage. These late time-point analyses suggest that IRCA persist within irradiated populations and do not herald mitotic death. To test this, HMEC were clonally propagated (+/-TGF-β) following IR (200cGy). Clonal propagation alone, as well as irradiation, significantly increased CA in a manner inhibited by TGF-β. To differentiate whether TGF-β PREVENTS or SUPERVISES stress-induced CA, IRCA were examined at early time-points (0-72hr). TGF-β did not prevent IRCA, which occur within one cell cycle independent of treatment and without an associated cycle delay. These data strongly argue that exogenous TGF-β SUPERVISES CA resulting from cellular stress. Consistent with this hypothesis, the frequency of spontaneous CA is significantly higher in *Tgfβ1* null compared to heterozygous keratinocytes and in HMEC treated with TGF-β neutralizing versus control antibodies. In conclusion, p53 competent HMEC are extremely sensitive to CA, HMEC with CA are replication competent and TGF-β is essential for supervising cells containing spontaneous and stress-induced CA.

2477

**Centriole Copy-number Control System**

W. Marshall, J. Feldman; Biochemistry, UCSF, San Francisco, CA

Cells maintain a precise centriole copy number of two per cell. We asked whether this precision might reflect an error-correction mechanism, by examining centriole number in Chlamydomonas mutants with defects in centriole segregation. We found that cells appear to modulate the efficiency of centriole duplication as a function of copy number. Dynamical systems modelling of centriole inheritance indicates that number-dependent duplication coupled with de novo assembly leads to a robust copy number control system. Further modeling studies predict the phenotype to be expected for mutants defective in the specific processes of de novo assembly, templated duplication, or copy-number dependent duplication.

2478

**Centriole Function in Cytokinesis**

E. S. Kannegaard, W. F. Marshall; Biochemistry, University of California San Francisco, San Francisco, CA

Centrioles were the subject of intense research in the early days of cell biology due to their central location within the cell division machinery. However, despite a century of research, the function of centrioles in cell division remains unknown. Previous studies have suggested a direct role for centrioles in cytokinesis by correlating centriole movement with resolution of cytokinesis and an indirect role via the implication of astral microtubules in contractile ring positioning and direction of new membrane deposition. The unicellular green alga *Chlamydomonas reinhardtii* is an ideal system to further study the direct function of centrioles in cytokinesis because it undergoes a closed mitosis and there are a number of strains available that are mutant in centriole number and structure that can be used to probe the precise role of centriole. Additionally, the recently published centriole proteome provides a wealth of candidate proteins that may be tested for functional roles through RNAi knockdown studies. Preliminary evidence suggests that centriole number mutants exhibit increased rates of cytokinetic failure as compared to wild type cells.

2479

**Repeated Duplication of the Centrosome during S-phase Does Not Require Microtubules**

E. S. Halpin, J. Young, E. H. Hinchcliffe; Biological Sciences, Notre Dame, South Bend, IN

Centrosome duplication normally occurs once per cell cycle, as each centriole assembles a daughter or pro-centriole. While centriole number determines the number of centrosomes, it remains unclear whether or not centrosomes can duplicate in the absence of centriole elongation. To test this, we use Chinese hamster ovary (CHO) cells arrested in S-phase, which are capable of undergoing repeated rounds of duplication without coordinate cell cycle progression. We then inhibit microtubule polymerization, allowing the centrosome duplication cycle to continue but preventing the elongation of centrioles. We assay for centrosome number by immuno-labeling with anti-gamma tubulin and by GFP-centrin. We find that during 60 hrs of S-phase arrest in the absence of microtubules, multiple gamma tubulin-containing structures form, often close to the nuclear envelope. These structures do not contain centrioles. When the colcemid is washed out, each of these structures assembles a morphologically normal centrosome that nucleates a microtubule aster. Furthermore, when the colcemid is washed out and the S-phase arrest is released, these structures will go on to form functional mitotic spindle poles. We show that cells treated in this fashion can assemble up to 48 distinct spindle poles. Importantly, the number of “centrosomes” that assemble following colcemid wash-out is similar to the number of true centrioles that assemble during S-phase arrest alone (i.e. with microtubules). Our findings reveal that the re-duplication of centrosome during S-phase arrest does not require an intact microtubule network. Our work also suggests that there is a duplication event that repeatedly occurs during S-phase that does not require the formation or elongation of daughter centrioles. Such a duplication event could represent the formation of a centrosome precursor structure, which has the capacity to nucleate a true centriole-containing centrosome.

2480

**The Duplication of the Centrosome Does Not Require Cell Cycle Progression into S-phase in Mammalian Cells**

T. M. Durcan, T. Rao, E. H. Hinchcliffe; Biological Sciences, University of Notre Dame, South Bend, IN

In animal cells, centrosome duplication occurs once per cell cycle, and is commonly thought to initiate near the G1/S phase transition or during S phase. However, evidence from sea urchins suggests that centrosome duplication can occur prior to the onset of S-phase. We examined the ability of Chinese hamster ovary cells stably transfected with GFP-centrin arrested prior to the onset of S phase to duplicate their centrioles. The GFP-centrin allows for the visualization of centriole number before and after duplication. To arrest cells prior to S phase, cells were initially synchronized in G0 by serum starvation then released in media containing serum and the well-characterized G1 inhibitor mimosine. After 48hrs in G1, 97% of cells had undergone centrosome duplication: 46% possessed 4 centrioles, whilst 51% possessed 5 or more centrioles. G1 arrest was confirmed by flow cytometry, bromodeoxyuridine (BrdU) incorporation, and time-lapse video microscopy. This is in contrast to CHO cells arrested in S phase with aphidicolin - 90% of S-phase cells contained greater than 5 centrioles, with many cells having greater than 14 centrioles. We also repeated these experiments in the non-transformed Chinese Hamster Embryonic Fibroblast (CHEF) cell-line; centriole number was assayed using a centrin antibody. 53% of CHEF cells arrested with mimosine were found to possess 4 centrioles after 48 hrs; we did not find greater than 4 centrioles in CHEF cells. Centriole duplication in G1-arrested cells was inhibited by addition of the Cdk2 inhibitor roscovitine; 67% of CHO cells

contained 2 centrioles after 48hrs in G1 + roscovitine, and only 6% contained more than 4 centrioles. Thus, we conclude that both transformed and un-transformed mammalian cells do not require the onset of S-phase in order to undergo centriole duplication.

2481

**Regulation of Centrosome Duplication by SCF Ubiquitin Ligases**

G. C. Rogers, S. L. Rogers; Biology, University of North Carolina, Chapel Hill, NC

During mitosis in higher eukaryotic cells, centrosomes organize the poles of the mitotic spindle in order to guide segregating chromosomes to each daughter cell. However, in cells that have either too many or too few centrosomes, chromosome segregation may occur asymmetrically (on a multipolar spindle) or may not occur at all (on a monopolar spidle), resulting in aneuploid cell divisions and genomic instability. In order to ensure proper chromosomal inheritance, cells must duplicate the centrosome only once per cell cycle. Although we know that the regulatory pathways that govern centrosome duplication are closely tied to cell cycle progression, the molecular components involved remain largely unknown. Recent genetic analyses of centrosome duplication in *Drosophila* have implicated ubiquitin-mediated protein degradation as mutations in subunits of the SCF E3 ubiquitin ligase (SkpA and the F-box protein, Slimb) result in the production of supernumerary centrosomes . To expand upon these initial findings, we have conducted a functional genomic analysis of SCF components using RNAi in cultured *Drosophila* cells. Using a bioinformatic approach, we find that the *Drosophila* genome encodes 42 F-box proteins, 7 Skp subnits, 6 Cullin subunits, and 3 Roc protein family members. Systematic inhibition of these genes using RNAi has replicated the mutant phenotypes of known genes, with respect to centrosome duplication and cell cycle progression, and has implicated novel genes in these processes, as well. We will present our bioinformatic analysis of the SCF ubiquitin ligase subunits along with our phenotypic analyses using RNAi.

**Aurora-A Activates D-TACC/Msps Complexes Exclusively at Centrosomes to Stabilise Centrosomal Microtubules during Mitosis**

T. Barros,[1] K. Kinoshita,[2] A. Hyman,[3] J. W. Raff[1]; [1]The Gurdon Institute, University of Cambridge, Cambridge, United Kingdom, [2]The Gurdon Institute, Max-Planck-Institute of Molecular and Cell Biology and Genetics, Dresden, Germany, [3]Max-Planck-Institute of Molecular and Cell Biology and Genetics, Dresden, Germany

Centrosomes are the dominant sites of microtubule (MT) assembly during mitosis in animal cells, but it is unclear how this is achieved. The transforming acidic coiled-coil (TACC) proteins stabilise MTs during mitosis by recruiting Msps/XMAP215 proteins to centrosomes. TACC proteins can be phosphorylated *in vitro* by Aurora-A kinases, but the significance of this remains unclear. We show that *Drosophila* TACC (D-TACC) is phosphorylated on Ser863 in an Aurora-A-dependent manner exclusively at centrosomes during mitosis. In embryos expressing only a mutant form of D-TACC that cannot be phosphorylated on Ser863 (GFPS863L), spindle MTs are only partially destabilised, while astral MTs are dramatically destabilised. GFPS863L is concentrated at centrosomes, and recruits Msps there, but cannot associate with the minus ends of MTs. We propose that the centrosomal phosphorylation of D-TACC on Ser863 allows D-TACC/Msps complexes to stabilise the minus ends of centrosome-associated MTs. This stabilisation is essential for the stabilisation of centrosomal MTs, but is not essential for the stabilisation of spindle MTs, presumably because an acentrosomal pathway of spindle assembly can largely compensate for the destabilisation of the centrosomal MTs. Our findings suggest that the phosphorylation of D-TACC by Aurora A ensures that centrosomes are the dominant site of MT assembly during mitosis.

2483

**Distinct γ-tubulin Complexes in Flies: Does Form Follow Function?**

C. Wiese, M. Tremaine, P. Dobrzyn; Dept. of Biochemistry, University of Wisconsin-Madison, Madison, WI

γ-Tubulin is an indispensable component of the animal centrosome. Within the cell, it exists in a multi-protein complex containing between two (yeast) and seven or more (frogs, flies, humans) additional proteins named gamma ring proteins (Grips/GCPs). Most of the components of the metazoan γ-tubulin complex (named γTuRC) are highly conserved among phylogenetically distant species. Curiously, many organisms (including humans and our model system, *Drosophila*) have two separate γ-tubulin genes that are developmentally regulated. In flies, one γ-tubulin isotype is expressed only in the ovary and functions during early embryonic cell divisions. It is subsequently replaced by the other isotype, which persists in somatic tissues throughout the adult fly. While the complexes formed by the embryonic γ-tubulin have received much attention, little is known to date about the γ-tubulin that nucleates and organizes microtubules during most of the life of the organism, or about the proteins that interact with this γ-tubulin. Similarly, little is known about how molecular differences between the two γ-tubulins might influence their function. In this study we isolated γ-tubulins from *Drosophila* embryos or tissue culture cells and discovered that they form discrete complexes with similar but distinct compositions. Surprisingly, each γ-tubulin isotype associates with a different splice variant of one of the Dgrips, Dgrip84/GCP2. This may indicate a role for Dgrip84/GCP2 in regulating the activity and/or the location of the different γ-tubulin complexes.

2484

**Ste20-related Mammalian Protein Kinase Losk is Involved in Development of Cellular Microtubule Radial Array**

A. V. Burakov,[1] O. V. Kovalenko,[1] L. A. Zinovkina,[1] E. S. Potekhina,[1] O. N. Zhapparova,[2] S. A. Kuznetsov,[2] E. S. Nadezhdina[3]; [1]Biochemistry, Beloserskiy Institute of Physico-Chemical Biology, Moscow, Russian Federation, [2]Molecular Biology, Lomonosov Moscow State University, Moscow, Russian Federation, [3]Cell Biology, Institute of Protein Research, Russian Academy of Science, Moscow, Russian Federation

Ste20-related serine-threonine protein kinase LOSK has been identified as a microtubule- and centrosome- associated protein. Bacterialy expressed LOSK N-terminal catalytic domain (LOSK-DT) is active *in vitro* and phosphorylates histone H1 and MBP. $LOSK^{K63R}$-DT is a competitive inhibitor of LOSK-DT activity. Over-expression of LOSK-DT in Vero cells had no obvious effect to microtubule organization, but over-expression of $LOSK^{K63R}$-DT led to a disoranization of radial microtubule array and inhibition of microtubule re-growth from the centrosome after their depolymerization by chilling. Conversely, $LOSK^{K63R}$-DT over-expression did not influence microtubule-polymerizing activity of centrosome *in vitro*. The effect of $LOSK^{K63R}$-DT was prominent also in CHO cells and less clear in HeLa where control microtubules were not organized into radial array. Both LOSK-DT and $LOSK^{K63R}$-DT induced equial rate of apoptotic events, did not influence actin cytoskeleton and caused moderate reduction of gamma-tubulin and pericentrin abundance in centrosome. However, $LOSK^{K63R}$-DT over-expression induced much more significant

decrease of centrosomal dynamitin and active (recognized with monoclonal antibody) form of $p150^{Glued}$ than over-expression of LOSK-DT. Thus, protein kinase LOSK is involved into centrosomal dynactin regulation, and its activity is required for both the development and maintenance of the microtubule radial array in certain cell types.

**Centriole Generation during Ciliogenesis in Airway Epithelial Cells**

E. Vladar,[1] T. Stearns[1,2]; [1]Department of Genetics, Stanford University School of Medicine, Stanford, CA, [2]Biological Sciences, Stanford University, Stanford, CA

Ciliated epithelial cells generate hundreds of centrioles/basal bodies during differentiation. Thus these cells must overcome the normal controls that limit centriole duplication to one round per cell cycle in dividing cells. Ciliated epithelial cells present an ideal model system for understanding both the structural requirements for centriole formation, and the regulatory mechanisms that normally limit centriole number. To study centriole generation in ciliated epithelial cells we set up a primary mouse culture system that allows ciliogenesis to occur *in vitro*. Cells for this culture are derived from trachea of a transgenic mouse strain expressing GFP under the control of a ciliated cell-specific promoter. In these cultures, ciliating cells are GFP-positive even before the appearance of ciliary axonemes, allowing sorting for an enriched population during the stages of ciliogenesis. Immunofluorescence showed that many known structural and functional components of the centrosome also localize to the basal body of the cilia. We have characterized the dynamics of these proteins during ciliogenesis by light and electron microscopy. To investigate the function of these proteins at the basal body, we developed a method for efficient lentiviral gene transfer into cultured ciliated epithelial cells. Lentiviral constructs are being used to validate the localization of centrosomal proteins at the basal body using GFP fusion proteins, and to test the effect of perturbing expression levels for several candidate proteins by overexpression or RNAi-mediated depletion.

**Molecular Analysis of Centriole Assembly in C elegans**

A. Dammermann,[1] I. McLeod,[2] J. R. Yates,[2] K. Oegema[1]; [1]Ludwig Institute for Cancer Research, University of California, San Diego, La Jolla, CA, [2]Department of Cell Biology, The Scripps Research Institute, La Jolla, CA

Centrioles recruit pericentriolar material to form centrosomes and template the formation of cilia. Their duplication, which occurs once per cell cycle in dividing cells and during ciliogenesis in differentiated cells, proceeds in a number of discrete steps, which have been extensively characterized at the morphological level. However, very little is known about the molecular basis underlying these events. We have previously used a fixed assay based on incorporation of the centriolar structural protein SAS-4 to examine the molecular requirements for centriole assembly in the C. elegans early embryo. Of the 7 proteins currently known to be required, 5 (SAS-4, -5, -6, ZYG-1 and SPD-2) localize exclusively or primarily to centrioles. To further characterize their role in centriole duplication, we are examining their recruitment to centrioles during the first embryonic division in live embryos. Our results suggest that these proteins act at distinct stages in the duplication process. In addition, we are pursuing biochemical means to characterize the nature of the complexes within which these proteins are found. Mass spectrometry performed on complexes isolated by tandem affinity purification has so far yielded one novel centriolar protein, validating this approach.

**The SUN Domain of Mps3 is Required for Formation of a Function Spindle Pole Body in *Saccharomyces cerevisiae***

S. L. Jaspersen, S. N. Shelton; Stowers Institute, Kansas City, MO

SUN domain-containing proteins (for Sad1 UNC-84 homology) are a family of structurally conserved inner nuclear envelope proteins that share an approximately 150 amino acid region of homology in their C-termini. SUN proteins have been identified in the proteomes of virtually all eukaryotes, and we have recently shown that the budding yeast spindle pole body (SPB) component Mps3 is structurally and functionally related to Sad1, a *Schizosaccharomyces pombe* SPB protein that contains a SUN domain. We identified essential residues within the Mps3 SUN domain through mutational analysis and demonstrated that this domain is important for Mps3 function during SPB duplication, nuclear migration following mating and establishment of sister chromatid cohesion. Genetic and cytological analysis of Mps3 SUN domain mutants indicated that the SUN domain is required for formation of a functional SPB possibly by tethering proteins in the nuclear envelope. Consistent with this hypothesis, we have found that overproduction of another membrane component of the SPB, Mps2, rescues the growth defect of Mps3 SUN domain mutants. We currently are investigating the possibility that Mps2 and Mps3 physically interact through the Mps3 SUN domain and are examining in greater detail the effect that mutation of the Mps3 SUN domain has on SPB structure. The importance of the Mps3 SUN domain for SPB duplication and integrity raises the interesting possibility that vertebrate SUN proteins may be involved in maintaining a physical association between centrosomes and the nuclear envelope.

**Proteomic Characterization of Early Basal Body Assembly in *Tetrahymena thermophila***

C. G. Pearson,[1] C. L. Kilburn,[1] E. P. Romijn,[2] J. R. Yates,[2] M. Winey[1]; [1]MCDB, CU at Boulder, Boulder, CO, [2]Dept of Cell Biology, Scripps Research Institute, San Diego, CA

Centrosomes promote the fidelity of chromosome transmission and aberrations in their number and structure is evident in the majority of tumors. Integral to centrosome duplication and organization, centrioles are a core structure around which centrosomes organize. Basal bodies, for the formation of cilia and flagella, are analogous to centrioles with a conserved molecular composition and structural organization. Initial events in the assembly of nascent centrioles and basal bodies are highlighted by the formation of an amorphous disk and cartwheel followed by the microtubule rich blades to form a barrel structure. Centriole study is constrained by the limited number of known components. To identify the constituents that generate these early steps in assembly, we have utilized a preparation that enables cartwheel reassembly, *in vitro* (Gavin, 1984). Basal body enriched, biochemical preparations were isolated from *Tetrahymena* and placed into cartwheel reassembly conditions. Structures resembling early steps in basal body and centriole assembly were reassembled and subjected to mass spectrometry (MudPIT) to identify basal body components necessary for cartwheel assembly. We are currently localizing these components using GFP fluorescence imaging and high resolution immuno-EM. Furthermore, using a subtractive proteomic approach, proteins dependent upon γ-tubulin for localization to basal bodies were also identified. γ-

tubulin is essential for the maintenance of basal bodies in *Tetrahymena* (Shang et al, 2002), and its depletion was used to generate enriched samples with and without basal bodies. MudPIT with subtractive computational methods were used to identify components that require γ-tubulin for association with basal bodies. In addition to predicting amorphous disk and cartwheel proteins, these studies identified a number of known and potentially novel basal body and centriole components whose analysis will elucidate the assembly pathways for basal bodies and, ultimately, centrioles.

**The *UNI2* Gene in *Chlamydomonas reinhardtii* Encodes a Component of Basal Bodies and Probasal Bodies**

B. P. Piasecki, W. Wu, M. LaVoie, L. W. Tam, P. A. Lefebvre, C. D. Silflow; Plant Biology, University of Minnesota, St. Paul, MN

The unicellular biflagellate alga *Chlamydomonas reinhardtii* provides a model system for the study of eukaryotic basal bodies/centrioles. Among strains with aberrant flagellar number generated by insertional mutagenesis, we identified mutants at the *UNI2* locus with approximately 50% aflagellate cells, 25% uniflagellate cells, and 25% biflagellate cells. The majority of uniflagellate cells fail to assemble the younger of the two flagella, positioned cis to the eyespot. The mutant cells contain ultrastructural defects in the transition zone at the base of the axoneme. The gene containing these mutations was identified using DNA rescue. The gene transcript, deduced from RT-PCR experiments, encodes a predicted protein with a molecular mass of 134 kD. A predicted rat protein shows significant homology with the Uni2p in two regions. Both proteins are predicted to have a similar isoelectric point and to contain a coiled-coil domain. The phenotype of a null *uni2* mutant allele was rescued to wild-type with a gene construct containing an epitope tag. Immunofluorescence microscopy of the tagged protein showed localization at positions coinciding with basal bodies and probasal bodies in $G_1$ cells. Immunogold electron microscopy is underway to identify the subcellular localization of Uni2p. Preliminary results indicate that the protein localizes to the probasal bodies and the transition zones of mature basal bodies. These results suggest that Uni2p assembles on probasal bodies prior to elongation of the triplet microtubules to form the mature basal body. Immunoblot analysis shows Uni2p is present in at least two molecular-weight variants. Treatment of whole-cell extracts with phosphatase converted the protein to a single molecular-weight form, indicating Uni2p is phosphorylated. Preliminary results indicate the phosphorylation pattern of the Uni2p changes during the cell cycle but not during flagellar assembly of $G_1$ cells.

**Septation in the Fission Yeast *Schizosaccharomyces pombe* Requires the Presence of a Single Spindle Pole Body**

V. Magidson,[1] F. Chang,[2] A. Khodjakov[1]; [1]Molecular Medicine, Wadsworth Center, Albany, NY, [2]Microbiology, Columbia University, New York, NY

Cytokinesis in *S. pombe* is regulated by a cascade of GTPase and protein kinases known as the Septation Initiation Network (SIN). This pathway promotes contraction of the medially positioned actin ring and formation of the septum that separates daughter cells from each other. SIN components localize to the spindle pole bodies (SPBs, yeast centrosomes), suggesting that these organelles act as the activation sites for the SIN. To directly test whether SPBs are necessary for cytokinesis, we laser-ablated SPBs at different stages of mitosis. We find that ablation of both SPBs during metaphase (in a mad2 null background) induces disassembly of the actin ring and prevents initiation of cytokinesis. When both SPBs are ablated during early-to-mid anaphase B the ring begins to contract but then disassembles before cytokinesis is completed. Thus, SPB activities are necessary for not only the initiation of ring contraction, but also the maintenance of the actin ring during cytokinesis. It has been shown that some of the SIN components (*e.g.*, cdc7p) associate with only the daughter SPB during anaphase. These observations suggested that only the daughter SPB is responsible for SIN function. To test this hypothesis we ablated just one SPB during metaphase. All of these cells complete cytokinesis normally. Further, when we ablate just the daughter SPB during anaphase B in cells expressing cdc7-GFP, the mother SPB transiently recruits cdc7p and most of these cells complete cytokinesis. Thus, only one SPB (either the daughter or mother) is sufficient for successful cytokinesis. These studies also suggest that the daughter SPB inhibits SIN activation on the mother SPB.

**Mps1 Phosphorylation of the Kinetochore Component Dam1 Alters the Metaphase Kinetochore Arrangement**

D. R. Gestaut,[1] M. M. Shimogawa,[1] B. Graczyk,[1] M. K. Gardner,[2] M. Ess,[1] A. Zelter,[1] C. Ruse,[3] S. Niessen,[3] T. J. Yoder,[1] J. N. Molk,[4] K. Bloom,[4] J. R. Yates,[3] D. J. Odde,[2] T. N. Davis[1]; [1]Department of Biochemistry, University of Washington, Seattle, WA, [2]Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, [3]Department of Cell Biology, Scripps Research Institute, La Jolla, CA, [4]Department of Biology, University of North Carolina, Chapel Hill, NC

Advances in fluorescent protein tagging allow us to observe metaphase in yeast, providing a model system for the study of forces that regulate spindle length and kinetochore positioning. Using computational methods, we can quantitatively compare metaphase kinetochore arrangements and develop models that predict the observed phenotypes. In a screen for mutations that increase the forces on the spindle pole body (SPB), we isolated *DAM1-765*, a dominant allele of *DAM1* that positions kinetochores closer to SPBs at metaphase. Dam1 is a kinetochore protein required for attachment to kinetochore microtubules. The *DAM1-765* allele contains a single serine to phenylalanine substitution at one of several residues phosphorylated by Mps1 kinase. Two of these Mps1 phosphorylation sites play a role in regulating microtubule length. Alanine substitution at either site results in long microtubules and kinetochores adjacent to SPBs. The distributions of tubulin and kinetochores in the mutant can be simulated computationally by decreasing the microtubule catastrophe frequency, which results in long microtubules. We propose that Mps1 phosphorylation of Dam1 is required for proper positioning of metaphase kinetochores.

**Comparative Atomic Force and Optical Microscopy of Neuronal Growth Cones**

E. L. Grzywa,[1] A. Lee,[2] G. U. Lee,[1] D. M. Suter[2]; [1]School of Chemical Engineering and Bindley Bioscience Center, Purdue University, West Lafayette, IN, [2]Department of Biological Sciences and Bindley Bioscience Center, Purdue University, West Lafayette, IN

The *Aplysia* neuronal growth cone has been established as an excellent model system to study growth cone motility and cytoskeletal dynamics

because of its large size and well defined cytoplasmic regions. While the morphology of these growth cones has been well characterized with optical techniques such as Differential Interference Contrast (DIC) and fluorescence microscopy, there is very little quantitative information on the three dimensional structure of these growth cones available. Therefore, we measured the heights of various growth cone regions using Atomic Force Microscopy (AFM) of fixed *Aplysia* bag cell neurons. The average height of the peripheral domain was determined with 53 nm, while the central domain was in average 1020 nm high. Interestingly, the tips of filopodia were found to be significantly thicker (96 nm) than the base of the filopodia (38 nm). These data correlate well with the visual appearance of growth cone morphology using DIC or fluorescence microscopy. However, a direct comparison of volume determination by AFM and fluorescence intensity measurements of neurons injected with Texas Red-labeled dextran revealed that AFM provides height and volume information with significantly higher resolution and accuracy than fluorescence methods frequently used in cell biology. Our results provide important quantitative information for future analysis of biophysical properties of neuronal growth cones, such as force transduction and protein diffusion, as well of the signal transduction processes underlying neurite outgrowth and guidance.

**Experimental Evidence for Protracted Pausing of Neurofilaments in Axons**

N. Trivedi,[1] P. Jung,[2] A. Brown[1]; [1]Center for Molecular Neurobiology, The Ohio State University, Columbus, OH, [2]Department of Physics and Astronomy, Ohio University, Columbus, OH

Short-term tracking of GFP-tagged neurofilaments in cultured neurons using live-cell fluorescence imaging has shown that the actual rate of movement is fast (average≈0.2-0.3μm/s), whereas long-term tracking *in vivo* using radio-isotopic pulse-labeling has shown that the overall rate is slow (average≈0.003-0.03μm/s). Using computational modeling, we have shown that these data can be explained if we assume that the neurofilaments pause 97% of the time. However, the short-term tracking studies in cultured neurons indicate that the moving neurofilaments pause only 40-70% of the time. One possible explanation for this discrepancy is that our live-cell imaging studies underestimate the true pausing kinetics. Alternatively, neurofilament transport could be faster in cultured neurons than *in vivo*. To test these hypotheses, we investigated neurofilament pausing dynamics in cultured rat sympathetic neurons using a photoactivatable green fluorescent protein fused to rat neurofilament M (PA-GFP-NFM). PA-GFP-NFM protein was activated in a defined axonal region to create a “pulse” of fluorescent neurofilaments, and the “escape” of these neurofilaments from this region was monitored. Time-lapse imaging using this novel “pulse-escape” paradigm revealed the departure of neurofilaments from the activated regions, resulting in a gradual loss of fluorescence. Remarkably, 30% of the neurofilaments remained after 2 hours. The loss of fluorescence was sensitive to metabolic inhibitors, indicating that it was ATP-dependent. Computational simulations revealed that on average the neurofilaments spent 97% of their time pausing, with an average pause duration of 27 minutes. These data show that axonal neurofilaments can pause for very long periods and they demonstrate that short-term tracking of neurofilaments in cultured neurons on a time scale of seconds or minutes greatly underestimates the true pausing behavior. The observed pulse-escape kinetics are consistent with a net transport rate of approximately 0.004μm/s, consistent with slow axonal transport rates *in vivo*.

2494

**An Acto/Myosin Contractile Node Functions to Coordinate Microtubule Dynamics and Entry into the base of Neuronal Growth Cone**

D. T. Burnette, A. W. Schaefer, N. A. Medeiros, P. Forscher; MCDB, Yale University, New Haven, CT

Actin arcs are Myosin II contractile structures in the neuronal growth cone which form in the Transition (T) zone from a condensation of the Peripheral (P) domain’s actin meshwork. We report that the actin arcs are part of a more extensive acto/myosin contractile system that extends proximally into the neurite shaft and coordinates microtubule extension. Fluorescent actin speckle microscopy (FSM) revealed slow (1.5 um/min) but persistent retrograde movement of F-actin structures within the growth cone Central (C) domain that terminated in a Myosin II rich region near the neck of the growth cone. F-actin movement into this region was strongly inhibited by Blebbistatin, suggesting the presence of a Myosin II based contractile node (CN) here. Multimode FSM was used to investigate potential microtubule-actin interactions near the CN. Microtubules entered the growth cone by tracking along actin bundles emanating from the CN. Microtubules in the neurite shaft were more dynamic than CN microtubules. When CN F-actin was depleted with Cytochalasin B, microtubule catastrophe frequency increased. These results suggest the presence of factor(s) in the CN that bias microtubule advance into the growth cone via effects on their assembly dynamics.

2495

**Cytoplasmic Dynein Integrates Microtubules and Actin Filaments during Growth Cone Turning**

I. Tint,[1] Y. He,[2] P. W. Baas,[2] M. M. Black[1]; [1]Anatomy and Cell Biology, Temple University School of Medicine, Philadelphia, PA, [2]Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA

Microtubules extending into filopodia align with bundles of actin filaments during growth cone turning. Here we sought to determine whether dynein-driven forces might play a role in this process. Turning was assayed by culturing rat sympathetic neurons on a patterned substrate consisting of laminin-containing and laminin-free zones. When growth cones reach laminin-free zones, they typically turn to continue elongating. To evaluate the contribution of cytoplasmic dynein, dynein heavy chain was depleted from the neurons using siRNA. Also included in these experiments were neurons depleted of MAP1b, a structural protein that has been implicated in the turning of other types of growth cones. Treatment with siRNA for 2 days reduced MAP1b by ≥95% and dynein heavy chain by ≈70%, after which the neurons were re-plated onto the patterned substrate. Interestingly, depletion of MAP1b had no effect on growth cone turning. In contrast, partial depletion of dynein heavy chain strongly suppressed growth cone turning, such that most growth cones stopped at borders between laminin-containing and laminin-free zones. In dynein-depleted growth cones, microtubules were largely confined to the central zone, often appearing to curve back on themselves, with very few extending into filopodia. By contrast, microtubules in control siRNA-treated growth cones commonly extended into filopodia and aligned with actin bundles. These results suggest that cytoplasmic dynein is instrumental in growth cone turning via on effect on microtubule-actin interactions. Given that cytoplasmic dynein rapidly transports short microtubules down the axon in part by pushing against actin filaments, we speculate that it is essentially the same type of force interaction that accounts for the role of dynein in growth cone turning.

2496

**Microtubule-associated Proteins Regulate the Severing of Microtubules by Katanin and Spastin**

L. Qiang,[1] W. Yu,[1] A. Andreadis,[2] M. Luo,[2] A. Karabay,[1] S. Korulu,[1] P. W. Baas[1]; [1]Drexel University College of Medicine, Philadelphia, PA, [2]Neurobiology Division, Shriver Center, Waltham, MA

The microtubule severing proteins katanin and spastin are important in the neuron for breaking long immobile microtubules into short mobile pieces. It is essential that the severing of microtubules by these enzymes is spatially and temporally regulated so that the entire microtubule array is not severed continuously into subunits. We have hypothesized that fibrous microtubule-associated proteins (MAPs) may regulate the severing of microtubules by restricting the access of katanin and/or spastin to the microtubule lattice. In this view, the severing of microtubules is controlled locally in the neuron by signaling cascades that affect the binding of relevant MAPs to the microtubule. Our goal in the present study was to test whether particular MAPs have the capacity to function in this manner. When katanin or spastin is overexpressed in fibroblasts, the microtubules break into short pieces accompanied by marked depolymerization. However, when the severing proteins are overexpressed together with MAP2c, tau, or MAP4, this effect is markedly attenuated. These three MAPs share a similar microtubule-binding domain. In experiments on tau, the microtubules are partially protected against severing when the microtubule-binding domain alone is expressed, but not when the rest of the molecule absent the binding domain is expressed. The protection is more pronounced with the 4-repeat isoform of tau than the 3-repeat isoform. The protection is not observed when microtubules are stabilized and bundled by taxol, indicating that the presence of the MAP is crucial for the protection. No protection is observed with MAP1b. We conclude that certain MAPs protect microtubules from being severed, while others do not. We are currently using siRNA to deplete MAPs from cultured neurons in order to determine if the microtubules become less resistant to severing proteins in the absence of the MAP.

2497

**Stathmin Family Phosphoproteins and the Microtubule Cytoskeleton in Differentiating Neurons**

F. Poulain,[1,2] S. Chauvin,[1,2] S. Lachkar,[1,2] S. Ozon,[1,2] A. Sobel[1,2]; [1]U706, INSERM, Paris, France, [2]UPMC, Paris, France

Microtubules are major components of the cytoskeleton that regulate essential processes of cell life, including during the different stages of neuronal differentiation. They are particularly dynamic in the growth cone and thus play an essential role in the control of neurite formation. Molecules regulating microtubule assembly and dynamics are thus also key regulators of neuronal differentiation, from early neuritogenesis to process elongation, branching, and structural stabilization. Among such proteins, phosphoproteins of the stathmin family (including SCG10, SCLIP and RB3/RB3'/RB3") share the common ability to sequester tubulin and hence contribute to the control of microtubule assembly and dynamics. Their developmentally regulated expression and their specific localization at membrane compartments of elongating processes and growth cones suggest that they may participate in regulating neuronal differentiation by locally controlling microtubule assembly. In a study aimed at better characterizing the common and specific functional properties of the various proteins of the stathmin family, we found that they are strongly expressed during the first stages of neuron differentiation and specifically targeted to the regions where microtubules are highly dynamic. They are accumulated in the central domain of the growth cone where they appear to be associated with bundled microtubules, and are also observed in the peripheral actin-rich region, in proximity of individual tyrosinated "exploratory" microtubules. Furthermore, pharmacological treatments affecting microtubule organization induced a complete redistribution of the proteins, confirming their close association with microtubule integrity and dynamics in the various growth cone domains. Finally, preliminary functional perturbation experiments, including RNA interference, advocate for a role in neurite outgrowth and differentiation. Altogether, our results suggest that the proteins of the stathmin family are likely regulators of microtubule dynamics within the growth cone and hence participate to the control of process formation during neuronal differentiation.

**Septin Function in C elegans Axonal Migration**

F. P. Finger, C. A. Morton; Biology Department, Rensselaer Polytechnic Institute, Troy, NY

Septins are a family of GTP binding proteins involved in cytokinesis in diverse organisms. They are also expressed in post-mitotic cells, suggestive of other cellular functions. *C. elegans* have two septins, encoded by the *unc-59* and *unc-61* genes. We have recently described a novel role for the worm septins in ventral cord motor neuron axonal migration. To further define the role of septins in axonal migration, we are studying process outgrowth in primary cultures derived from wild-type and septin mutant worm embryos expressing the pan-neuronal *unc-119::GFP* reporter. Extension of processes in *unc-119::GFP* expressing cells derived from wild type embryos begins soon after plating, with approximately 40% of neurons displaying processes after one day in culture. Processes continue to extend and elaborate over the first week in culture, at the end of which approximately 70% of wild type *unc-119::GFP* expressing cells display processes. In contrast, fewer than 20% of *unc-119::GFP* expressing cells derived from null mutant *unc-61(e228)* embryos or from *unc-59(n391)* embryos extend processes during the week in culture. Those processes that are seen in the *unc-61(e228)* cells and in *unc-59 (n391)* cells are shorter and less elaborate than those cultured from wild-type strains. Similar effects are seen when *unc-59* or *unc-61* dsRNA are added to the culture medium. During the first week in culture approximately 70% of cells cultured from the wild-type or septin mutant strains express *unc-119::GFP*, and essentially all cells are viable as revealed by Trypan Blue exclusion. These results are consistent with our previous *in vivo* findings. The actin and microtubule cytoskeletons both display abnormal morphology in septin mutant cultured neurons, suggesting that the septins may regulate cytoskeletal assembly. We hypothesize that the septins are required for establishment and/or maintenance of cortical domains that are necessary for process outgrowth.

**Neurofilaments are Transported Normally along Axons of Cultured Neurons Lacking Myosin Va**

N. Alami, A. Brown; Center for Molecular Neurobiology, The Ohio State University, Columbus, OH

Neurofilaments are transported along axons at slow rates, characterized by fast bidirectional movements interrupted by prolonged pauses. The motors are thought to be dynein and kinesin, which move along microtubules. Recently the Nixon lab reported that neurofilaments also interact with myosin Va (myoVa), which moves along microfilaments, and that neurofilament number and density is increased in axons of dilute lethal *(dl)* mice, which lack myoVa. These data suggest a role for myoVa in neurofilament transport. For example, myoVa could act to increase the frequency of neurofilament movement, perhaps by delivering these polymers to microtubules or by facilitating their association with microtubules in some

other way. According to this hypothesis, the increased neurofilament content of axons in the absence of myoVa could be due to a decrease in neurofilament transport rate. To test this hypothesis, we cultured neurons from superior cervical ganglia of *dl* mice. The neurons extended axons containing neurofilaments and were morphologically indistinguishable from wild type *(wt)*cells. To analyze the transport behavior, we transfected neurons with GFP-tagged neurofilament proteins and tracked neurofilament movement by time-lapse imaging of naturally occurring gaps in the axonal neurofilament array. Statistical comparison of the frequency, directionality, peak velocity, and average velocity including and excluding pauses for 53 neurofilaments in *dl* neurons and 58 neurofilaments in *wt* neurons revealed no significant differences. Thus myoVa has no apparent influence on neurofilament transport in these axons. If myoVa is responsible for short-range longitudinal or lateral movement of axonal neurofilaments in these axons, then any effects of these movements on the transport kinetics are too subtle to detect. We speculate that myoVa may have a more significant effect on neurofilament transport behavior in larger axons with more abundant neurofilaments, such as those encountered *in vivo*.

**Netrin Signaling in Nerve Growth Cones Requires Soluble Adenylyl Cyclase**

K. Y. Wu, J. H. Zippin, M. Kamenetsky, U. Hengst, J. Buck, L. R. Levin, S. R. Jaffrey; Pharmacology, Weill Medical College of Cornell University, New York, NY

The response of growing axons to guidance cues is controlled by cyclic nucleotides. Manipulation of cyclic AMP (cAMP) or its effectors can reverse the polarity of turning responses to molecules such as netrin-1, a secreted molecule that has key roles in the development of the central nervous system. The specific pathways by which cAMP levels are regulated in growth cones and in netrin-1 signaling are unclear. Here we show that soluble adenylyl cyclase (sAC), a noncanonical cAMP-generating enzyme that has previously been found to control sperm facilitation, is expressed in neurons and in developing axons and growth cones. sAC expression in neurons results in an increase filopodial formation and size of growth cones. Furthermore, inhibition of sAC blocks netrin-induced stimulation of growth cone elaboration and chemotropic turning responses of axons to gradients of netrin-1. We also find that netrin-induced cAMP levels increases are mediated by the activation of sAC. Taken together, these results identity a new signaling mechanism for netrin-1, in which sAC is activated and mediates netrin-1 function, and indicate a fundamental role for sAC in axon guidance.

2501

**Frazzled Signaling at the *Drosophila* Embryonic CNS Midline**

J. N. Talbot, M. Sabramanian, M. F. A. VanBerkum; Biological Sciences, Wayne State University, Detroit, MI

Frazzled (Fra) is a key receptor in axon guidance. At the *Drosophila* embryonic midline Fra functions as a chemoattractive receptor guiding exploring neurons across developing commissures. It is likely to regulate actin and myosin dynamics and movement using a variety of signaling pathways. By reducing or over-expressing Fra in a subset of CNS neurons (pCC/MP2 pathway) we provide genetic evidence that several signaling pathways are involved in Fra regulation of myosin. Over-expression of Fra enhances crossovers seen with constitutively active myosin light chain kinase (ctMLCK), while heterozygous *fra* mutations suppress ctMLCK-mediated crossovers. Interestingly, heterozygote mutations affecting Abelson tyrosine kinase (Abl) suppress the frequency of these crossovers. Three Rho family GTPases, Rho, Rac and Cdc42, show ectopic crossovers when co-expressed with Fra; *abl* mutations alter these interactions. Rac and Cdc42 may regulate MLCK or myosin II through p-21 activated kinase (Pak) or indirectly via regulation of actin dynamics. Rho, via its major effector Rho kinase (Rok), alters myosin II activity by inhibiting myosin phosphatase via phosphorylation of its myosin binding subunit. Indeed, we hypothesize that Fra regulates myosin dynamics at the midline through a Rho-Rok dependent pathway and actin dynamics through a Cdc42-Rac dependent pathway. We are testing this hypothesis using profilin and myosin loss-of-function alleles to tease apart the respective roles of actin versus myosin regulation downstream of Fra. Our work in deciphering how activation of Frazzled translates into forward movement of the growth cone at the CNS midline will help our understanding of the mechanisms of cell motility in general.

**Role of Cofilin Phosphocycle by LIM-Kinase and Slingshot in NGF-Induced Neurite Outgrowth**

M. Endo, K. Ohashi, K. Mizuno; Graduate School of Life Sciences, Tohoku University, Sendai, Japan

Neuronal growth cone motility and neurite extension are based on actin filament dynamics. Cofilin plays an essential role for the rapid turnover of actin filaments by severing and depolymerizing actin filaments. Cofilin is inactivated by phosphorylation of Ser-3 by LIM-kinases (LIMKs) and reactivated by dephosphorylation by Slingshots (SSHs). We have previously shown that the overexpression of LIMK1 inhibits growth cone motility and neurite extension, and the overexpression of SSH1L accelerates growth cone motility and neurite extension in nerve growth factor (NGF)-induced neurite outgrowth of dorsal root ganglion (DRG) neurons. Here we report that the regulation of cofilin activity by LIMKs and SSHs is involved in signaling pathways that regulate NGF-induced neurite outgrowth. When undifferentiated PC12 cells were stimulated with NGF, cofilin dephosphorylation and activation of LIMKs were induced at the same time, and the dephosphorylation of cofilin was dependent on SSH1L and SSH2L. RNA interference revealed that LIMK1, LIMK2, SSH1L and SSH2L were required for NGF-induced neurite outgrowth. Furthermore, during NGF-induced neurite outgrowth of DRG neurons, inhibition of LIMKs activity by a synthetic peptide containing a cofilin phosphorylation site suppressed growth cone motility and neurite extension rate, although the growth cones showed well expanding morphology. Immunostaining analysis showed that cofilin concentrated at the leading edge of the control growth cones, and this distribution was enhanced by overexpression of SSH1L. On the contrary, cofilin was diffusively distributed in the growth cones treated with S3-peptide. These findings suggest that the acceleration of cofilin phosphocycle by LIMK and SSH is important in NGF-induced growth cone motility and neurite extension, and the phosphocycle may play a role for the establishment of the polarity of the growth cone.

**Agrin-induced Formation of Filopodia Depends on GAG Chains and Cdc42**

L. Lin, S. McCroskery, J. M. Ross, M. P. Daniels; Cell Biology, NHLBI, NIH, Bethesda, MD

Agrin is a proteoglycan with heparan sulfate (HS) and chondroitin sulfate (CS) glycosaminoglycan (GAG) chains. Transmembrane (TM) agrin is

expressed in the central nervous system, but its functions are poorly understood. Overexpression of TM-agrin in myotubes and hippocampal neurons causes extensive formation of filopodia, while agrin knockdown reduces neuronal filopodia number. (J. Neurosci. 21:9678; ASCB Abstr. 2004, 281). To investigate the role of agrin GAG chains in the induction of filopodia, we created full-length agrin-GFP mutants lacking HS, CS or HS and CS GAG chains by site-directed mutagenesis (to nullify GAG chain attachment sites). Western blots of mutant agrin-GFPs showed narrowing and reduced molecular weight of the ~300-600 kD band representing glycosylated forms. Filopodia formation in transfected COS7 cells was decreased by ~ 70% with the GAG chain mutants compared to wild-type agrin-GFP. In 3-day-old cultures of rat hippocampal neurons transfected with the mutants, the number of filopodia per µm neurite length was decreased 50-60% compared to wild type. We also found that the mean length of the longest neurite was reduced by ~ 50% in neurons transfected with the HS GAG chain mutant. In contrast, the mean length of the longest neurite increased more than 2-fold in neurons transfected with the CS GAG-chain mutant compared to wild type. Furthermore, the number of large growth cones per neuron was reduced ~ 60%. We examined the role of Cdc42 activation in agrin-induced filopodia induction by cotransfecting COS7 cells with agrin and a dominant negative mutant of Cdc42. The dominant negative reduced filopodia formation by 68%. Moreover, activation of wild-type Cdc42 increased strongly in cells co-transfected with TM-agrin. We propose that GAG chain-dependent interactions of agrin with other proteins leads to activation of Cdc42 and resultant formation of filopodia.

### Regulation of Growth Cone Motility and Axon Growth by Akt and Rac

Y. Chen, F. Zhou, W. D. Snider; Neuroscience Center, University of North Carolina, Chapel Hill, Chapel Hill, NC

PI3K signaling is known to be required for NGF-induced axon growth. We have recently described a PI3K-mediated pathway that regulates axonal microtubule assembly via GSK-3β in dorsal root ganglion (DRG) neurons. Surprisingly, the role of PI3K in regulating the actin cytoskeletion in neurons remains largely unknown. In our previous studies (Zhou et al., *Neuron*, 2004), we have shown that a major downstream mediator of PI3K, active Akt, co-localizes with actin filaments in the neuronal growth cone. This result suggests that Akt may play an important role in regulating the actin cytoskeleton in the growth cone. By using immunofluorescence and time-lapse imaging, we show here that specific inhibition of Akt activity in the growth cone of mouse DRG neurons induces dramatic changes in actin organization and growth cone motility. However, these changes in actin cytoskeleton that result from Akt inhibition have no effect on NGF-induced axon growth. We also demonstrate that active Akt co-localizes with the small GTPase Rac, an important regulator of actin dynamics. Over-expression of wild-type Rac in DRG neurons in the presence of NGF leads to dramatic increases in growth cone size. Surprisingly this effect impedes axon growth, suggesting that Rac-induced actin reorganization negatively regulates axon growth. Taken together, our data suggest that Akt and Rac may act in the same pathway to regulate actin dynamics and growth cone motility. However, Akt/Rac mediated actin regulation may play a negative role during axon extension.

### Ral GTPases: New Regulators of Integrin-Dependent Neurite Branching

G. Lalli, A. Hall; MRC Laboratory for Molecular Cell Biology, University College London, London, United Kingdom

Recent studies have uncovered a role for Ral, a Ras-like GTPase, in a variety of cellular processes, such as regulation of cell morphology, vesicle sorting and neurosecretion. In addition, the identification of the exocyst complex as a downstream effector of active Ral indicates that this GTPase could act as a regulator of polarized membrane delivery. The two Ral isoforms, RalA and RalB, display an abundant but non-overlapping punctate pattern in superior cervical ganglia (SCG) neurons, suggesting an association with vesicular compartments. Based on this evidence, we asked if Ral could influence neurite growth, a key neuronal process requiring a precise coordination between the cytoskeleton and the secretory pathway. We transfected or microinjected freshly plated cortical and SCG neurons with constitutively active or dominant negative versions of Ral, or with membrane-targeted Ral guanine nucleotide exchange factors (GEFs). Observation of living and fixed cells shows that active Ral causes a significant increase in neurite branching. In addition, cortical neurons depleted of endogenous Ral by RNA interference (RNAi) are characterized by a reduced branching complexity, further supporting a role for Ral in promoting branching. In our search for extracellular signals leading to Ral activation, we have found, using both Ral-GTP pull-down experiments and quantitative analysis of branching in SCG neurons plated on different substrates, that Ral is necessary for integrin-mediated neurite branching. RalA and RalB promote branching through distinct pathways involving the exocyst complex and phospholipase D (PLD), respectively. Our findings establish a novel role for Ral in the regulation of neurite morphology and provide a cellular context for identifying the downstream effectors of integrin-mediated neurite branching.

### IQGAP3, a Novel Effector of Rac1 and Cdc42, Regulates Neurite Outgrowth through Actin Cytoskeletal Reorganization

S. Wang,[1] T. Watanabe,[1] J. Noritake,[1] K. Sato,[1] M. Fukata,[2] K. Kaibuchi[1]; [1]Department of Cell Pharmacology, Graduate School of Medicine, Nagoya University, Nagoya, Japan, [2]Laboratory of Genomics and Proteomics, National Institute for Longevity Sciences, Obu, Japan

Rac1 and Cdc42, members of Rho family GTPases, play critical roles in diverse cellular processes such as axon guidance and neuronal morphogenesis. They exert the physiological functions through the reorganization of cytoskeleton and adhesion molecules in the concert with their effectors. Here, we identified IQGAP3 as a novel effector of Rac1 and Cdc42. We found that IQGAP3 directly binds to actin filaments through its calponin homology domain and is predominantly expressed in brain. In cultured hippocampal neurons, all IQGAP isoforms were detected at the different levels. Each IQGAP showed the specific localization within the growth cones. We also found that the depletion of IQGAP3 inhibits neurite outgrowth and axonogenesis. Furthermore, IQGAP3 was indispensable for the Rac1/Cdc42-induced neurite elongation and branching in PC12 cells. These results indicate that IQGAP3 specifically regulate the neuronal morphogenesis downstream of Rac1 and Cdc42 and each IQGAP has the different physiological implication.

### Modulation of Axonal Protein Synthesis by Local Stimuli

G. G. Williams,[1] D. E. Willis,[1] M. Kendall,[1] J. Zheng,[1] J. L. Twiss[1,2]; [1]Nemours Biomedical Research, Alfred I duPont Hosp for Children, Wilmington, DE, [2]Biological Sciences, University of Delaware, Newark, DE

It has become clear that vertebrate axons are capable of synthesizing proteins and that this localized translation plays a role in axonal growth. In

developing neurons, growth cone turning in response to axonal pathfinding stimuli, including trophic factors and chemorepulsive signals, requires localized axonal protein synthesis (Piper and Holt, 2004). Work from our lab indicates that axonal protein synthesis is activated during regeneration (Zheng et al., 2001; Hanz et al., 2003). We have recently shown that local application of neurotrophins to regenerating sensory axons alters the transport of mRNAs from cell body into axons (Willis et al., 2005). Here we have asked if the translational capacity of regenerating adult rat sensory axons is locally modulated by extracellular stimuli. Nerve growth factor (NGF) increases neurite outgrowth in adult DRG cultures, and growing axons will turn toward a localized source of NGF. Application of lysophosphatidic acid (LPA) to developing neurons causes neurite retraction. Localized sources of NGF and LPA, immobilized onto polystyrene beads, were used to limit stimulation to axonal subdomains of cultured adult rat sensory neurons. Activity of these immobilized ligands was demonstrated by the turning of growing axons toward or away from the NGF- and LPA-coated beads, respectively. Compared to control cultures, LPA induced an increase in phospho-eIF2a immunoreactivity in the axons while NGF caused a decrease in axonal phosopho-eIF2a immunoreactivity. Phosphorylation of eIF2a on serine 51 is typically associated with an overall decrease in cap-dependent translation. Consistent with this notion, LPA and NGF directly modified the local translation of mRNAs in these axons. Thus, axonal protein synthesis is regulated both by modulation of axonal mRNA levels through altered transport and local changes in specific mRNA translation.

**Profilin:actin Operates in Signaling Synapses in the Lamprey Spinal Chord**

S. Grenklo,[1,2] N. Tomilin,[2] E. Evergren,[2] L. Brodin,[2] R. Karlsson,[1] O. Shupliakov[2]; [1]Department of Cell Biology, Wenner-Gren Institute, Stockholm University, Stockholm, Sweden, [2]Department of Neuroscience, Center of Excellence in Developmental Biology, Karolinska Institutet, Stockholm, Sweden

The role of actin dynamics in synaptic signaling was studied by microinjecting a cross-linked variant of profilin:actin into the lamprey giant reticulospinal synapse. This non-dissociable profilin:actin (PxA) blocks actin polymer-forming complexes operating at filament (+)-ends and hence blocks filament growth. After microinjection and subsequent stimulation of the synapses at 5 Hz for 30 min, a significant number of omega-shaped structures were observed at active zones as compared to control synapses. Most of these structures had a size corresponding to synaptic vesicles, although larger profiles were also observed, possibly reflecting actin-dependent dynamic stages in the presynaptic membrane-vesicle interplay captured by the introduced PxA. Isolation and subsequent characterization of neuronal lamprey profilin:actin, demonstrated that it has similar *in vitro* properties in an actin polymerization assay as mammalian profilin:actin, and antibodies generated against the lamprey profilin partly co-distributed with the synaptic marker SV2 in the lamprey spinal cord. Together these observations indicate a role for profilin:actin in the active zone of the nerve synapse, possibly in connection with synaptic vesicle trafficking.

**Disruption of Actin Polymerization Suggests Two Mechanisms of Dendritic Branch Formation in Neurons**

B. G. Changstrom, E. M. Gibbs, G. S. Withers; Biology, Whitman College, Walla Walla, WA

The actin cytoskeleton regulates the complexity of the dendritic field of neurons, but what local cytoskeletal events initiate the formation of a new branch are not known. Here, we tested the hypothesis that changes in actin polymerization are necessary for dendritic branches to form in cultured hippocampal neurons. During early stages of dendritic development (i.e. the first 5 days in culture) an increase in actin-based lamellipodia appears to parallel the addition of higher order branches, with both increasing about 2-fold. To determine if lamellipodial frequency relates to branching, we treated neurons with drugs that disrupt actin polymerization (cytochalasin D, jasplakinolide, or latrunculin-A) as branches formed. Lamellipodia were clearly disrupted within 1 hour, and were not present after 24 hours. After 24-48 hours, higher order branching was reduced by about 2-fold. Dendritic length, however, increased with exposure to cytochalasin or latrunculin. These data suggest that actin dynamics are important for the formation of new branches, but not for net extension. In addition, actin disruption clearly altered branch angle. For example, after 24 hours of drug treatment, over 40% of the dendritic branches occurred at angles less than 40°; 10% of the branches in control cells fell within this range. From these observations, we propose two mechanisms of dendritic branch formation: the first is actin-based and branches arise from lamellipodia on the dendritic shaft; the second is not dependent on actin dynamics or lamellipodia, but perhaps branches arise via a microtubule-based mechanism from the tip of a dendrite. These data also suggest that actin is important in establishing the geometry of the dendritic arbor. Support: NSF CAREER and REU awards (GW)

**Localization of Protein Kinase A to Actin-rich Cytoskeletal Elements in Neuronal Growth Cones**

M. D. Birger, K. J. Gaston, A. K. Howe; Pharmacology, University of Vermont, Burlington, VT

Proper formation of the neural network is dependent upon the specific regulation of growth cone motility and guidance in response to various environmental cues. This guidance is driven by regulation of actin cytoskeletal dynamics and the signal transduction pathways utilized by guidance cues to effect cytoskeletal regulation are under intense investigation. Recent results from our laboratory have shown that the cAMP-dependent protein kinase (PKA) is enriched in the protrusive structures formed at the leading edge of migrating fibroblasts and that this localization is important for chemotactic cell movement. Because it is well established that growth cone guidance can be modulated by PKA signaling, we have examined the sub-cellular location of PKA in growth cones and peripheral edge structures of migrating and differentiating neuronal cells. Initial efforts focused on PKA type II regulatory subunits (RIIα), as these are known to be spatially regulated through interactions with A-kinase anchoring proteins (AKAPs). Immunofluorescence of endogenous RIIα in differentiating N1E-115 and NG108-15 cells revealed that RIIα co-localizes with cortical actin filaments and microspikes in growth cones and peripheral membrane regions. Co-localization with microspikes was also seen in NG108-15 cells expressing an RIIα-GFP fusion protein. Furthermore, point mutation or deletion of the AKAP-binding region of RIIα altered the its localization. These data support the hypothesis that PKA is recruited to cytoskeletal structures in the periphery of neuronal cells where its activity is likely needed to modulate actin dynamics in response to guidance cues.

### Actin Rods Disrupt APP Transport Leading to Localized Aβ Accumulation in Cultured Neurons

M. T. Maloney,[1] J. N. Fass,[1] L. S. Minamide,[1] A. W. Kinley,[1] J. R. Bamburg[1,2]; [1]Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO, [2]Program in Molecular, Cellular and Integrative Neuroscience, Colorado State University, Fort Collins, CO

Cargo transport along the cytoskeleton is particularly vulnerable to blockage in axonal and dendritic neuronal processes. Transport defects are a common feature of neurodegenerative diseases including Huntington's Chorea and Alzheimer's. Late stage Alzheimer's disease brain is characterized by extra-cellular amyloid plaques resulting from deposition of secreted amyloid-beta (Aβ), a proteolytic product of amyloid precursor protein (APP). Beta-cleavage of APP occurs in endosomes, which undergo retrograde transport in neurites before releasing their contents extra-cellularly. Transport defects are one of the earliest functional deficits observed in brains of TG2576 mice, a model for Aβ-induced neurodegeneration. Here we show as little as 10nM soluble Aβ oligomers induce the formation of rod shaped aggregates containing ADF/cofilin and actin in neurites of cultured embryonic rat hippocampal neurons. Rods disrupt microtubules and develop vesicular accumulations containing APP, β-secretase, presenilin-1 and β-cleaved APP (the immediate precursor to Aβ) at their ends. We hypothesize that rods disrupt transport and represent a site for localized Aβ production leading to rod induction in surrounding neurites in a progressively degenerative cycle. To test this hypothesis transport is followed in living neurons by adenoviral-mediated expression of APP conjugated to yellow fluorescent protein (APP-YFP). Spontaneous rods are induced and visualized using adenoviral-mediated expression of *Xenopus* ADF/cofilin conjugated to cyan or red fluorescent proteins (XAC-CFP/RFP). Co-expression of APP-YFP with XAC-CFP/RFP demonstrates impaired APP-YFP transport at rods. Future experiments will measure the levels of Aβ produced at rods in two ways: via ratio imaging of immunostained Aβ to total APP in fixed neurons, and by measuring total Aβ content in medium of neurons with and without rods by immuno-assay. (Supported by grants NS40371, NS 43115 and GM35126 from NIH, IIRG-01-2730 from the Alzheimer's Association and a grant-in-aid from Sigma Xi).

## Intermediate Filaments II (2512-2531)

2512

### Intermediate Filament Assembly Probed with Small-Angle X-ray Scattering: Three-Dimensional Structure of Assembly Intermediates

A. V. Sokolova,[1] L. Kreplak,[2] D. I. Svergun,[3] T. Wedig,[4] H. Herrmann,[4] U. Aebi,[2] S. V. Strelkov[2]; [1]Institute of Bioorganic Chemistry, Moscow, Russian Federation, [2]M.E. Mueller Institute, Biozentrum, Basel, Switzerland, [3]EMBL, Hamburg, Germany, [4]German Cancer Research Centre, Heidelberg, Germany

10-nm wide intermediate filaments (IFs) are the least characterised of the three major cytoskeletal filament systems. While crystallographic data on the dimer representing the elementary IF 'building block' have recently become available, little structural detail is known on both the mature IF architecture and their assembly pathway. We have applied solution small-angle X-ray scattering (SAXS) to investigate the *in vitro* assembly of the wild-type human IF protein vimentin and its two assembly-deficient mutants K139C and NΔ30 by systematically varying pH and ionic strength conditions, and complemented these experiments by electron microscopy observations. We show that tetramers, octamers and 32-mers corresponding to the so-called unit-length filaments represent the principal steps along the vimentin assembly pathway. Based on the SAXS data supplemented by the atomic structure of the elementary dimer and additional structural constraints, first ever three-dimensional models for these assembly intermediates are constructed and refined. Together with most recent crystal structures of vimentin fragments, these results represent a major advance towards unveiling the structural basis of both the normal IF function and the mechanism of human disease caused by mutations in IF proteins.

### Cryo-Electron Tomography of *In Vitro* Assembled Vimentin Filaments

K. N. Goldie,[1,2] A. Hoenger,[1] H. Herrmann[3]; [1]Structural and Computational Biology, EMBL, Heidelberg, Germany, [2]School of Biological Sciences, The University of Auckland, Auckland, New Zealand, [3]Division of Molecular Genetics, German Cancer Research Center, Heidelberg, Germany

Of the three major cytoskeletal systems found in eukaryotic cells, which includes microtubules (MTs) and actin microfilaments (MFs), the structural architecture of intermediate filaments (IFs) remains the least understood. Structurally, IFs are much more diverse than MTs and MFs. Recently employed methods such as chemical cross-linking, X-ray fibre diffraction, site-directed spin labeling and electron paramagnetic resonance have given us new insights into the successive assembly steps of the IF molecule up to the tetrameric level. X-ray crystallographic studies on short fragments are also expanding our structural knowledge, but the arrangement of higher order oligomers within the full-length filament is still unknown. With the aim to resolve filament architecture for a typical IF at the molecular level, we have employed cryo-electron microscopy (cryo-EM) and cryo-electron tomography (CET) to *in vitro* assembled recombinant human vimentin. Typically, vimentin is expressed in mesenchymal cells of higher vertebrates and it is able to form homo-polymeric filaments in the test tube without the need for any cofactors. Cryo-EM allows observation of complex biological systems at close to physiological conditions. We demonstrate that unfixed cryo-EM preparations exhibit a mixed population of compact and loose filament morphologies, which clearly contrasts the findings of most EM studies on conventionally fixed, negatively stained filaments. The filaments exhibit a right-handed twist and in some cases, where they show partial unravelling, four distinct protofibrils can be disseminated. This is in agreement with the four protofibril, (each composed of four dimers) model [Herrmann H. and Aebi U. (2004) Annu. Rev. Biochem., 73:749-89]. Thus, our results provide the first EM-derived structural information in 3-D of *in vitro* assembled vimentin filaments under near physiological conditions and contribute to an increased understanding of the IF architecture at molecular resolution.

### PKCζ is Required for the Shear Stress-Induced Structural Reorganization of Keratin Intermediate Filaments in Alveolar Epithelial Cells (AEC)

S. Sivaramakrishnan, N. Na, R. G. Goldman, K. M. Ridge; Northwestern University, Chicago, IL

Keratin intermediate filaments (KIF) in AEC undergo structural reorganization when subjected to shear stress. Since the assembly state of KIF is

known to be influenced by phosphorylation we determined whether known phosphorylation sites are involved in their reorganization. Specifically, the role of K18pSer33 in the structural reorganization of the KIF network in human AEC was studied in response to shear stress. Shear stress (30 d/cm$^2$, 1h) induced the reorganization of the KIF network from thin cytoplasmic fibers to thick wavy bundled filaments or tonofibrils as determined by immunofluorescence. Ratio imaging of K18pSer 33 to K18 immunofluorescence revealed that the increase in phosphorylation was associated primarily with the tonofobrils observed under shear stress. These results were confirmed by keratin-enriched cytoskeletal preparations from control and shear stress AEC. Equal amounts of protein were resolved by SDS-PAGE and immunoblotted with anti-K18 and anti-K18pSer33. There was a three-fold increase in K18pSer33 in shear stressed AEC. The phosphorylation of K18pSer33 under shear stress was inhibited by pre-treatment with 10μM bisindolymaleide (protein kinase C [PKC] inhibitor) but not by U0126 (Erk 1/2 specific inhibitor). Inhibition of classical and novel PKC isozymes by a phorbol ester (PMA, 1μM, 24hrs) did not prevent K18pSer33 phosphorylation under shear stress. Shear stressed AEC expressing a dominant-negative mutant of PKCζ (AEC DN PKCζ) showed reduced K18pSer33 phosphorylation. The AEC DN PKCζ did not show the structural reorganization of the KIF network under shear stress, rather, the KIF network remained as thin fibers. These results show that PKCζ mediated K18pSer33 phosphorylation is required for the shear stress induced structural reorganization of the KIF network in AEC. Funded by AHA and NIH-NHLBI.

**The Intermediate Filament Protein, Synemin, Anchors Protein Kinase A at the Sarcolemma and Z-lines of Cardiac Myocytes**

L. M. Lund,[1] M. Russell,[2] R. Haber,[2] K. McKeegan,[2] N. Cianciola,[2] G. Vives-Rodriguez,[1] M. Bond[1,2]; [1]Physiology, University of Maryland, Baltimore, Baltimore, MD, [2]Dept. of Molecular Cardiology, The Cleveland Clinic Foundation, Cleveland, OH

In cardiac myocytes (CM), stress generated at sarcomeres is transmitted to the extracellular matrix through costameres by the intermediate filament (IF) network. Synemin binds to desmin, vimentin, α-dystrobrevin and vinculin using its amino-terminus, as well as α-actinin and vinculin via its carboxy-terminus. We have shown that synemin is an A-kinase anchoring protein (AKAP). AKAPs regulate cAMP-dependent protein kinase (PKA) distribution by binding the regulatory (RII) subunit of PKA, to target it near substrates. A human heart expression library was screened using phage display, and novel RII-binding peptides were sequenced. Three synemin clones were identified and an RII overlay assay demonstrated that RII bound a FLAG-tagged synemin peptide. Next, we immunoprecipitated RII from adult rat CMs and identified synemin as a co-immunoprecipitating protein. Using immunohistochemical studies with adult rat ventriclar myocytes, we showed colocalization of synemin with RII at the Z-line and perinuclear region. Because several sarcolemmal proteins also bind to synemin, we isolated rat neonatal CMs to examine this region. Synemin localized at the sarcolemma and did not colocalize with desmin, which was filamentous and cytoplasmic. The two isoforms of synemin (α and β) differ by a 932bp deletion in the tail domain. To determine whether changes in localization were related to differential expression of α- or β-synemin, NCMs were transfected with α- or β-synemin plasmids. After 4 days, cultures overexpressing α-synemin were more elongate with processes present, while β-synemin cultures were similar in size and shape to control CMs. α-Synemin cultures showed more intense staining of the sarcolemma and the processes, whereas β-synemin cultures stained Z-lines. We hypothesize that synemin-anchored PKA phosphorylates substrates present at cell adhesion sites and the sarcolemma through localization by α-synemin and at Z-lines through localization by β-synemin.

**Insights into the Role of Kazrin in Mammalian and Amphibian Epithelia**

L. M. Sevilla,[1] A. A. Rana,[2] K. R. Groot,[1] J. C. Smith,[2] F. M. Watt[1]; [1]Keratinocyte Laboratory, Cancer Research UK London Research Insititute, London, United Kingdom, [2]Wellcome Trust/Cancer Research UK Gurdon Institute and Department of Zoology, University of Cambridge, Cambridge, United Kingdom

Kazrin was identified as a binding partner of the cornified envelope precursor protein periplakin and has been found to colocalize with periplakin and desmoplakin at desmosomes and with periplakin at the interdesmosomal plasma membrane. Kazrin is alternatively spliced resulting in N- and C- terminal splice variants. Overexpression of kazrin isoforms results in alterations in the cytoskeleton and in keratinocyte cell shape. We have analysed the role of kazrin in *Xenopus* embryo development. In Xt embryos expression of kazrin is widespread, with highest levels in the head, eyes, neural tube, and somites. Kazrin expression in *Xenopus* embryos was greatly reduced by injection of morpholino-modified antisense oligonucleotides. This reduction of expression results in multiple developmental abnormalities including perturbation of axial elongation and abnormal head, eye and neural tube development. These results indicate that kazrin plays a fundamental developmental role in *Xenopus*.

**Investigating the Regulation of Keratin 17 Gene Expression in Live Mouse Tissue**

D. J. DePianto, N. P. Bianchi, K. McGowan, C. Gu, P. A. Coulombe; Biological Chemistry, Johns Hopkins University, Baltimore, MD

Keratin genes afford, given their large number (>50) and differential regulation, a unique opportunity to study the mechanisms underlying specification and differentiation in epithelia of higher metazoans. Moreover, the small size and regulation in cis of many keratin genes enable the use of their regulatory sequence to achieve targeted gene expression in mice. Here we show that 2 kilobases of 5' upstream region from the mouse keratin 17 gene (mK17) confers expression of green fluorescence protein (GFP) in major epithelial appendages of transgenic mice. Like mK17, onset of {mK17 5']-GFP reporter expression coincides with the appearance of ectoderm-derived epithelial appendages during embryonic development. In adult mice, [mk17 5']-GFP is appropriately regulated within hair, nail, glands, and oral papilla. Tracking GFP fluorescence allows for visualization of growth cycle-related changes in hair follicles, and the defects engendered by the hairless mutation, in live skin tissue. Deletion of an internal 48 bp-interval, which encompasses a sonic hedgehog responsive element, from this promoter results in loss of GFP fluorescence in most appendages in vivo. The compact mK17 gene promoter provides a novel tool for appendageal-preferred gene expression and manipulation in transgenic mice.

2519

**Changes in Cytoskeletal and Nucleoskeletal Intermediate Filament (IF) Expression during the Epithelial/Mesenchymal Transition in Human Embryonic Stem Cells (hESC)**

M. G. Mendez, R. D. Goldman; Cell and Molecular Biology, Northwestern University Feinberg School of Medicine, Chicago, IL

Human IF proteins are encoded by ~65 developmentally regulated genes, and while developmental changes in IF expression are hypothesized to reflect functional differences, these changes have been difficult to study. Human ESC provide an excellent opportunity to study the assembly and functions of different types of IF during differentiation. Pluripotent hESC are cuboidal epithelial cells that grow in tightly packed colonies, and they express nuclear lamin B and keratins 8/18. Cuboidal epithelial cells near the edge of a colony frequently acquire a mesenchymal shape and migrate away. In the earliest stages of this epithelial-to-mesenchymal transition (EMT) lamin A, nestin and vimentin are detected. Initially, pre-LA and nestin appear to be diffusely organized in the nucleus and cytoplasm, respectively. Cells close to the edge of colony begin to express vimentin precursor particles and in more distal regions of the colony they begin to exhibit particles and squiggles (short IF) containing both vimentin and nestin. At the same time, mature lamin A is seen in a largely nucleoplasmic speckle pattern. Finally mature vimentin/nestin IF networks appear in the extensively flattened mesenchymal cells that are moving away from the colony. These cells also express a typical lamin A pattern that colocalizes with lamin B. The expression of lamin A also correlates with significant nuclear shape changes. Interestingly, the nestin/vimentin IF network appears to assemble along the keratin IF network. To date, the data suggest that IF networks expressed early in development provide scaffolds or templates which direct the assembly of IF networks later in development. We are in the process of developing methods for employing siRNA and transient transfection to determine the functional significance of these changing expression patterns. Supported by NIGMS and NCI.

**Autophagy Eliminates Keratin-containing Inclusion Bodies in Cultured Cells**

M. Harada,[1,2] D. M. Toivola,[1] B. M. Omary[1]; [1]Medicine, VA Palo Alto Health Care System and Stanford University, Palo Alto, CA, [2]Medicine, Kurume University School of Medicine, Kurume, Japan

Intracellular inclusions are typically composed of abnormal misfolded proteins, and are found in association with various neurodegenerative and liver diseases. The major components of intracellular inclusions are intermediate filament proteins, which are represented by keratins 8 and 18 (K8/K18) in the liver. To clarify the mechanism of hepatocyte inclusion formation in a model system, we exposed the hepatoma cell line Huh7 to proteasome inhibitors and examined the effects of agents that affect protein synthesis and the autophagy-lysosomal pathway. The proteasome inhibitors ALLN, MG132, lactacystine and epoxomicin induce K8/K18-containing inclusions. Formation of the inclusions is reduced by cycloheximide, an inhibitor of protein synthesis, and rapamycin, a stimulator of autophagy. Immunofluorescence staining showed the inclusions to be in proximity to GFP-LC3 (an autophagic vacuole marker), lysosome-associated membrane proteins 1 and 2, and Lyso-Tracker. Ultrastructural analysis confirmed many autophagic vacuoles and electron dense lysosomes in the proteasome inhibitor-treated cells. Removal of the proteasome inhibitors decreased the number of inclusions over time. This decrease was accelerated by rapamycin, but delayed by bafilomycin A1 which inhibits fusion of autophagic vacuoles and lysosomes. In inclusion-containing cells, the Golgi apparatus was fragmented, as visualized using galactosyl transferase, membrin and GM130 staining, and mitochondria clustered around the inclusions, as visualized using DsRed-Mit. Therefore, formation of keratin-containing inclusions in Huh7 cells depends on a balance between the production of misfolded proteins and degradation by the proteasome and autophagy-lysosome pathway. Inclusion formation alters the distribution of mitochondria and the Golgi apparatus, and autophagy plays an important role in inclusion body elimination. Modulation of protein synthesis or the autophagic pathway may offer a novel strategy to treat patients with inclusion-associated diseases.

**Denaturing Temperature Conditions May Underestimate Keratin Mutation Detection by DHPLC**

P. Strnad,[1] T. C. Lienau,[1] G. Tao,[1] N. Ku,[1] T. M. Magin,[2] M. B. Omary[1]; [1]Dept of Medicine, VA Palo Alto Health Care System and Stanford University, Palo Alto, CA, [2]Institute of Physiological Chemistry, University of Bonn, Bonn, Germany

Keratins 8 and 18 (K8/K18) are the major intermediate filament proteins in digestive organs. K8/K18 variants are risk factors for developing end-stage liver disease and may be associated with inflammatory bowel disease and chronic pancreatitis. However, the frequency of K8/K18 variants in American, British, German, and Italian populations varies. For example, two independent studies showed no amino-acid-altering K8/K18 mutations in 256 German patients with liver disorders, whereas 58 of 467 American liver disease patients had mutations. Both studies used the WaveSystem™, which utilizes denaturing high-performance liquid chromatography (DHPLC). We hypothesized that experimental conditions likely contribute to the discrepancy, and tested this hypothesis using previously described K8/K18 variants to optimize the DHPLC conditions under a range of denaturing temperatures. Several variants, including the frequent K8 G61C, I62V and R340H could not be reliably detected when using temperatures suggested by the prediction software, but all these variants were readily detectable at 2°C higher denaturing temperatures. Using optimized temperatures, we tested for K8 exons 1 and 6 variants, where most of the American cohort K8 variants were reported, using available genomic DNA from 151 of the 256 German liver disease patients. We identified 12 exonic and 2 intronic K8 variants: one G61C, two I62V, seven R340H, one E376E, two intronic E6+46 A-to-T, and one novel K8 V380I. Therefore, although DHPLC offers a robust and high throughput means for mutation analysis, assessment of a denaturing temperature range and possible inclusion of control mutants should be considered.

**Keratins Modulate Mitochondrial HMG-CoA Synthase in the Colon**

D. M. Toivola,[1] A. Habtezion,[1] J. Liao,[2] Q. Zhou,[1] E. C. Butcher,[3] M. B. Omary[1]; [1]Dept. of Medicine, VA Palo Alto Health Care System and Stanford University School of Medicine, Palo Alto, CA, [2]Applied Biomics, Inc., Hayward, CA, [3]Dept. of Pathology, VA Palo Alto Health Care System and Stanford University School of Medicine, Palo Alto, CA

Keratin 8 (K8) was the first intermediate filament (IF) protein targeted for deletion in transgenic mice. In addition to a liver injury susceptibility phenotype, K8-null mice develop, within 2-3 weeks of birth, colonic hyperproliferation and colitis with diarrhea that respond to antibiotic therapy, and enterocyte mistargeting of ion transporters. We used a proteomic approach as a handle to better understand the function of keratins in the colon, and the colitis that is induced by their absence. Proteins were isolated from wild-type (WT) and K8-null colonic crypts using calcium-free

conditions and analyzed using two-dimensional differential in gel electrophoresis (2-D DIGE) coupled with mass spectrometry. Equal amounts of isolated crypt proteins were labeled with Cy3 (WT) and Cy5 (K8-null) and the combined samples were separated using 2-D DIGE. In K8-null enterocytes, eleven major nonkeratin proteins were down-regulated which include selenium binding protein, 3-hydroxy-3-methylglutaryl Coenzyme A (HMG-CoA) synthase and carbonic anhydrase I. Fourteen major proteins were up-regulated including dimethylglycine dehydrogenase, and argininosuccinate synthase 1. We focused on HMG-CoA synthase, an important mitochondrial regulator of ketogenesis, whose four isoforms were downregulated 3-6 fold in K8-null colonic crypts. The decreased expression of HMG-CoA synthase was confirmed at the protein (by immunoblotting and immunofluorescence staining) and RNA levels. Changes in colonic HMG-CoA synthase were specific to the colon in that they were not found in the liver. Peroxisome proliferator-activated receptor α (PPARα), an HMG-CoA synthase transcriptional activator was also down-regulated in K8-null colon. These results suggest that colonic keratins may be involved in lipid and ketone body metabolism, which is likely relevant to the colitis phenotype since bacteria are the major source of colonic butyrate.

2523

**Alterations in Intermediate Filament (IF) Assembly Modulate Lamellipodial Activity**

B. Helfand,[1] S. Khoun,[1] E. R. Kuczmarski,[1] H. Herrmann,[2] U. Aebi,[3] R. Goldman[1]; [1]Cell and Molecular Biology, Northwestern University Feinberg School of Medicine, Chicago, IL, [2]Department of Cell Biology, German Cancer Research Center, Heidelberg, Germany, [3]M.E. Muller Institute Biozentrum, University of Basel, Basel, Switzerland

Growth factors stimulate cell motility by inducing the formation of lamellipodia. This involves organizational changes in microfilaments and microtubules, but the role of IF in this response remains unknown. Therefore, we have studied vimentin IF following the addition of growth factors to serum-starved mouse embryo fibroblasts (MEF). To monitor changes in living cells, MEFs expressing GFP-vimentin were serum-deprived for 2 days. These cells contained complex IF networks extending to their quiescent cell surfaces. Immediately following growth factor addition, the peripheral IF network disassembled as lamellae formed and only highly motile vimentin particles and squiggles were detected in this region. IF network disassembly and the appearance of vimentin particles and squiggles could also be observed by immunofluorescence in non-transfected MEFs treated identically. Vimentin particles were concentrated in the lamellipodial region and colocalized with antibodies against actin associated proteins such as cortactin. The disassembly of IF concomitant with the appearance of vimentin particles and squiggles suggest that IF disassembly modulates lamellipodial formation. To test this possibility further, a specific peptide inhibitor of vimentin assembly was microinjected into serum-starved MEFs which had been transfected with GFP-vimentin. At low concentration in injection buffer, this peptide (residues 355 to 412 of the alpha-helical 2B domain of vimentin), preferentially disassembled long IF adjacent to the cell surface. Coincidently these serum-deprived cells began to ruffle (in the absence of serum) and form lamellipodia, and only vimentin particles and squiggles were detected in these regions. Injected controls remained quiescent. We propose that polymerized IF stabilize the cell surface and that their local disassembly is sufficient to promote the formation of lamellae/lamellipodia. This appears attributable to a local reorganization of insoluble IF subunits, since biochemical studies of serum-replenished cells did not reveal any Triton-soluble vimentin. Supported by NIGMS.

**Co-translational Assembly of Intermediate Filaments (IF): Messenger RNA Clustering May Be Involved in the Formation of Coiled Coils**

L. Chang,[1] Y. Shav-Tal,[2] R. H. Singer,[2] R. D. Goldman[1]; [1]Cell & Molecular Biology, Northwestern University Medical School, Chicago, IL, [2]Anatomy & Structural Biology, Albert Einstein College of Medicine, Bronx, NY

Peripherin IF networks are formed from precursor particles that are most likely composed of essential building blocks such as dimers and tetramers. Using a combination of RNA fluorescence in situ hybridization (FISH) and the simultaneous live imaging of both peripherin mRNA and its product in PC12 cells, we have shown that ~35% of peripherin particles are associated with peripherin mRNA in a puromycin sensitive fashion. There is no significant association with other species of mRNA such as actin. Quantitative analyses demonstrate that individual peripherin mRNA containing particles (mRNPs) can contain up to 30 copies of transcript. Microtubules appear to be involved in mRNA clustering as nocodazole markedly decreases the number of clusters. To determine the potential role of peripherin nascent protein in clustering, a translation incompetent peripherin mRNA was constructed. In the absence of nascent protein, the majority of mRNA still forms clusters. However nascent peripherin appears to be involved in the formation of large RNA clusters (6-30). We are currently examining the specific role of the peripherin 3'UTR in mRNA clustering. We have also initiated studies on keratin IF whose building blocks are heterodimers. A sub-population of keratin 8 and 18 mRNAs in Hela cells appear to co-exist in common mRNPs further suggesting that IF precursor particles are formed co-translationally. The formation of a coiled coil has been traditionally believed to involve a polysome containing a single transcript. The asynchronous translation in a polysome would give rise to protein chains of varying lengths that complicates in-register dimer formation. Coiled coils may be more efficiently formed from peptide chains that are being simultaneously synthesized at the same rate from neighboring mRNAs within a translation factory. Supported by NIGMS

**Insights into the Effects of the Common Lamin A Mutation in Hutchison-Gilford Progeria Syndrome (HGPS)**

T. Dechat,[1] S. A. Adam,[1] M. R. Bozovsky,[1] A. E. Goldman,[1] D. K. Shumaker,[1] A. Rusinol,[2] M. S. Sinensky,[2] R. D. Goldman[1]; [1]Cell and Molecular Biology, Northwestern University, Feinberg Medical School, Chicago, IL, [2]Biochemistry and Molecular Biology, East Tennessee State University, JH Quillen College of Medicine, Johnson City, TN

HGPS is a premature aging disease commonly caused by a heterozygous mutation in the lamin A (LA) gene leading to a deletion of 50 residues at the C-terminus of LA (LAΔ50). Pre-LA is farnesylated and methylated at its C-terminal CAAX box. The carboxyl terminal 15 amino acids are then removed by a second cleavage step producing LA. Since LAΔ50 lacks the second cleavage site it may be stably farnesylated/methylated. This study shows that this is indeed the case. LAΔ50 is shown to be processed at the CAAX-box to approximately the same extent as lamin B. This results in LAΔ50 being associated with the nuclear lamina/membrane as opposed to the nucleoplasmic localization of wild type (wt) LA. Microscopic studies of HeLa cells expressing GFP-LAΔ50 or HGPS patients' cells reveal that LAΔ50 localizes exclusively to the nuclear envelope throughout interphase. At the same time, nucleoplasmic wt LA disappears and it is only detected in the lamina region. During mitosis LAΔ50 stays membrane associated in contrast to wt LA, which is soluble and dispersed throughout the cytoplasm. During early G-1 there is a delayed reentry of

LAΔ50 into daughter cell nuclei. Cell fractionation studies of mitotically arrested cells demonstrate that LAΔ50 is membrane associated in contrast to wt LA. In conclusion, LAΔ50 is stably associated with the nuclear membrane. This appears to recruit wt LA to the nuclear periphery causing a depletion of LA from nucleoplasmic complexes involved in cell cycle regulation and other activities causing loss of functions in HGPS. **Keratin Mutation Predisposes to Thioacetamide- but not CCl4-induced Mouse Liver Fibrosis**

P. Strnad, Q. Zhou, N. Ku, M. B. Omary; Department of Medicine, VA Palo Alto Health Care System and Stanford University, Palo Alto, CA

Keratins 8 and 18 (K8/K18) protect mouse liver from a variety of stresses, and K8/K18 mutations predispose their human carriers to end-stage liver disease. Since the relationship of keratin mutation to cirrhosis is based on human association studies, we sought to provide direct evidence for a keratin mutation-related predisposition to liver fibrosis using mouse models. We compared the development of liver fibrosis in mice overexpressing human Arg89-to-Cys (R89C mice) or wild-type K18 (WT mice). Liver fibrosis was induced by intraperitoneal injection of carbon tetrachloride or thioacetamide for 6-8 weeks. Expression of fibrosis-related genes was measured by quantitative real time PCR, and trichrome or Sirius red staining were used to evaluate the extent of fibrosis. CCl4 led to liver and hemorrhagic lung injury but there were no differences in the extent of CCl4-induced liver fibrosis between WT and R89C mice when accessed by histological staining and quantitative real time PCR. In contrast, thioacetamide caused a more severe fibrosis in R89C as compared to TG2 mice as determined by histological staining and by increased levels of collagen, TIMP1, MMP2, MMP13 mRNA. Therefore, overexpression of mutant K18 predisposes transgenic mice to thioacetamide- but not CCl4-induced liver fibrosis. Differences in the keratin mutation-related response to the thioacetamide versus the CCl4 model raise the hypothesis that keratin mutations may preferentially predispose to fibrosis in unique human liver diseases.

**Keratins Modulate Hepatocyte Mitochondria: A Likely Contributor To Keratin Cytoprotective Function**

G. Tao,[1] D. M. Toivola,[1] J. Liao,[2] B. Liang,[1] M. B. Omary[1]; [1]Medicine, Palo Alto VAMC and Stanford University, Palo Alto, CA, [2]Applied Biomics Inc, Hayward, CA

Keratin polypeptides 8 and 18 (K8/K18) mutations are a risk factor for developing human end-stage liver disease. Studies in K8-null and K18 mutant-expressing mice showed that K8/K18 mutation or absence predisposes hepatocytes to apoptosis and consequent liver injury and primes them towards oxidative damage. We addressed the molecular mechanism for such predispositions using proteomic two-dimensional differential in gel electrophoresis (2-D DIGE) coupled with mass spectrometry to analyze changes in livers isolated from K8-null and control mice. Among the most prominent alterations noted in the total liver homogenates were in mitochondria-specific proteins and their charged isoforms, which were verified by 2-D DIGE of mitochondria preparations isolated from K8-null and wild-type livers. The altered proteins in K8-null versus control hepatocytes include those involved in ATP-producing respiratory chain at the mitochondrial inner membrane (e.g. an increase in NADH-ubiquinone oxidoreductase 75 kDa subunit of complex I), those involved in apoptosis (e.g. a decrease in cytochrome c content of mitochondria) and those that serve an antioxidant role (e.g. a decrease in mitochondrial superoxide dismutase-2). Ultrastructural analysis showed that mitochondria of K8-null livers were rounder and significantly smaller as compared with mitochondria from WT livers. Therefore, the mechanical and nonmechanical roles of keratins in regulating hepatocyte function may extend to similar roles in regulating the shape and function of mitochondria. Loss of keratin function via mutation or ablation and the consequent effects on mitochondria are likely to contribute to hepatocyte predisposition to apoptosis and oxidative injury.

**Localization of Keratin Intermediate filaments, Fas-receptor and Phospho-Akt in Griseofulvin Treated Hepatocellular Carcinoma Cells HepG2**

A. Fortier, É. Asselin, M. Cadrin; Chimie-Biologie, Université du Québec à Trois-Rivières, Trois-Rivières, PQ, Canada

Keratin 8 and 18 (K8/18) are the intermediate filament (IF) proteins present in hepatocytes. IFs protect hepatocytes from mechanical and toxic injuries as demonstrated by studies using different genetically altered mouse models. For instance, treatment of K8 null mice with a diet containing griseofulvin (GF) is highly toxic and causes animal death by liver failure. The same treatment on wild type mice is not fatal and induces modifications, in hepatocytes, of K8/18 expression, phoshorylation and in the long-term formation of K8/18 containing aggregates named Mallory bodies. The aim of the present study was to gain insight into the molecular mechanism underlying keratin protective role in hepatocytes. Hepatocellular carcinoma cells HepG2, were treated with GF (0.2µg/ml in 0.1% DMSO) for 8h, 24h and 72h. We investigated the existence of a relationship between K8/18 IFs, and the serine/threonine kinase Akt/PKB (pAkt) which plays a pivotal role in cell survival. We also analyzed Fas an important inducer of the extrinsic apoptosis signaling pathway. Our results show that in control HepG2 cells, K8/18 forms a filamentous network that extend from the nucleus to the cell periphery. Fas and pAkt are diffusely distributed in the cytoplasm of the cells with some accumulation in the Golgi apparatus. GF treatment induces Fas rearrangement and its re-localization to the plasma membrane. Fas form also cytoplasmic filamentous structures that co-localize with K8/18 IFs. Staining of pAkt is increased after treatment and as for Fas, co-localization of pAkt and K8/18 IFs is observed. Together, these results suggest that keratins could accomplish their protective roles by modulating specific signal transduction pathways through their association with regulatory molecules such as Akt and Fas.(Supported by NSERC)

**Molecular "Memory" via Chaperone Modification as a Potential Mechanism for Rapid Mallory Body Induction**

P. Strnad,[1] J. Liao,[2] K. Lau,[3] J. Schilling,[3] M. B. Omary[1]; [1]Dept of Medicine, VA Palo Alto Health Care System and Stanford University, Palo Alto, CA, [2]Applied Biomics Inc, Hayward, CA, [3]Department of Pediatrics, Stanford University School of Medicine, Palo Alto, CA

Cytoplasmic inclusions termed Mallory bodies (MB) are characteristic of several liver disorders including alcoholic and non-alcoholic steatohepatitis. In mice, MB can be induced by long-term feeding with 3,5-diethoxycarbonyl-1,4-dihydrocollidine (DDC) for 3-4 months or rapidly re-formed in DDC-induced then recovered mice by DDC re-feeding for 5-7 days. We hypothesized that molecular changes are likely to be retained after DDC priming, which may explain the rapid re-induction of MB and may contribute in general terms to MB formation. We tested this

hypothesis using two-dimensional differential in gel electrophoresis (2-D DIGE) coupled with mass spectrometry to characterize changes in liver proteins isolated from the various treatment groups. Tissue lysates from different mice were labeled with Cy3 or Cy5 and analyzed by 2-D DIGE. Image analysis was performed with ImageQuant V5.0 and DeCyder 4.0 software. Proteins representing individual spots were identified using MALDI-TOF analysis. DDC treatment led to pronounced charged isoform changes in several chaperones including Hsp 25, 60, 70, 72, 75, GRP58, GRP75 and GRP78, which lasted at least for 1 month after discontinuation of DDC feeding. Furthermore, recovered mice had persistent isoform changes in several mitochondrial proteins (GRP75, ALDH4A1, Hsp70, GST Mu). Posttranslational modifications that can account for such changes included arginine and lysine oxidation, asparagine and glutamine deamidation, and methylation of several residues. We conclude that persistent posttranslational modifications in chaperone proteins with possible mitochondrial dysfunction likely contribute to the rapid MB formation, and provide a form of molecular "memory". We hypothesize that chaperone dysfunction via oxidation and other posttranslational modifications is an important contributor to inclusion body formation in several diseases.

2530

**New Dimensions in Intermediate Filament Dynamics: Quantitative Analysis of Vimentin Speckles by Cross Correlation of Intensity Profiles Reveals Non-random Movement of Speckles Along Individual Fibers**

L. Chang,[1] S. Sivaramakrishnan,[1] C. M. Waterman-Storer,[2] T. Wittmann,[2] R. D. Goldman[1]; [1]Cell & Molecular Biology, Northwestern University Medical School, Chicago, IL, [2]Cell Biology, The Scripps Research Institute, La Jolla, CA

GFP-vimentin intermediate filaments (IF) appear speckled when expressed at low levels in Ptk1 cells. Unlike the coordinated treadmilling of kinetochore fiber speckles and the sparkling of actin speckles in leading edges of cells, vimentin speckles display a remarkable variety of motile properties. These include tandem movements of linear speckle arrays at varying speeds as well as independent movements of speckles toward or away from each other, possibly within a single filament or filament bundle. The various types of speckle movements may represent whole filament movements, subunit movements within a filament, or the sliding movements of filaments within bundles. In addition, some of these movements could be attributed to non-filamentous IF precursor particles moving along side an existing filament. Particle tracking of individual speckles is not feasible as movement along apparent filament paths occurs in short bursts with the filaments themselves drifting and changing shape within the cytoplasm. We have developed a novel technique to analyze the apparent coordinated movement of IF speckles by examining the cross correlation coefficients of intensity profiles along filaments between time frames. This analysis allows us to quantify speckle velocities and displacements and is providing insights into the molecular mechanisms that contribute to speckle movement. Analysis of intensity fluctuations of speckles by correlating the intensity distributions of several speckles suggests bidirectional movement along relatively straight paths with varying velocities, strongly suggesting either motor directed movement or wave propagation along individual filaments. This is the first study to quantitatively explore speckling of IF in live cells and reveals fascinating dynamics underlying IF networks. Funded by NIGMS AND AHA

**Colitis-Associated Autoantibody Production in Keratin-8 Deficient Mice**

D. M. Toivola,[1] A. Habtezion,[1] L. Y. Zhang,[1] W. H. Robinson,[1] P. J. Utz,[1] E. C. Butcher,[2] M. B. Omary[1]; [1]Dept of Medicine, VA Palo Alto Health Care System and Stanford University Digestive Disease Center, Palo Alto, CA, [2]Dept of Pathology, VA Palo Alto Health Care System and Stanford University Digestive Disease Center, Palo Alto, CA

Keratin 8 (K8)-null mice develop an early-onset intestinal phenotype with colorectal hyperplasia, colitis with diarrhea, mistargeting of enterocyte ion transporters as well as increased susceptibility to liver damage. Several human autoimmune diseases, such as inflammatory bowel disease, are associated with autoantibody production which led us to hypothesize that K8-null mice may produce such antibodies. To test this hypothesis, we analyzed whether sera from wild-type and K8-null mice recognize autoantigens by immunoblotting total tissue lysates of normal mouse liver, pancreas and colon as well as lysates of human/mouse cell lines of various origins. We identified one major autoantibody that was present in six of eleven (55%) sera from K8-null mice but not in wild-type sera. Presence of the autoantibody is age and disease severity related since the six positive K8-null sera were from mice >7 months old. The autoantibody recognizes a ubiquitous 42-48 kD autoantigen that partitions in a non-ionic detergent fraction, and is present in all normal tissues and cell lines tested, as well as in livers and colons of K8-null mice. Immunofluorescence staining of NIH-3T3 cells showed that the autoantigen concentrates in cytoplasmic and perinuclear structures but not the nucleus or plasma membrane. Our data support the hypothesis that K8-null colitis is associated with age-enhanced autoantibody production, which also associates with a worsening colonic disease. The 42-48 kDa ubiquitous autoantigen is cytoplasmic and detergent soluble, and is conserved across human and mouse species. Characterization of this antigen may unmask a similar autoantibody response in patients with inflammatory bowel disease who harbor K8 mutations.

## Extracellular Matrix & Cell Behavior II (2532-2546)

**Encapsulation of Human Mesenchymal Stem Cells in a 3D Extracellular Matrix Environment for the Direction of Osteogenesis**

A. W. Lund,[1] E. P. Lunsford,[1] G. Lin,[2] B. Roysam,[2] J. P. Stegemann,[3] G. E. Plopper[1]; [1]Biology, Rensselaer Polytechnic Institute, Troy, NY, [2]Electrical, Computer, & Systems Engineering, Rensselaer Polytechnic Institute, Troy, NY, [3]Biomedical Engineering, Rensselaer Polytechnic Institute, Troy, NY

Adult human mesenchymal stem cells (hMSC) have demonstrated potential for osteogenesis and their ability to self replicate and differentiate along this pathway is significant within the field of functional tissue engineering. Two dimensional cultures alone are insufficient for the study of such processes as well as incomplete in terms of application to natural systems. A method of encapsulating these cells within a controlled extracellular matrix (ECM) has been developed resulting in the production of distinct spherical microenvironments. These "beads" have a defined size and composition that can be manipulated to help induce and maintain a desired cellular phenotype. It is proposed that controlled manipulations of the structure and composition of the ECM beads will create an osteoconductive matrix and produce more robust and natural bone formation as compared to traditional methods alone. These changes are monitored through biochemical assays, immunofluorescence and novel image analysis technologies to yield a predictive model for the path of osteogenic differentiation. Calcification, mineralized matrix deposition, protein expression,

and gene expression provide the markers to define differentiation. Fluorescence images, along with analysis software, provide a new way of characterizing and quantifying cellular response within the 3D environment that allows for the preservation of spatio-temporal relationships. It is proposed that there is a correlation between the information gathered through traditional biochemical assays and that gathered by imaging software which can be exploited to create a new and easier approach to functional tissue engineering. This ability to control the ECM environment surrounding the cells, while assessing the functional state of the cells in intact constructs, should have broad application to studies of cell growth and differentiation.

2533

**Physiological Activities of Human Fetal Osteoblast Cells Cultured on Gamma Titanium Aluminide Determined by Immunoassays of Collagen Type I and Osteonectin Proteins**

O. Rivera-Denizard,[1] N. Diffoot-Carlo,[1] V. Navas,[1] P. Sundaram[2]; [1]Biology, University of Puerto Rico-Mayaguez, Mayaguez, PR, [2]Mechanical Engineering, University of Puerto Rico-Mayaguez, Mayaguez, PR

Commercially pure (cpTi) and titanium alloys, such as Ti-6Al-4V, are among the most common used implant materials. There is a continuous search for new materials for use in implants with better biocompatibility properties than the current cpTi and Ti-6Al-4V alloys. Gamma titanium aluminide (γTiAl), a new titanium alloy originally designed for aerospace applications, appears to have better properties compared to Ti-6Al-4V. The biological response to γTiAl implant is expected to be similar or better than those of Ti-6Al-4V. hFOB 1.19 cells (ATCC CRL-11372) were cultured at 37C on 1 cm diameter discs of γTiAl and Ti-6Al-4V, with variable roughness. Metals were removed after incubation periods of 14, 21 and 28 days and immunohistochemistry analysis was performed in order to detect the presence of collagen type I and osteonectin, proteins of the bone extracellular matrix. Normal growth and the presence of collagen type I and osteonectin was observed for cells cultured on both metals, with better results for γTiAl. The use of γTiAl does not appear to affect the biological activity of the osteoblast cells.

2534

**Coordinate Regulation of Pre-Osteoblastic MC3T3-E1 Cell Phenotype by ECM Chemistry and Mechanics**

C. B. Khatiwala,[1] A. J. Putnam[2]; [1]Chemical and Biochemical Engineering, University of California, Irvine, Irvine, CA, [2]Chemical and Biochemical Engineering, Biomedical Engineering, University of California, Irvine, Irvine, CA

Mechanical cues present in the extracellular matrix have been hypothesized to provide instructive signals that dictate cell behavior, and may be equally as important as chemical information. We probed this hypothesis in the context of bone by culturing pre-osteoblastic MC3T3-E1 cells on the surface of ECM-functionalized hydrogels with tunable mechanical properties. On gels functionalized with low density of type-I collagen, the rate of cell proliferation increased linearly with increasing stiffness. Quantitative time-lapse video microscopy analysis revealed random cell motility speeds were significantly retarded on the softest substrate (0.25 ± 0.05 μm/min), in contrast to maximum speeds on polystyrene substrates (0.42 ± 0.04 μm/min). Immature focal contacts and a poorly organized actin cytoskeleton were observed in cells cultured on the softest substrates, in contrast to mature focal adhesions and robust actin stress fibers on more rigid substrates. In parallel, focal adhesion kinase activity was modulated by ECM rigidity, with maximum Y397-FAK levels observed in cells cultured on polystyrene. When gels were functionalized with a high density of collagen-I, migration speed was found to depend on ECM compliance in a biphasic manner, with maximum speeds (0.36 ± 0.04 μm/min) observed on gels of intermediate stiffness and minimum speeds (0.24 ± 0.04 μm/min) occurred on both the softest and most rigid (i.e., polystyrene) substrates. In parallel, focal adhesion-associated vinculin and Y397-FAK levels were significantly increased on the soft substrates, but remained unaltered by ECM ligand density on stiff substrates. Finally, mineral deposition by the cells was also modulated by ECM compliance as early as day 4 in culture. These results suggest that tuning ECM chemistry and mechanics, which presumably coordinately influence the degree of actin contractility, can regulate focal adhesion formation, signaling, migration, proliferation, and, ultimately, differentiation towards an osteoblastic phenotype.

2535

**Tenascin-C Plays a Crucial Role in Progression of Myocardial Fibrosis**

T. Nishioka, M. Suzuki, T. Yoshida, K. Imanaka-Yoshida; Pathology, Mie University, Tsu, Japan

Tenascin-C (TN-C) is an extracellular glycoprotein with strong bioactivity to control cell behavior. In the normal heart, tenascin-C is detected only at very early stage of embryogenesis but re-expressed in the various heart disease. During scar formation after myocardial injury, TN-C deposition precedes maturation of collagen fibers and is supposed to play important roles in progression of fibrosis. To elucidate the role of TNC in myocardial fibrosis in hypertensive heart, we treated mice. Balb/c wild type (WT/AgII) mice and TNC KO (TNKO/AgII) mice were treated with 500 ng/kg body weight/min AgII subcutaneously by osmotic minipump for 4 weeks. In both wild type and TNKO mice, AgII treatment increased blood pressure, and heart weight/Body weight ratio, but no significant differences were detected between WT/AgII and TNKO/AgII mice. AgII treatment caused increase of interstitial collagen fibers increased at perivascular regions. In KO/AgII, increase of interstitial collagen fibers in was less than those in WT/AgII. Accumulation of macrophages and myofibroblsts were evaluated by immunohistochemistry staining with either antibody anti Mac-3 or anti alpha-SMA, respectively. In WT/AgII mice, accumulation of macrophages and myofibroblasts aobserved at peivascular region. accumulation of macrophages and myocfiroblasts were reduced in TNKO/AgII. Alcian Blue staining showed dense deposition of glycosaminoglycans (GAGs) at perivascular area in WT/AgII. In contrast, TNKO/AgII showed sparce and rough fibrillar staining pattern. These results suggest that, TNC plays important roles in progression of fibrosis in hypertensive heart.

**Fibroblast Mechanics in Three Dimensional Collagen Matrices: Microtubules Take the Load**

S. Rhee, F. Grinnell; Department of Cell Biology, UT Southwestern Medical Center, Dallas, TX

The interaction between cells and three dimensional collagen matrices provides a useful model to study cell physiology under conditions that approximate normal tissue better than conventional 2D culture. A variety of evidence shows that important aspects of cell form and function differ in 3D matrices compared to 2D culture. Mechanisms underlying these differences, however, remain speculative. The tensegrity hypothesis of cell mechanics predicts that the balance between structures that resist compression (e.g., microtubules) and structures under tension (e.g., actin

filaments) determines cell organization. We tested the role of microtubules in cell mechanics using human fibroblast-3D collagen matrix cultures. In contrast to cells on collagen-coated coverslips, fibroblasts interacting with 3D collagen matrices became completely dependent on intact microtubules for mechanostabilization. If microtubules were disrupted, then cells could not change shape or migrate. The influence of the collagen matrix on microtubule-dependence of cell mechanics depended on the physical properties of the cell-matrix interface rather than on cells becoming completely surrounded by matrix. Only if contractile tension in the actin cytoskeleton was blocked, were cells then able to protrude dendritic extensions without intact microtubules. Our studies suggest that fibroblasts in 3D collagen matrices utilize different mechanisms of mechanical stabilization compared to cells in conventional 2D culture. The rigid culture surface can provide external mechanical resistance that balances tension in the actin filament network and, as a result, decrease the importance of microtubules for cell organization and migration. In 3D matrix cultures, on the other hand, in the absence of a rigid, planar culture surface, microtubules take the mechanical load as predicted by tensegrity. These observations emphasize that at the fundamental level of cytoskeletal organization, regulation of cell mechanics depends on the physical interface between cells and their environment.

**The Intrinsic Mechanical Properties of the Extracellular Matrix Regulate Smooth Muscle Cell Phenotype**

S. R. Peyton,[1] C. B. Raub,[2] A. J. Putnam[2]; [1]Chemical Engineering and Materials Science, University of California, Irvine, Irvine, CA, [2]Biomedical Engineering, University of California, Irvine, Irvine, CA

An emerging paradigm in cell biology hypothesizes that intrinsic mechanical cues present in the extracellular matrix (ECM) may be equally important as its chemical identity in regulating tissue development. In a variety of cardiovascular pathologies, the mechanical properties of blood vessels may be dramatically altered due to cholesterol deposition, changes in fluid shear, or changes in blood pressure. These local mechanical cues can affect smooth muscle cell (SMC) migration, proliferation, and matrix deposition within arteries. To investigate the influence of changing ECM mechanics during these pathologies, we have adopted synthetic model systems from polyacrylamide and poly(ethylene glycol) (PEG) that contain tunable mechanical properties and can support cell adhesion via functionalization with native, full-length proteins and bioactive peptide sequences. Specifically, using 2-D polyacrylamide substrates, we found that the migration speed of SMCs depends on ECM mechanics in a novel, biphasic fashion, suggesting the existence of an optimal substrate stiffness capable of supporting maximal migration. The value of this optimal stiffness shifted depending on the concentration of ECM protein covalently attached to the substrate. Additionally, this phenomenon appears to be controlled by the RhoA-ROCK pathway as blocking ROCK activity via Y27632 retards the maximum migration speed of SMCs on optimally stiff substrates. To investigate the long-term effects of substrate mechanics on the phenotypic conversion of SMCs from a contractile to synthetic phenotype in a 3-D environment, we have begun to use a PEG-based biomaterial system in which the surrounding substrate mechanics and ligand density presented to the cell can be independently controlled. Combined, our results demonstrate the utility of synthetic hydrogel systems to decipher how ECM chemistry and mechanics coordinately regulate SMC phenotype, and that the use of synthetic ECM analogs can contribute to our understanding of cardiovascular disease.

2538

**The Role of Rho-kinase in Local and Global Cell-induced 3-D Matrix Remodeling**

A. Kim, W. M. Petroll; Department of Ophthalmology, UT Southwestern Medical Center, Dallas, TX

The purpose of this study was to investigate the role of Rho-kinase on the pattern and amount of cell-induced collagen matrix remodeling. Human corneal fibroblasts were plated at low density inside 100 μm thick fibrillar collagen matrices and cultured for 1 day in serum-containing media (S+) and S+ with the Rho-kinase inhibitor Y-27632. Cells were then fixed and stained with rhodamine phalloidin. Fluorescent (for f-actin) and reflected light (for collagen fibrils) 3-D optical section images were acquired using laser confocal microscopy. Fourier transform analysis was used to assess local collagen fibril alignment, and changes in cell morphology and collagen density were measured using MetaMorph. Culture in S+ induced significant global matrix contraction, which was inhibited by blocking Rho-kinase ($44.2 \pm 2.1\%$ vs. $24.3 \pm 3.5\%$, $p < 0.05$). Local collagen fibril density was greatest at the ends of cells in S+, and these fibrils were aligned nearly parallel to the pseudopodial tips ($|\Delta\theta| = 5.0 \pm 6.3°$, where $\Delta\theta$ is the difference between collagen and pseudopodial alignment). Fibril alignment was more random adjacent to the cell body ($|\Delta\theta| = 45.9 \pm 25.1°$, $p<0.05$). Both the fibril density and co-alignment with pseudopodia were significantly reduced by blocking Rho-kinase ($p < 0.05$). Cells also had fewer stress fibers and a more stellate morphology following Rho-kinase inhibition; and the height of the cells (extension of processes along z-axis) was significantly increased ($28.4 \pm 3.5$ μm vs. $15.9 \pm 4.2$ μm, $p < 0.05$). The data suggest that force generation by pseudopodia leads to local compaction and alignment of collagen fibrils, and that this mechanism underlies global matrix contraction. This process is dependent, in part, on Rho-kinase.

**Fibroblast Shape and Organization Changes within Contracting Load Bearing Collagen Gels**

B. Johnson-Wint, B. Coon; Department of Biological Sciences, Northern Illinois University, DeKalb, IL

We are interested in physical organization of collagen fibers by fibroblasts and osteocytes during dense connective tissue and bone formation, and the role of tissue load on cell function. In the present study we examined fibroblast filopodia formation and cell-cell interaction during reorganization of type-I collagen in weight bearing cell populated collagen gels (CPCGs). To track cell bodies and filopodia, isolated rat tendon fibroblasts were stained in vitro with Cell Tracker Green or Cell Tracker Orange (Molecular Probes). Stained cells were mixed and seeded into type I collagen gels. CPCGs were placed under load and imaged live at multiple times with a Zeiss laser scanning confocal microscope. Data stacks were analyzed using Image J. An extensive interconnected network of filopodia formed between fibroblasts in contracting CPCGs. By 4 hours cells had extended multiple, frequently branched, thin 9 micron long filopodia. By 16 hours these filopodia were 3 to 5 times longer and often in point or lateral contact with filopodia of adjacent cells. By 36 hours the cells were closer together and had shorter and thicker filopodia with a larger surface of contact between them. Finally, by 55 hours cells had aligned into long branching strings of laterally adherent cells within a now highly compact CPCG. In conclusion, we found that early in collagen gel contraction fibroblasts extend multiple thin filopodia that attach to each other forming a tight filopodial network. Later, cells adhere side-by-side forming a network of branching cell strings. These two types of network appear to be under tension and may represent two mechanisms whereby cells squeeze fluid out of collagen gels and compact the collagen fibers into denser

stronger tissue of a particular shape.

**Regulation of Fibronectin Receptor Engagement by Manipulating Cell-binding Site Availability in a 3-D Matrix**

Y. Mao, J. E. Schwarzbauer; Molecular Biology, Princeton University, Princeton, NJ

The extracellular matrix protein fibronectin (FN) plays an important role in regulating cell adhesion and migration through interactions with integrin receptors. Many cells express both α5β1 and αvβ3 integrins; α5β1 requires the RGD cell binding sequence along with the synergy site for maximal binding to FN, whereas αvβ3 requires only RGD. This difference in binding sites may provide a mechanism for matrix regulation of receptor usage by cells. To address this possibility, we manipulated the receptor binding sites in FN and tested the effects on cell migration in a 3-dimensional (3-D) matrix. Migration of CHO(B2) cell lines expressing one or both of these integrins was examined on 3-D matrices containing wild type and mutant FNs. CHOα5 cells showed decreased cell adhesion, spreading, and migration on 3-D matrix containing FN(RGD-) which lacks the RGD sequence. Similarly, incorporation of FN(syn-) lacking the synergy site caused a reduction in CHOα5 cell migration. In contrast, the absence of the synergy site had no effect on migration of CHOαvβ3 cells. Interestingly, CHOα5/αvβ3 cells, which express both integrins at similar levels, selectively used α5β1 to mediate migration on wild type FN matrix but used αvβ3 integrin for migration on FN(syn-) matrix, as shown using specific function-blocking antibodies. To determine whether αvβ3 and α5β1 integrins used different intracellular machinery, we isolated and analyzed the pseudopodia extended by CHOα5 and CHOαvβ3 cells on FN. The signaling and cytoskeletal proteins FAK, Src, p130CAS and ERM were present at similar levels, but paxillin and activated FAK were significantly enriched in CHOα5 cell pseudopodia. These results show selective usage of FN receptors and downstream signals depending on the availability of binding sites within the extracellular matrix.

**Effects of Mechanical Stimulation on Gene Expression of Chondrocytes Embedded in 3D Hydrogel; the Comparison among Different Modes of Stimulation**

Y. Hirano,[1] N. Ishiguro,[1] M. Sokabe,[2,3] K. Naruse[2,4]; [1]Department of Orthopaedic Surgery, Nagoya University Graduate School of Medicine, Nagoya, Japan, [2]Department of Physiology, Nagoya University Graduate School of Medicine, Nagoya, Japan, [3]Department of Molecular Physiology, National Institute for Physiological Science, Okazaki, Japan, [4]Institute for Advanced Research, Nagoya University, Nagoya, Japan

Articular cartilage is a tough, elastic tissue that covers the ends of bones, enables the bones to move smoothly over one another, and is always subjected to mechanical stress. To study the effects of mechanical stress on the chondrocytes, various kinds of experimental methods including 3-dimensional (3D) culture have been developed. The objective of this study is to develop novel experimental methods to load cells embedded in 3D hydrogel with different modes of mechanical stimulation and to compare gene expressions of chondrocytes embedded in 3D hydrogel among four kinds of mechanical stimulation. The modes of mechanical stimulation used were dynamic strain (10% elongation, 50 cycles/min), 10% static strain, dynamic compression (10% compression, 50 cycles/min), and 10% static compression. Unstimulated control was made at the same time. Mechanical stimulations were loaded to articular chondrocytes from NZW rabbit embedded in collagen gel for strain experiments and agarose gel for compression experiments. After stimulation for 24hours, total RNA was extracted and reverstranscripted. Gene expression of type2 collagen and aggrecan were quantified using real-time PCR. GAPDH was used as endogenous control. Dynamic compression significantly increased expression of type2 collagen and aggrecan compared with control, However, static compression significantly decreased expression of aggrecan and had no significant effect on expression of type2 collagen compared with control. Dynamic strain significantly decreased expression of type2 collagen and aggrecan compared with control, However static strain had no significant effects on both expressions compared with control. These results suggest that dynamic compression has an important role in healthy homeostasis of articular cartilage and static compression or dynamic strain leads to degradation of articular cartilage and that alls may use different mechanotransduction pathway to sense these modes of mechanical stimulations.

**Nanoscale Topographic Features that Mimic the Native Basement Membrane Modulate Vascular Cell Behaviors**

S. J. Liliensiek,[1] P. F. Nealey,[2] C. J. Murphy[1]; [1]Surgical Sciences, University of Wisconsin, Madison, WI, [2]Department of Chemical and Biological Engineering, University of Wisconsin, Madison, WI

Basement membranes have many features including a complex three dimensional topography which influences cell behaviors. The majority of studies investigating the effects of topographic cuing on cells have been conducted on large scale (>1 micron) features, which does not accurately represent the range of feature sizes present in the basement membrane. We have recently conducted morphological analysis of the architecture of the basement membrane underlying the vascular endothelium from aorta, carotid and saphenous vessels from the Rhesus Macaque using SEM. We found that the average pore diameter (62$\pm$37 nm) and fiber size (30$\pm$11 nm) was similar across vessel types and to feature sizes described for the basement membrane of the porcine aortic valve (Brody et al, In Press). Based on the morphological characterization, silicon and polyurethane surfaces with feature sizes mimicking the native basement membrane were produced. The anisotropic surfaces were composed of ridges and grooves containing features ranging from 200 nm to 2000 nm. These surfaces were used to characterize the impact of topographic cueing on endothelial behaviors including orientation/elongation and proliferation. HUVEC and HMVEC cells, representative of endothelial cells from large and small vessels, respectively, were plated onto substrates at a density of 9,000 cells/cm$^2$ and allowed to adhere for 24 hours, fixed , stained and analyzed for orientation/elongation. We found that both HUVECS and HMVECS exhibit alignment and elongation with the topography (40% or more) compared to planar surfaces (10%). At 5 days post plating, proliferation of HUVECS was inhibited by topographic features of widely varying pitch (pitch=ridge+groove) while proliferation of HMVECs was unaffected by topographic cues. Our data indicate a heterogeneous response of endothelial cells to topography and suggest that endothelial cells from large and small vessels respond differentially to topographic cues.

**Probing Cellular Responses to Extracellular Signals through Direct Writing of Proteins with a Microfabricated Patterning Tool**

J. Werbin,[1] C. Lemmon,[2] G. Ledung,[3] W. F. Heinz,[1] L. H. Romer,[4] J. H. Hoh[1]; [1]Physiology, Johns Hopkins University School of Medicine,

Baltimore, MD, [2]Biomedical Engineering, Johns Hopkins University School of Medicine, Baltimore, MD, [3]Mälardalen University, Eskilstuna, Sweden, [4]Anesthesiology & Crit Care Med, Johns Hopkins University School of Medicine, Baltimore, MD

Interactions between cells and the extracellular environment play a central role in a number of biological phenomena such as tissue growth, cell differentiation and migration. Patterning biomolecules at high resolution on solid supports is a powerful means to investigate how cells interpret and respond to spatially defined extracellular cues. We used a new technology based on microfabricated surface patterning tools, which delivers a protein solution ($10^{-15}$-$10^{-18}$ liters) to the surface via a micro-channel in small cantilever (NanoArrayer, Bioforce Nanosciences). This direct writing process transfers proteins to the substrate by capillary action when the tool touches the surface for times ~100 ms. Proteins can be bound to the surface by adsorption, or via covalent chemistry. The resulting feature sizes range from submicrometer to tens of micrometers, and pattern dimensions are typically 0.5 x 0.5 mm. A series of patterning parameters and conditions have been optimized, and we have constructed glass substrates with a number of different proteins and peptides in complex patterns with multiple components. For example, patterns that are composed of fibronectin and vitronectin where the distance between the two molecules is subcellular, such that a single cell can contact both fibronectin and vitronectin at several well-defined points, have been produced. These patterns have been characterized by immunofluorescence, and are stable under cell culture conditions. In experiments with Mouse Embryo Fibroblasts plated on micropatterned fibronectin in serum-free medium, immunofluorescence labeling revealed that vinculin was localized to the patterned fibronectin foci in semilunar adhesions with concavities toward the cell center. These findings demonstrate spatial control over focal adhesion formation, and provide a foundation to investigate mechanisms by which different molecules contribute to the contacts these cells make with the extracellular environment.

### Taking Cell Mechanics to the Third Dimension

P. Panorchan,[1] J. S. Lee,[1] Y. Tseng,[2] D. Wirtz[1]; [1]Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD, [2]Chemical Engineering, University of Florida, Gainesville, FL

Cell function and morphology are profoundly affected by the dimensionality of the extracellular environment confining the cell. How cells mechanically sense the dimensionality of their local environment - whether plated on a 2D substrate or embedded in a 3D matrix - is mostly unknown, partly because individual cells in an extended 3D matrix are inaccessible to physical probes. Here we develop a high-resolution functional assay to measure the intracellular micromechanical response of single human umbilical vein endothelial cells (HUVECs) imbedded in a matrix and compare the response of single HUVECs plated a flat substrate coated with the same matrix. In addition to their different morphology and actin cytoskeleton organization, the cytoplasmic viscoelasticity of cells in a matrix differ sharply from that of cells flattened on a substratum. Treatment with vascular endothelial growth factor (VEGF), a promoter of angiogenic migration, induces opposite micromechanical responses in 2D and 3D. This differential mechanical response is abrogated by Y-27632, a specific inhibitor of Rho-kinase (ROCK). These results suggest that endothelial cells sense mechanically the dimensionality of their confining environment and respond to VEGF primarily through ROCK-mediated contractility.

### Stressed Polystyrene Causes Increased Membrane Sensitivity of Adherent Cells to Fluid Shear Force

J. Y. Lau, R. Tchao; Pharmaceutical Sciences, Div. of Pharmacology & Toxicology, University of the Sciences in Philadelphia, Philadelphia, PA

Adherent cells are able to transduce signals from its underlying extracellular matrix (ECM) resulting in changes in various cell functions, including cell spreading and morphology. However, changes in the mechanical properties of the cell membrane due to adherence to a substratum have not been studied. Adherent NBT II cells, a rat bladder carcinoma cell line, on polystyrene (PS) discs made from pure, atactic polystyrene appear to respond to the topographical difference between the peripheral 1mm zone and the center of the disc. Cells on the peripheral zone resulted in 91.5±0.42% cell death due to instantaneous rupture of the cell membrane after application of a fluid shear force, as determined by the Live/Dead® cell assay kit (Molecular Probes). NBT II cells on the center of the disc and on the surrounding glass surface showed little cell death with a viability of 89.7±1.06% and 94.7±0.14%, respectively. Under cross-polarized light, the edge of the PS disc showed a low degree of birefringence with no birefringence at the center of the disc. Since birefringence suggests a more orderly arrangement of the PS polymer molecules, we applied various weights (1g, 5g, 10g, 20g, and 40g) to the PS disc at 100°C for 2 hours and then cooled rapidly at 4°C. We have found that increasing weights resulted in increasing degrees of birefringence. In contrast to NBT II cells on the center of the PS disc or unstressed PS, cells on the stressed PS resulted in 50.7±10.9% cell death due to membrane rupture after a fluid shear force. Interestingly, increased birefringence is also associated with increased lipophilicity, as determined by Nile Red staining. We propose that NBT II cell interaction with stressed PS results in cell sensitivity to mechanical forces.

### Evaluating the Behavior of Neural Cells Near an Electrode in Rat Brain Slice Cultures

B. A. Koeneman,[1] A. Panitch,[2] J. He,[3,2] D. G. Capco[1]; [1]School of Life Sciences, Arizona State University, Tempe, AZ, [2]Harrington Department of Bioengineering, Arizona State University, Tempe, AZ, [3]Arizona Biodesign Institute, Arizona State University, Tempe, AZ

Glial scarring in the brain impedes the optimal functionality of implanted neural recording electrodes. Composition of the electrode is a leading cause of the scar formation. By utilizing a three-dimensional tissue model, a method to evaluate the biocompatibility of novel electrode materials is described. The model involves organotypic tissue culture for maintaining healthy neuronal tissue slices in the absence of the systemic response. While limitations of any in vitro model exist, brain slice culture better mimics the in vivo conditions of glia and neurons than the more traditional two-dimensional cell culture. Another important advantage of brain slice cultures is that fewer animals can be used, since several slices can be obtained per animal. Living brain slices derived from the hippocampal regions of 100 g CD rats were utilized to evaluate the biocompatibility of the BCB neural electrodes. Due to the low water uptake and inherent flexibility when formed in thin sheets, poly(benzylcyclobutene) (BCB) electrodes were developed as test materials. Cellular response to the electrodes was evaluated at 0, 7, and 14 days. At the various time points live/dead viability assays were performed as well as immunohistochemistry to determine the effects of the neural electrodes. Living cells were observed both in the vicinity of the implant, within the brain slice, as well as migrating onto the shank of the electrode. In conclusion, both neurons and glia can be successfully evaluated in a native three-dimensional state by utilizing brain slice cultures, while sacrificing fewer animals.

Supported by DARPA funding.

## Integrins (2547-2568)

2547

### Amino Acid Changes in Drosophila αPS2βPS Integrins that Affect Ligand Affinity

T. A. Bunch,[1] T. L. Helsten,[2] T. L. Kendall,[1] K. Shakalya,[3] D. Mahadevan,[3] S. J. Shattil,[2] D. L. Brower[1]; [1]Molecular and Cellular Biology, University of Arizona, Tucson, AZ, [2]Department of Medicine, University of California San Diego, La Jolla, CA, [3]Department of Medicine, Arizona Cancer Center, Tucson, AZ

We have developed a ligand-mimetic antibody Fab fragment specific for *Drosophila* αPS2βPS integrins to probe the ligand binding affinities of these invertebrate receptors. TWOW-1 was constructed by inserting a fragment of the ECM protein, Tiggrin, into the backbone of the αvβ3 ligand-mimetic antibody WOW-1. As seen for other integrins, αPS2βPS affinity for TWOW-1 is increased by mutations in the αPS2 membrane-proximal cytoplasmic GFFNR sequence, or by exposure to $Mn^{2+}$. Although $Mn^{2+}$ is sometimes assumed to promote maximal integrin activity, we find that TWOW-1 binding in $Mn^{2+}$ can be further increased by the αPS2 GFFNR > GFANA mutation. A mutation in the βPS I domain (βPS-b58; V409 > D) greatly increases integrin binding to TWOW-1, as predicted from cell spreading studies. Mutations that potentially reduce interaction of the integrin β subunit PSI and stalk domains have been shown to have activating properties. We find that complete deletion of the βPS PSI domain enhances TWOW-1 binding. Moreover, the PSI domain is dispensible for at least some other integrin functions, as these mutants display an enhanced ability to mediate cell spreading. Integrins containing the αPS2m8 (missing exon 8) splice variant show reduced binding to TWOW-1 relative to the full length αPS2C. However, the two forms display similar affinities in the presence of $Mn^{2+}$, suggesting that previously characterized differences in αPS2m8 and αPS2C ligand preference result from conformational differences, as opposed to specific contacts between ligand and exon 8-encoded residues. These studies establish a means to evaluate mechanisms and consequences of integrin affinity modulation in a tractable model genetic system.

### SDF-1 and Cytochalasin D Effects on Beta2 Integrin Avidity Differ in their Functional Consequences for Cooperativity Between Beta2 Integrins and E-selectin Ligands

K. Gupta,[1] X. Wu,[1] T. Yu,[1] D. F. Kucik[1,2]; [1]Pathology, UAB, Birmingham, AL, [2]Pathology, Birmingham VA Medical Center, Birmingham, AL

$\beta_2$ integrins on leukocytes increase their adhesiveness both by affinity changes and by rearrangements (clustering). Selectin ligands on leukocytes also rearrange in response to selectin binding and as yet incompletely defined extracellular and intracellular signals. Although selectins and $\beta_2$ integrins have been thought to act sequentially, recent evidence indicates that the functions of these adhesion molecules overlap. Our recent work has shown that cooperation between E-selectin ligand and $\beta_2$ integrins is particularly important in a key phase of monocyte activation: avidity enhancement by integrin rearrangement. In the current study, we used low-dose cytochalasin D, an established method that separates avidity from affinity effects on $\beta_2$ integrins by releasing the integrins from cytoskeletal constraints on their motion (confirmed by diffusion measurements). This treatment has been shown to increase avidity and clustering without changing binding affinity. Low-dose cytochalasin D (0.3-1.0 μg/ml) increased the number of cells captured under flow on a substrate of mixed E-selectin and ICAM-1 (E+I); however it had no effect under flow conditions on adhesion to a substrate of either adhesion molecule alone. SDF-1α induces both affinity changes and rearrangement of $\beta_2$ integrins. SDF-1α had little or no effect on the number of cells captured by an E+I substrate, but transiently slowed rolling velocity; this was inhibited by pertussis toxin. The SDF-1α and cytochalasin D effects were additive, suggesting that the mechanisms of action differ at the level of the adhesion molecules. Both effects, however, required the presence of both integrin ligand and selectin in the adhesive substrate. These experiments demonstrate that SDF-1α avidity changes are less effective in promoting capture on E+I than cytochalasin D-induced clustering, but SDF-1α has a greater effect on rolling velocity.

### Effects of Amino Acid Substitutions in and Around the Arginine-Glycine-Aspartic Acid (RGD) Sequence on Fertilization and Parthenogenetic Development in Mature Bovine Oocytes

B. R. Sessions, K. I. Aston, A. P. Davis, B. J. Pate, K. L. White; Animal Dairy and Veterinary Sciences and Center for Integrated Biosystems, Utah State University, Logan, UT

Integrins have been shown to be involved in the process of fertilization and many integrin-ligand interactions are mediated through the recognition of an arginine-glycine-aspartic acid (RGD) sequence. Despite the fact that the RGD domain is a principal player in determining the functional characteristics of an adhesive protein, increasing evidence has accumulated implicating the flanking amino acids adjacent to the RGD sequence determine the functional properties of the RGD-containing protein. A set of linear peptides with modified amino acid sequences in and around the RGD tri-peptide was synthesized to better understand the specificity of the RGD-receptor interaction. Mature oocytes were fertilized in vitro in the presence of RGD-containing, RGD-modified, and non-RGD peptides. Both the RGD-containing and RGD-modified peptides impaired the ability of sperm to fertilize the bovine oocyte, illustrated by a reduction in cleavage. The linear modified RGD containing peptides were also examined for their ability to induce parthenogenetic development with the objective of providing a linear RGD peptide with greater biological activity than the one (G**RGD**SPK) reported previously by this laboratory (Campbell et al. 2000). The data demonstrate the specificity of the receptor for the RGD sequence and further implicate the involvement of integrins in the process of fertilization. The data support the findings that a linear RGD peptide can block fertilization and that amino acids around the RGD sequence have an impact on the biological activity of the receptor. These data also illustrate the importance of the amino acids surrounding the RGD sequence in determining the binding and functional properties of RGD-containing peptides.

### Integrin-Ligand Bonds are Catch Bonds

D. Boettiger, Q. Shi; Microbiology, University of Pennsylvania, Philadelphia, PA

The function of adhesive bonds requires that they be able to resist an applied force. When force is applied to a receptor-ligand bond, the resulting tension can alter the molecular interactions in the binding interface. If these result in no increase or a decrease in binding strength, the bond are slip bonds. If tension results in an increase in binding strength, the bonds are catch bonds. We analyzed the function of adhesive α5β1 integrin-fibronectin bonds using chemical cross-linking and the spinning disc. In Ht1080 fibroblasts spreading on a fibronectin-coated surface the α5β1-fibronectin bonds are tensioned by the action of myosin contracting the actin cytoskeleton. When this reaction was blocked with pharmacological inhibitors, the bonds were not tensioned and could not be cross-linked using DTSSP (cell impermeant homobifunctional) cross-linkers. Appling tension to the bonds with the spinning disc restored the ability of DTSSP to crosslink the α5β1-fibronectin bond. Blocking actin assembly did not prevent the formation of α5β1-fibronectin bonds but prevented both the DTSSP cross-linking and the tensioning of the bonds by the spinning disc. In the presence of low doses of cytochalasin D, increasing of the force using the spinning disc resulted in an increase in the force required for cell detachment. These results show that tension alters the α5β1-fibronectin bond and converts it to a bond that shows a higher resistance to detachment. The ability of these bonds to resist higher tension could be a property of single bonds, as suggested for selectins, or it could be a property of α5β1 as presented on the cell surface involving other binding proteins. Previous analysis have shown that α5β1-mediated signaling to induce the phosphorylation of FAK Y397 was tension dependent. The conformation changes that accompany tension would provide a mechanism to connect adhesion to cell signals.

### Integrins and Syndecans Mediate Unique Cellular Responses to Nanoscale Topographic Cues

J. D. Foley,[1] T. J. Porri,[2] F. Yokoyama,[3] M. Nomizu,[3] P. F. Nealey,[2] C. J. Murphy[1]; [1]School of Veterinary Medicine, University of Wisconsin, Madison, WI, [2]Chemical and Biological Engineering, University of Wisconsin, Madison, WI, [3]Laboratory of Clinical Biochemistry, Tokyo University of Pharmacy and Life Sciences, Tokyo, Japan

Objective: We have shown that nanometer length features affect a wide range of fundamental behaviors differently than do micron scale features. In addition we have found that nanometer length topographic features modulate Rho GTPase family members as well as multiple kinase signaling pathways. The mechanism(s) by which signaling pathways and behaviors are modulated remain unknown, but may involve ligation of specific cell matrix receptor families. Therefore, we used receptor-specific ligands to test the individual and cooperative roles of integrins and syndecans in these processes. Results: Self-assembled monolayers (SAMs) in which 0.1% of the triethylene glycol (EG(3)) was conjugated to specific ligands were formed on gold-coated silicon surfaces with pitches (groove width + ridge width) ranging from 400 to 4,000 nm. Primary human corneal epithelial cells (HCECs) were cultured on these surfaces for 12 hours and their spreading and alignment responses were measured. We found that an RGD-containing peptide promoted a scale-dependent shift in HCEC orientation such that cells preferentially aligned parallel to 400 nm pitch patterns, but perpendicular to 4,000 nm pitch. Surprisingly, this shift in alignment mirrors what was observed when EF-1, a non-RGD integrin peptide, was adsorbed onto 400 versus 4,000 nm pitch topographic features. This suggests that this scale-dependent shift in alignment is a general feature of integrin ligation and not sub-type specific. Co-presentation of a syndecan ligand significantly decreased the RGD-induced alignment on 400 nm pitch surfaces and promoted a roughly equal preference for parallel and perpendicular alignment on 4,000 nm pitch. Conclusions: These data suggest that integrin and syndecans promote unique cellular responses to topography, that integrins play a role in scale-dependent modulation of cellular behaviors and that this modulation can be altered by co-presentation of syndecan ligands.

2552

### Functional Overlap between Dystrophin and the α7β1 Integrin

J. E. Rooney; Pharmacology, University of Nevada, Reno, Reno, NV

Duchenne muscular dystrophy (DMD) is the most common X-linked human disease, with a prevalence of 1 in every 3,500 live male births. DMD patients and *mdx* mice (the murine model for DMD) have mutations in the dystrophin gene that result in the absence of the dystrophin protein. A second laminin binding complex in skeletal muscle is the α7β1 integrin. The absence of the α7 integrin results in congenital myopathy in mice and humans. The transgenic over-expression of the α7 integrin chain in the skeletal muscle of severely dystrophic mice has been show to partially rescue the diseased phenotype. These correlations suggest that dystrophin and the α7β1 integrin may have complementary and overlapping functional and structural roles in maintaining skeletal muscle integrity. In order to test this hypothesis, mice deficient for both dystrophin and the α7 integrin (*mdx*/$\alpha7^{-/-}$) were generated. These animals display severe signs of muscular dystrophy and die prematurely at 3-4 week of age. The muscle fibers of *mdx*/$\alpha7^{-/-}$ mice display extensive loss of membrane integrity, increased inflammatory cell infiltrate, fibrotic deposition and degeneration. These mice were also found to have increased muscle regeneration and changes in the expression patterns of laminin-2/4 and utrophin. Collectively, these results point to overlapping roles for dystrophin and the α7β1 integrin in skeletal muscle structure and function. The elucidation of these overlapping functional capacities may lead to the identification of novel therapies for muscular dystrophy through the exploitation and manipulation of cell signaling pathways or proteins shared by both complexes.

2553

### Role of Integrin αIIbβ3 in Platelet Activation

D. Westrup, T. Scholz, W. Wegert, C. M. Kirchmaier; Deutsche Klinik fur Diagnostik, Wiesbaden, Germany

During the early phase of blood clot formation platelets play a critical role (i) by forming clumps at the site of injury and (ii) by amplifying a proteolytic coagulation cascade that culminates in the activation of thrombin, cleavage of fibrinogen and formation of the fibrin network. Platelet aggregation depends on the integrin αIIbβ3 (glycoprotein IIb/IIIa; CD41/CD61). Upon activation, αIIbβ3 forms high-affinity interactions with fibrinogen, fibronectin and von Willebrand factor. Binding of fibrinogen to αIIbβ3 mediates clot formation by crosslinking platelets to each other. In addition, binding of ligands to αIIbβ3 has been shown to trigger a reorganization of the actin cytoskeleton. Here we have studied the role of αIIbβ3 for platelet-mediated amplification of the proteolytic coagulation cascade. Platelets were obtained from patients with Glanzmann's thrombasthenia, a bleeding disorder caused by mutations in αIIbβ3. Compared to controls, platelets with defects in αIIbβ3 exhibited significantly reduced induction of markers for platelet activation, including reduced surface expression of phosphatidylserine and impaired exocytosis of secretory granules. Moreover, αIIbβ3-deficient platelets failed to optimally catalyze the activation of thrombin. Taken together, these results support the conclusion that activation of αIIbβ3 is required for optimal induction of platelet-mediated fibrin formation.

**Vav Guanine Nucleotide Exchange Factors and Rac are Required for Actin Polymerization during Complement-mediated Phagocytosis**

A. B. Hall,[1] M. Angelica Martinez Gakidis,[1] M. Glogauer,[2] J. Wilsbacher,[1] W. Swat,[3] J. S. Brugge[1]; [1]Cell Biology, Harvard Medical School, Boston, MA, [2]Faculty of Dentistry, University of Toronto, Toronto, ON, Canada, [3]Pathology and Immunology, Washington University School of Medicine, St. Louis, MO

Phagocytosis is an important biological process and represents a useful model for studying spatially and temporally defined events involved in actin cytoskeletal rearrangements triggered by the engagement of signaling receptors. Vav family guanine nucleotide exchange factors (GEFs) have been implicated in cell adhesion by integrin and immune response receptors through the regulation of the Rho GTPases. We are examining the role of Vav and the Rho GTPases in phagocytosis using primary bone marrow-derived murine macrophages. The genetic deletion of both Rac1 and Rac2 prevents phagocytosis mediated by integrin and Fcγ receptors (FcγR), whereas the genetic deletion of Vav1 and Vav3 or all three Vav family members prevents only integrin-mediated phagocytosis through the complement receptor $\alpha_M\beta_2$. In addition, a Rac1/2 or Vav1/3 deficiency blocks Arp2/3 recruitment and actin polymerization at the complement-induced phagosome, indicating that Vav and Rac family proteins regulate these early steps in phagocytosis. In contrast, the specific inhibition of Rho with C3 transferase prevents both complement and FcγR-mediated phagocytosis at a step distinct from actin polymerization. Moreover, a constitutively active mutant of Rac, but not Cdc42, is able to rescue actin polymerization and complement-mediated phagocytosis in Vav-deficient macrophages. These studies indicate that Rac is critical for both complement and FcγR- mediated phagocytosis and plays a broader role than originally revealed in studies of immortalized cell lines. In contrast, Vav is specifically required for complement-mediated phagocytosis, suggesting that Rac is regulated by GEFs other than Vav downstream of the FcγR.

**Novel Role for Tetraspanin CD81 in Photoreceptor Outer Segment Phagocytosis by Retinal Pigment Epithelial Cells**

Y. Chang,[1,2] S. C. Finnemann[1,2]; [1]Graduate Program of Physiology, Biophysics & Systems Biology, Weill Medical College of Cornell University, New York, NY, [2]Departments of Ophthalmology, and of Cell and Developmental Biology, Dyson Vision Research Institute, Weill Medical College of Cornell University, New York, NY

Retinal pigment epithelial (RPE) cells are among the most active phagocytic mammalian cell types. Every day, each RPE cell engulfs and digests numerous outer segment fragments (OS) shed in a circadian rhythm by adjacent photoreceptor cells. αvβ5 integrin receptors of the RPE and their downstream signaling pathways are required for this rhythmic phagocytic event that is critical for vision. We hypothesize that the activity of αvβ5 integrin itself may be regulated in the RPE to synchronize phagocytosis. Tetraspanins are a family of transmembrane proteins that can regulate integrin receptor activity. Integrin-tetraspanin complexes have been shown to localize in cholesterol-rich membrane domains to initiate integrin downstream signaling. Here, we test whether the tetraspanin protein CD81 functionally interacts with αvβ5 integrin in RPE cells. CD81 is known to localize to the apical, phagocytic surface of the RPE in the eye. We used confocal microscopy to characterize RPE cells labeled live on ice with CD81 and αvβ5 antibodies. We found that CD81 partially co-localized with αvβ5 integrin at the phagocytic surface of RPE cells in culture. Optiprep gradients showed that CD81 co-fractionated with αvβ5 in low-density domains of RPE cell lysates. Furthermore, we identified CD81 in a complex with αvβ5 integrin by co-immunoprecipitation. Finally, phagocytosis assays showed that CD81 blocking antibody reduced phagocytosis of isolated photoreceptor OS by human and rat RPE cells in culture. These data suggest that apical surface CD81 plays an important role in the phagocytic function of the RPE, possibly through its interaction with αvβ5 integrin and membrane microdomains. This could provide a novel mechanism for modulating αvβ5 integrin receptor activity and thus RPE phagocytosis. We are currently studying CD81 and integrin αvβ5 complex formation and subcellular localization during active RPE phagocytosis.

**β1 Integrin Regulates αvβ3 Integrin Ligand Binding Via a PKA/Calcineurin-Dependent Pathway**

A. M. Gonzalez, J. Claiborne, J. C. R. Jones; Cell and Molecular Biology, Northwestern University, The Feinberg School of Medicine, Chicago, IL

The interaction of endothelial cells with certain extracellular matrix components is regulated by a complex interplay between αvβ3 integrin and β1 containing integrins (Gonzalez et al., 2002, PNAS). To understand the mechanism underlying this interplay, we have analyzed endothelial cell interaction with the G domain of the α4 laminin which contains distinct high affinity binding sites for αvβ3 and α3β1 integrin. A β1 integrin antagonist efficiently inhibits αvβ3 integrin-mediated adhesion of endothelial cells to ligand indicating that β1 integrin-containing heterodimers function to regulate αvβ3 integrin ligand affinity via an inside-out mechanism. Clustering of β1 integrin with an antibody antagonist results in a two-fold increase in PKA activity in endothelial cells and a concomitant increase in serine phosphorylation of the β3 integrin subunit. Moreover, pharmacological inhibition of PKA rescues αvβ3 integrin-mediated endothelial cell adhesion to ligand in the presence of a β1 integrin antagonist. Since the β3 cytoplasmic tail lacks a PKA consensus site, it is unlikely that PKA is acting directly on β3 integrin. Rather, we have tested the hypothesis that PKA inhibits the calcineurin/inhibitor-1 pathway, blocking the activation of downstream protein phosphatase 1 (PP1) that, in turn, regulates the phosphorylation state of αvβ3 integrin. In support of this, endothelial cell adhesion to ligand is dramatically reduced if the cells are treated with either FK506 and cyclosporin A, inhibitors of calcineurin, or the phosphatase inhibitors okadaic acid and calyculin A, in combination with a PKA and a β1 integrin antagonist. Taken together these results indicate that PKA and the calcineurin/PP1 pathway play important roles in regulating αvβ3 integrin adhesion and signaling in endothelial cells by maintaining a balance between the phosphorylation/ dephosphorylation state of β3 integrin.

**Effect of Biologically Active Peptide-Chitosan Membrane on Cell Morphology and Proliferation**

T. Watanabe,[1] M. Mochizuki,[1,2] N. Yamagata,[1] Y. Kikkawa,[1] J. Yamada,[1] M. Nomizu[1]; [1]School of Pharmacy, Tokyo University of Pharmacy and Life Science, Tokyo, Japan, [2]Graduate School of Environmental Earth Science, Hokkaido University, Sapporo, Japan

Extracellular matrix (ECM) plays a critical role for diverse biological activities including promotion of cell adhesion, migration, spreading, neurite outgrowth, angiogenesis, and wound healing. Various biologically active peptides derived from extracellular matrix components, including laminin, collagen, and fibronectin, have been identified. Previously, we conjugated biologically active peptides derived from laminin to chitosan

membranes. The peptide-chitosan membranes showed strong cell attachment activities and have been suggested to have a potential to apply for tissue engineering as basement membrane mimetic. Here, we focused on integrin-binding peptides derived from ECM components. Integrins, a family of receptors for ECM components, mediate various biological activities including cell adhesion, migration, spreading, neurite outgrowth, angiogenesis, and wound healing. Various integrin-binding peptides were conjugated onto a chitosan membrane and examined their effect on cell adhesion, morphology and proliferation using HT-1080 human fibrosarcoma cells and human foreskin fibroblasts. Most of the peptide-chitosan membranes promoted cell spreading with cell-type specific manner. The morphological appearance of the cells on the peptide-chitosan membranes was peptide-specific. The RGD sequence containing peptide (A99: AGTFALRGDNPQG and FIB1: YAVTGRGDSPAS)-chitosan membranes interacted with αvβ3 integrins and promoted neurite outgrowth with PC12 rat pheochromocytoma cells. However, most of the integrin binding peptide-conjugated chitosan membranes did not promoted neurite outgrowth activity. These results suggested that biological activities on the integrin binding peptide-chitosan membranes are integrin type-specific. These integrin binding peptide-chitosan membranes are useful to develop biomedical materials.

**Molecular Basis of Integrin-Filamin A Interaction and its Competition by Talin**

Y. Lad,[1] T. Kiema,[2] P. Jiang,[3] K. L. Wegener,[3] I. D. Campbell,[3] J. Ylänne,[2,4] D. A. Calderwood[1]; [1]Department of Pharmacology and Interdepartmental Program in Vascular Biology and Transplantation, Yale University School of Medicine, New Haven, CT, [2]Biocenter Oulu and Department of Biochemistry, University of Oulu, Oulu, Finland, [3]Department of Biochemistry, University of Oxford, Oxford, United Kingdom, [4]Department of Bio and Environmental Science, University of Jyväskylä, Jyväskylä, Finland

Integrin-mediated cell migration is critical in many physiological and pathological processes such as embryonic development, leukocyte trafficking, angiogenesis and tumour metastasis. Binding of the large actin cross-linking protein filamin A to the cytoplasmic tails of integrin adhesion receptors regulates cell migration, and filamin A mutations cause a wide spectrum of diseases, including defective neuronal migration. Human filamins are composed of two 280 kDa subunits; each subunit contains an N-terminal actin-binding domain, composed of two calponin homology domains, followed by 24 tandem immunoglobulin-like domains (IgFln1-24) interrupted by flexible hinge regions between domains 15 and 16, and 23 and 24. Dimerization occurs through IgFln24. Here we map a major integrin-binding site in filamin A to a single filamin immunoglobulin-like (IgFln) domain and describe the three-dimensional structure of this domain bound to a peptide from the integrin β7 tail. NMR titration, X-ray crystallography and mutagenesis reveal that when bound to filamin, the C-terminal portion of the integrin β tail forms an extended β-strand that interacts with β-strands C and D of the IgFln domain. We show that this interaction is common to many integrins and suggest that the CD face of IgFln domains represents a general ligand-binding surface. The filamin-binding site on integrin overlaps with that of the key integrin-regulator talin, and these proteins compete for binding to integrin. Modulation of this competition, perhaps by phosphorylation, may regulate integrin function and cell migration.

2559

**Integrin α6β4 Contributions to an Invasive Phenotype in Pancreatic Carcinoma**

Z. Cruz-Monserrate, K. L. O'Connor; Sealy Center for Cancer Cell Biology, University of Texas Medical Branch, Galveston, TX

Pancreatic cancer is one of the most lethal human cancers due to an elevated incidence of tumor cell invasion and metastasis. The general mechanisms and molecules involved in this processes are not yet understood. Our study focuses on integrin α6β4, which correlates with the motile and invasive phenotype of multiple types of carcinomas. To assess the importance of integrin α6β4 in pancreatic cancer, pancreatic tumors and cell lines were screened for the presence of integrin α6β4 via immunohistochemistry, immunoblotting, and fluorescence activated cell sorting. We found that integrin α6β4 is upregulated in pancreatic tumors when compared to normal pancreas and its expression correlated with tumor progression. Integrin α6β4 cell surface expression correlated with their ability to migrate and invaded towards hepatocyte growth factor (HGF). HGF is a known mitogenic and motility factor of pancreatic carcinomas, whose receptor c-Met cooperates with integrin α6β4 to enhance cancer cell motility and invasion. When cells expressing high levels of integrin α6β4 where treated with siRNA targeting the β4 integrin subunit, we observe a reduction in the ability of cells to migrate and invade towards HGF when compare to cells treated with siRNA to a nonspecific target. Furthermore, integrin α6β4 is known to promote invasion of breast and colon cancer cells via the activation of phosphoinositide-3 kinase (PI3-K). We find that PI3-K inhibitors decreased the ability of cells that have high levels of integrin α6β4 expression on the cell surface to invade towards HGF. Furthermore, we find that the activity of the small GTPase Rac-1 is related to changes in α6β4 integrin expression. We conclude that integrin α6β4 plays an important role in the invasive phenotype of pancreatic carcinoma cells and that the PI3-K/Rac1 pathway is an important mediator of integrin α6β4-mediated invasion and migration.

2560

**Role of Beta-turn of Integrin αv-chain in the Regulation of CD44 Surface Expression, MMP2 Secretion and Migration of Human Melanoma Cells**

S. Venkatasababa, H. Wei, D. Ego-Osuala, M. A. Chellaiah; Department of BMS, University of Maryland, Baltimore, MD

The level of integrin αvβ3 and expression of its ligand osteopontin (OPN) has been directly correlated to tumorigenicity of melanoma. The M21-L is a melanoma cell line lacking αv expression and hence also the αvβ3 integrin. M21-L cell line was used for the expression of αv (M21 cells) and cytoplasmic domain deleted αv (M21-L/αv995). M21 cells were used for the expression of OPN (M21/OPN) and mutated OPN (RGA). An increase in c-Src kinase activity associated with αvβ3 was observed in M21/OPN cells as compared with M21 cells. This association was not observed in M21-L/αv995 cells. To further corroborate the binding site of c-Src in the cytoplasmic domain of αv, three peptides corresponding to the αv cytoplasmic domain were made. The β-turn peptide of αv consisting of aa sequence '995RPPQEEQERE1004' bound to several signaling such as, talin, Src, FAK, paxillin, and a few uncharacterized proteins. Either negligible or no binding of proteins with peptides corresponding to aa 986- 994 or aa 1005-1018 was observed. In a wound closure assay, M21/OPN cells exhibit an enhanced ability to migrate and this is blocked by αv and MMP2 inhibitors as well as by a blocking antibody to CD44. An increase in CD44 surface expression as well as MMP2 activity in the conditioned medium was observed in M21/OPN cells as compared with M21 cells. Basal level activity of MMP2 was observed in M21/OPN (RGA), M21-L, and M21-L/αv995 cells. Our observations suggest that the aa sequence in the β-turn of αv chain is indispensable for αv-associated

signaling complex formation and out-side-in signaling. OPN is a unique ligand for αvβ3. Its integrin activation potential increases CD44 surface expression and MMP2 activity in melanoma cells.

2561

**Integrin α6 Clipping: A Novel Mechanism to Modulate Cell Motility**

S. C. Pawar, M. C. Demetriou, R. B. Nagle, G. Bowden, A. E. Cress; Arizona Cancer Center, University of Arizona, Tucson, AZ

Integrins play a major role in cell adhesion and migration. A clipped form of the integrin α6 called integrin α6p has been detected in invasive human prostate cancer tissue and is absent in normal prostate tissue. Integrin α6p is generated by Urokinase-type plasminogen activator (uPA) mediated clippage of the integrin α6 at the cell surface. We identified the clippage site and determined if the clippage of integrin α6 to α6p altered cell migration. Using site-directed mutagenesis we identified residues R594 and R595 essential for clipping, in the "stalk" region of integrin α6. Prostate cancer cells (PC3N) were stably transfected to overexpress the clippable, wild-type form of integrin α6 (PC3N-α6-WT) or the unclippable form of integrin α6 (PC3N-α6-RR) in which the two required arginines were replaced by two alanines. Induced migration of PC3N-α6-RR cells on Laminin-5 was reduced up to 2.4 fold as compared to the PC3N-α6-WT cells. Stimulated migration on the integrin α6 ligand, Laminin-5, also induced production of integrin α6p in the PC3N-α6-WT cells and not in the PC3N-α6-RR cells. These data suggest that the cell surface clipping of the α6 integrin extracellular domain may be involved in tumor cell migration on Laminin-5.

2562

**The Integrin Alpha9beta1 Contributes to Granulopiesis by Enhancing G-CSF Signaling**

C. Chen, X. Huang, D. Sheppard; Lung Biology Center, UCSF, San Francisco, CA

The integrin α9 subunit forms a single heterodimer, α9β1. The integrin α9β1 is a receptor for a diverse group of ligands, including the extracellular matrix proteins osteopontin and tenacsin C, the cell surface immunoglobulin vascular cell adhesion molecule-1 and the lympangiogenic growth factors, VEGFC and D. Previous studies show that mice homozygous for a null mutation in the α9 subunit gene appear normal at birth but develop respiratory failure and die between 6 and 12 days of age from congenital chylothorax, suggesting a role for this integrin in lymphatic development. We now show that integrin α9-deficient mice also have a dramatic defect in neutrophil development. α9 knockout mice have decreased numbers of circulating neutrophils and decreased numbers of granulocyte precursors in bone marrow. Bone marrow cells from α9 knockout mice or human bone marrow cells blocked by anti-α9β1 antibody show a defect in differentiation to granulocytes in response to G-CSF. When stimulated with G-CSF in vitro, α9-deficient bone marrow cells or human bone marrow cells blocked with anti-α9β1 antibody demonstrated decreased STAT3 activation in response to G-CSF. When wild type or mutant integrin α9 and G-CSF receptor were co-expressed in CHO cells, STAT3 phosphorylation in response to GCSF required ligation of α9β1 and was dependent on the presence of the authentic α9 cytoplasmic domain. We conclude that integrin α9β1 is required for granulopoiesis and that integrin ligation plays a permissive role in the G-CSF signaling pathway, a process that depends on the presence of specific sequences within the α9 cytoplasmic domain.

2563

**The Mechanism of Angiogenesis Inhibition by Blocking of α1β1 Integrin**

I. Oliva, I. Staniszewska, C. Marcinkiewicz; Department of Neuroscience, Temple University, School of Medicine, Philadelphia, PA

Disintegrins are cystein-rich proteins that interact with cell surface receptors belonging to integrin family. Obtustatin is a KTS-disintegrin characterized as a potent and selective inhibitor of α1β1 integrin. Previous reports showed potential role of this collagen receptor in angiogenesis, but the mechanism which involves α1β1 integrin in vascularization process is still unknown. Endothelial cells proliferation and migration are the important phenomenon of new vessel formation and integrins are strongly involved in this process. Obtustatin appeared to be a potent inhibitor of proliferation of cultured human microvascular endothelial cells (HMVEC) induced by complete FBS, as well as by only VEGF. This inhibition was dose-dependent (0.125-4 μM) in BrdU incorporation assay and in cell number counting. The anti-proliferative effect of obtustatin is related to its pro-apoptotic effect. This disintegrin induced apoptosis in HMVEC tested in ADP/ATP ratio measurement, Annexin V assays, and Caspase 3 assay. We focused on the MAP kinase investigating signaling pathway that is induced after binding of obtustatin to α1β1 integrin. No effect was observed for p38 and JNK, but ERK 2/1 was strongly phosphorylated after exposure of HMVEC to obtustatin. Interestingly, incubation of HMVEC with obtustatin in the presence of VEGF did not change any phosporylation ratio of ERK 1/2 in comparison with effect of separate compounds. These data suggest that pro-survival factor (VEGF) and pro-apoptotic agent (obtustatin) affect the same elements of signaling pathway resulting in MAPK ERK 1/2 phosporylation. The interference between VEGF receptors and α1β1 integrin in signal transduction may identify a new paradigm helping a better understanding of cell survival/death mechanisms. Further studies will be preformed to characterize detailed "cross-talk" elements of VEGFR and α1β1 integrin.

2564

**Inhibition of Prostate Cancer Cell Migration by Bisphosphonates through Attenuation of MMP 9 Activity and CD44 Surface Expression: A Comparative Analysis with the Studies on Osteoclasts**

B. Desai, S. Venkatasababa, M. A. Chellaiah; Department of BMS, University of Maryland, Baltimore, MD

Osteopontin (OPN) has been identified to have a role in the determination of osteotropism and growth of prostate cancer cells. In osteoclasts, we have demonstrated that binding of OPN to αvβ3 initiates intracellular signals required for the surface expression of CD44. Much of what we have learned in the osteoclasts related to αvβ3 signaling is relevant to prostate cancer cells since both cell types express OPN as an autocrine motility factor. Our results identify that PC3 cells derived from bone metastasis as well as osteoclasts exhibit MMP-9 activity to a greater extent despite some MMP-2 was also observed in PC3 cells. An increase in CD44 surface expression as well as MMP 9 activity in the conditioned medium was observed in PC3 cells over expressing OPN (PC3/OPN) as compared with PC3 cells. A significant decrease in MMP-9 activity as well as CD44 surface expression below the control level (PC3) was observed in mutant OPN expressing (PC3/OPN (RGDΔRGA)) as well as in OPN-SiRNA transfected PC3 cells (PC3/OPN-/-). Bisphosphonates is an effective inhibitor of osteoclast activation and function. Bisphosphonates such as alendronate or pamindronate reduced MMP-9 activity in the conditioned medium of these cell lines. A significant inhibition of surface colocalization of MMP-9 and CD44 by bisphosphonates was observed on the cell surface in the immunostaining analysis. Bisphosphonates and

MMP-9 inhibitor significantly reduced the migration of both PC3 and PC3/OPN cells in the wound closure assay. Our findings suggest that bisphosphonates down regulates MMP- 9 secretion and CD44 surface expression in both osteoclasts and prostate cancer cells contributing to possible reduction in invasive nature of prostate cancer cells and decreased bone resorption potential of osteoclasts.

**Blocking of Collagen Receptors in Melanoma and Endothelial Cells Migration**

I. Staniszewska, I. Oliva, C. Marcinkiewicz; Department of Neuroscience, Temple University, School of Medicine, Philadelphia, PA

Collagen receptors, α1β1 and α2β1 integrins are highly expressed on the surface of endothelial cells and many metastatic tumoral cells, playing important role in tumor angiogenesis and metastasis. Viperistatin and VP12 were characterized as potent and selective inhibitors of α1β1 and α2β1 integrin, respectively. Viperistatin belongs to the snake venom disintegrins, whereas VP12 is a C-lectin type protein. We tested two human melanoma cell lines that differ in expression of αvβ3 integrin. MV3 is a cell line αvβ3 negative, while HS.939T cell line αvβ3 positive. Using an adhesion assay we observed that expression of both collagen receptors is increased on MV3 cells and this cell line showed doubled potency to adhere to immobilized collagen type I and type IV. The adhesion of both melanoma cell lines to both types of collagens was inhibited by viperistatin and VP12, but with different potency. Inhibitory effect of snake venom proteins was from one to three orders of magnitude higher for HS.939T cells in comparison with MV3. Interestingly, we observed highly synergistic effect using viperistatin in the presence of VP12. In the migration assay *in vitro* through endothelial cell layer plated on the membrane with immobilized collagen IV, viperistatin have no significant effect, whereas VP12 showed essential inhibitory effect. However, viperistatin was very potent inhibitor of transmigration of HS.939T cells in this assay, and VP12 had moderated effect. These data suggest that the major pro-migratory collagen receptor on MV3 cells is α2β1 integrin, while on HS.939T cells α1β1 integrin. VP12 also potently inhibited the dermal microvascular endothelial cell radial migration in collagen gel. Our results suggest that inhibitors of collagen receptors may have therapeutic implication in angiogenesis and metastasis of melanoma.

**SWAP-70 Regulates LFA-1 Mediated Integrin Signaling Leading to Mast Cell Adhesion**

R. Sivalenka,[1] R. Jessberger[2]; [1]Dept. of Gene and Cell Medicine, Mount Sinai School of Medicine, New York, NY, [2]Institute of Physiological Chemistry Medical School, MTZ, Dresden University of Technology, Dresden, Germany

SWAP-70 regulates rearrangements of the F-actin cytoskeleton in specific cell types, e.g. in bone marrow derived murine mast cells (BMMC) through signaling from their two major receptors - FcεR1 and c-kit. Recently we found that SWAP-70 negatively regulates c-kit induced homotypic adhesion of BMMC mediated by integrin $\alpha_L\beta_2$ (LFA-1). On the contrary SWAP-70 is required for efficient adhesion to extracellular matrix proteins like fibronectin and enhances c-kit mediated adhesion to fibronectin. Thus, SWAP-70 appears to play a role in inside-out signaling to integrins. Besides its role in adhesion of BMMC, SWAP-70 is also required for migration of mast cells towards SCF (c-kit ligand). $\alpha_L\beta_2$-ICAM-1 interactions have been implicated in mast cell interactions with B and T lymphocytes, contributing to their activation, and the function of SWAP-70 in such heterotypic interactions is being investigated. Besides, the present study aims at investigating SWAP-70's role in signaling to $\alpha_L\beta_2$ and in the associated cytoskeletal dynamics. SWAP-$70^{-/-}$ BMMC, which express integrin levels similar to wildtype, show enhanced adhesion to ICAM-1. This adhesion is further increased upon c-kit stimulation. Tyrosine phosphorylation of SWAP-70 is induced upon LFA-1 stimulation, and upon c-kit stimulation, SWAP-70 co-immunoprecipitates with $\alpha_L\beta_2$. We suggest that SWAP-70 acts in regulating interactions between integrins and the cytoskeleton.

2567

**Reconstruction and Deconstruction of Integrin αIIbβ3 Activation in Heterologous Cells**

J. Han,[1] D. A. Calderwood,[2] W. Puzon-McLaughlin,[1] M. H. Ginsberg[1]; [1]Department of Medicine, The University of California, San Diego, La Jolla, CA, [2]Department of Pharmacology, Yale University, New Haven, CT

The increase in integrins' affinity for extracellular ligands ("activation") in response to agonists is a form of inside-out signal transduction that controls cell migration, assembly of the extracellular matrix, and cell adhesion. We have now engineered heterologous cells to reconstruct a signaling pathway that mediates agonist-induced activation of platelet integrin αIIbβ3. Talin binding to the integrin β cytoplasmic domain is a final step in integrin activation and platelets are rich in talin 1. Activation of protein kinase C (PKC) leads to αIIbβ3 activation in platelets, but not in heterologous cells, such as CHO cells. When talin 1 expression was increased ~ 10 fold in αIIbβ3-bearing CHO cells, stimulation with phorbol esters lead to PKC-dependent activation of αIIbβ3. A number of PKC-mediated talin phosphorylation sites were identified using mass spectroscopy; however, mutation of those sites to Ala did not block PKC-mediated activation. In addition, transfection of CHO cells with RapGAP (Rap GTPase Activating Protein) completely blocked PKC-induced αIIbβ3 activation, whereas PKC inhibitors fail to block activated RapV12-induced αIIbβ3 activation, indicating that Rap1 is downstream of PKC in αIIbβ3 activation. In sharp contrast, expression of RapGAP failed to block activation of αIIbβ3 induced by expression of an integrin binding fragment of talin (F23); however, a full length talin point mutation which blocks binding to integrin β3, failed to support αIIbβ3 activation by either PKC or RapV12. Finally, in a talin-deficient cell line, integrin activation is rescued by talin but not by RapV12, any of several Rap-specific effectors, or any combination of RapV12 and its effectors. These data establish that talin is downstream of Rap1 in integrin activation. Thus, this first complete reconstruction of a cellular signaling pathway for agonist-induced integrin activation orders the pathway: Agonist→PKC→Rap→Talin→Integrin.

2568

**Placental Insufficiency in α7 Integrin Null Mice**

J. V. Welser, N. L. Flintoff-Dye, D. J. Burkin; Pharmacology, University of Nevada, Reno, Reno, NV

The α7β1 integrin is a heterodimeric laminin receptor expressed in vascular smooth muscle. Loss of the α7 integrin chain results in partial embryonic lethality. We have previously shown that α7 null embryos exhibit cerebral vascular hemorrhaging which may play a role in the partial embryonic lethality. Placental defects in α7 null embryos may also contribute to the partial embryonic lethality observed in α7 integrin knockout mice. To determine if these vascular defects extend to the placental labyrinth, placentas from ED9.5 and 13.5 wild-type and α7 knockout embryos were analyzed. Histological analysis of the placentas from hemorrhaging α7 null embryos showed structural defects, including a reduction in the

spongiotrophoblast layer, as well as infiltration into the decidua layer. To determine whether the loss of the α7 integrin affects placental vascular integrity, vascular smooth muscle cells were analyzed using placentas from ED13.5 wild-type, non-hemorrhaging α7 null, and hemorrhaging α7 null embryos. A 1.5 fold increase in the number of vascular smooth muscle cells in non-hemorrhaging α7 null placentas compared to wild-type placentas was observed. In contrast, a 1.5 fold decrease in the number of vascular smooth muscle cells in hemorrhaging α7 null placentas compared to wild-type placentas was found. Altered vascular integrity in non-hemorrhaging α7 null and hemorrhaging α7 null placentas may contribute to the observed partial embryonic lethality. Our results confirm a role for the α7β1 integrin in placental development and show for the first time that loss of the α7 integrin results in placental insufficiency.

## Metalloproteases (2569-2583)

2569

### Wild-Type and Spontaneously Active Matrix Metalloproteinase (MMP)-1 Mutants Induce Vascular Regression in Vitro and in Vivo

W. B. Saunders, G. E. Davis; Medical Pathology and Laboratory Medicine, Texas A&M University System Health Science Center, College Station, TX

Previous work has shown endothelial cells (ECs) regulate regression of capillary tubes in vitro via activation of interstitial collagenase (MMP-1) by multiple serine proteases and stromelysin-2 (MMP-10). Herein, we investigate the role of human MMP-1 as a downstream mediator of vascular regression in vitro and in vivo. Site-directed mutagenesis was utilized to induce point mutations within the propeptide domain of MMP-1, resulting in four spontaneously active MMP-1 mutants: MMP-1 Y18A, L19A, C73S, and V75G. Using a previously described, three-dimensional (3D) regression assay, ECs were induced to express MMP-1 mutants via adenoviral delivery. ECs expressing MMP-1 mutants underwent capillary tube regression and collagen gel contraction in the absence of serine proteases, while ECs expressing GFP control or wild type MMP-1 underwent normal EC vacuole/lumen formation and did not regress. Importantly, the time to tube regression and collagen gel contraction corresponded with the degree of MMP-1 activation visible on Western blot as well as the collagenase activity in conditioned media. This serine-protease independent regression response was inhibited by the MMP inhibitors TIMP-1, α2Macroglobulin, and GM6001, and not by the serine protease inhibitors aprotinin or PAI-1. To evaluate the role of MMP-1 as a vascular regression factor in vivo, fibroblasts expressing wild type or mutant MMP-1 were utilized to either inhibit formation or induce regression of VEGF induced angiogenic fields using the CAM model of angiogenesis. In both assays, wild-type or mutant MMP-1 induced regression of early angiogenic responses. This regression response was enhanced by the co-delivery of MMP-10, consistent with previous work. Collectively, these data further support the role of human MMP-1 as a vascular regression factor, and demonstrate that spontaneously active MMP-1 mutants may provide use therapeutically in the treatment of disorders of increased vascularity.

### Characterization of Matrix Metalloproteinase-1 Interaction with Human Type III Collagen

K. E. Williams, R. Chang, P. Hillas, C. Luehrs, F. Buschman, J. Polarek, D. Olsen; FibroGen, So San Francisco, CA

Matrix metalloproteinases (MMPs) are essential for normal collagen turnover, recovery from fibrosis, and vascular permeability. In this study we examine the biochemical interaction of MMP-1 and type III collagen through the use of a panel of recombinant human type III collagen mutants, including a single amino-acid mutation in the cleavage site (I785P). Pichia pastoris strains expressing the type III collagen alleles and human prolyl-4-hydroxylase were constructed, screened, and fermented prior to collagen purification from pepsin-digested cell lysates by repeated salt precipitation. The melting temperatures, hydroxyproline content, and CD spectra of FG-5013 (wild-type recombinant type III collagen) and FG-5015 (I785P) are comparable. Transmission electron microscopy analysis of fibrils formed with FG-5015 revealed the striated cross-banded structure typical of collagen fibrils, demonstrating that this mutation does not interfere with fibril formation. Biacore analysis revealed that MMP-1 binds to FG-5013 and FG-5015 with comparable affinity. However, the specific activity of MMP-1 for FG-5015 was 36-fold less than that for FG-5013. FG-5015 was also significantly less susceptible to proteolysis by MMP-8 and trypsin than FG-5013. N-terminal sequence analysis revealed that MMP-1 digestion of FG-5015 occurs at three sites: G781-I782, P785-T786, and G787-A788. These sites are in the vicinity of the wild-type cleavage site, suggesting that in the absence of the wild-type isoleucine, the relaxed tertiary structure of this region may contribute to the recognition of the new MMP-1 sites cleaved in FG-5015. This conclusion is further supported by the observation that an allele with increased hydroxyproline content in this vicinity shows no detectable cleavage. As collagen used in biomedical applications is susceptible to MMP proteolysis and ultimately degrades, FG-5015 may be used as a biomaterial with potentially enhanced *in vivo* persistence.

### Histamine Regulates β-catenin Localization and MMP-2 expression in Endothelial Cells

J. L. Doyle, T. L. Haas; Kinesiology and Health Sciences, York University, Toronto, ON, Canada

β-catenin is a junctional protein that, together with vascular endothelial cadherin, maintains the integrity of endothelial cell-cell junctions. β-catenin is also able to translocate to the nucleus, where it acts as a transcriptional co-activator. During angiogenesis, endothelial cell junctions are reorganized, signaling the cell to proliferate and migrate. Proteolysis of the basement membrane and interstitial matrix, via matrix metalloproteinases (MMPs), is the next crucial step in the angiogenic process. Matrix metalloproteinase (MMP)-2 and membrane type (MT)-1 MMP are two endothelial cell MMPs previously linked to angiogenesis. Permeability agents such as histamine have been shown to be pro-angiogenic and cause reorganization of junctional structures. We hypothesize that 1) histamine is able to increase the nuclear level of β-catenin and 2) histamine increases expression levels of the MMPs through a β-catenin -dependent mechanism. Rat microvascular endothelial cells were stimulated with 100 μM histamine for 24 hours, which caused increased nuclear levels of β-catenin versus control as assessed by western blotting of nuclear extracts (2 fold increase vs. control, n=2). Both MMP-2 total protein and mRNA levels also are increased with histamine treatment (1.7 ± 0.18, $p < 0.05$, n=3 and 1.4 ± 0.66, n=2 respectively ). These results indicate that the nuclear translocation of β-catenin occurs in response to permeability agents such as histamine and that histamine increases both total protein and mRNA levels of MMP-2. These results also indicate that permeability agents have a role in endothelial junction disruption leading to nuclear translocation of β-catenin and that this may be a mechanism through which MMP-2 expression is regulated. **Etoposide Disrupts MMP-2 Translation in Bone Marrow Stromal Cells**

S. D. Clutter,[1] L. F. Gibson[2,3]; [1]Microbiology, Immunology, and Cell Biology, West Virginia University, Morgantown, WV, [2]Pediatrics, West Virginia University, Morgantown, WV, [3]The Blood and Marrow Transplant and Hematologic Malignancy Program, Mary Babb Randolph Cancer Center, Morgantown, WV

We have previously reported that stromal cell MMP-2 is necessary for optimal support of pro-B cell chemotaxis. Following high dose exposure to the topoisomerase II inhibitor, etoposide, stromal cells display reduced MMP-2 protein expression that is not correlated with diminished mRNA, increased intracellular accumulation, or altered stability of MMP-2 protein. The MMP-2 gene contains a 5' polypyrimidine tract (5'TOP) and therefore has the potential to be translationally regulated by mTOR. To determine the mechanism by which MMP-2 protein expression is diminished in etoposide treated stromal cells we evaluated the expression or activity of proteins known to be components of the mTOR pathway including Akt, 4EBP-1, and $p70^{s6k}$. mTOR protein is phosphorylated by Akt and also binds PP2A, inhibiting its phosphatase activity. Dephosphorylation of mTOR frees PP2A, which then rapidly dephosphorylates translational regulatory proteins 4EBP-1 and $p70^{s6k}$. Phosphorylated $p70^{s6k}$ and 4EBP-1 both stimulate translation of genes containing 5'TOPs. To determine if etoposide inhibits translation of MMP-2 by disrupting this specific pathway, we evaluated phosphorylation of the translational regulatory proteins 4EBP-1 and $p70^{s6K}$ by western blot and activity of PP2A and Akt by specific activity assays. Stromal cells exposed to etoposide display decreased Akt activity and phosphorylation of 4EBP-1 and $p70^{s6K}$, and increased PP2A activity. These observations are consistent with regulation of stromal cell MMP-2 translation through the mTOR pathway.

**Invasion-associated MMP-2 and MMP-9 are Up-regulated Intracellularly with Apoptosis Linked to Melanoma Cell Detachment**

A. M. Mendes, M. Strasberg Rieber, M. Rieber; Tumor Cell Biology Laboratory, Center for Microbiology & Cell Biology, Instituto Venezolano de Investigaciones Cientificas, IVIC, Caracas, Venezuela

OBJECTIVE.-Matrix metalloproteinases, like MMP-2 and MMP-9 gelatinases, show multiple functions as extracellular / cell-surface enzymes , and are recognized for their matrix-degrading ability and involvement in cell motility. Given that adherent cells decrease attachment when migrating and also detach from their substratum during apoptosis , we now investigated whether extracellular-matrix -bound gelatinases and intracellular MMP-2 and MMP-9, are modified with progression of death-inducing stimuli. METHODS.- Apoptosis was evaluated by Annexin V binding and DNA fragmentation studies. Gelatinase activity was evaluated by zymography . MMP-2 expression and PARP fragmentation were determined by immune blotting . RESULTS.-This report shows that melanoma cells undergoing death in response to 2-acetyl furanonaphtoquinone (FNQ) , increase cytosolic expression of pro- MMP-2 and intracellular activation of particulate MMP-9. These changes were associated with early activation of a substrate- attached 40 kDa gelatinase reciprocal with changes in extracellular matrix-bound activated MMP-2 . A subsequent activation of secreted MMP-9 and induction of apoptosis-associated fragmentation of poly ADP-Ribose polymerase (PARP) correlated with cell detachment . CONCLUSIONS.- Our data suggests that intracellularly activated gelatinases may cleave survival-associated substrates other than gelatin that share the **Gly-Leu/Iso-Pro** like collagen-binding acetylcholinesterase , thereby linking them to apoptosis associated with cell detachment.

**Type IV Collagen Induces Matrix Metalloproteinase -9 Expressions in MCF7 Breast Cancer Cells**

P. Cortés Reynosa, T. Robledo, E. Perez Salazar; Bilogía celular, CINVESTAV, Mexico D.F., Mexico

**Background.** In breast cancer, cell migration/invasion is an important factor in the formation of solid tumours and necessary for spreading to other organs. In order to migrate, cells have to break extracellular matrix (ECM), including basement membrane (BM). ECM is a complex network of interacting molecules such as collagens and it regulates vital cell processes, including migration, growth, and differentiation. **Aims.** Our aim was to explore whether type IV collagen (CIV) induces metalloproteinase-9 (MMP-9) expression/activation and the role of Src kinase family members and epidermal growth factor receptor (EGFR) activities. **Methods.** Cells were stimulated with CIV and lysed. Cell lysates were analyzed by Western-blot using phosphospecific antibodies. EMSA's were performed using nuclear extracts and a probe representing a canonical NF-κB binding site. MMP-9 activity was determined by zymography using the supernants of MCF7 cells treated with CIV. **Results.** CIV induced FAK activation, phosphorylation of Src at Tyr-418, paxillin tyrosine phosphorylation, phosphorylation of MEK at Ser-217/Ser-221, formation of FAK-Src complex and NF-κB activation. In addition, CIV induced the expression and activation of MMP-9. Treatment with the Src kinase inhibitor PP-2 inhibited MMP-9 activity. In contrast, treatment with EGFR inhibitor AG-1478 did not inhibit MMP-9 activation.**Conclusions.** These findings demonstrate that CIV induces activation of diverse intracellular signaling molecules, including FAK, Src, MEK, the transcription factor NF-κB and the expression and activation of MMP-9. We suggest that these signaling molecules are modulating the expression of MMP-9, and then they are playing an important role in the migration/invasion process.

**Inhibition of Cell Spreading and MMP-9 Expression by the IFN-induced Large GTPase, mGBP-2, Does Not Require GTPase Activity**

S. Balasubramanian, D. J. Vestal; Biological Sciences, University of Toledo, Toledo, OH

Among the many consequences of exposure to interferons (IFNs) are changes in how cells interact with their extracellular environment. IFNs do this, primarily, by modulating the expression of a wide variety of gene products. One family of gene products that contains members that are down-regulated by IFNs is the matrix metalloproteinase family, in particular MMP-1, MMP-2, and MMP-9. We demonstrate that IFN-γ treatment of NIH 3T3 cells retards their ability to spread on fibronectin. This inhibition is accompanied by reduced expression of MMP-9. Ectopic expression of the IFN-induced GTPase, mGBP-2, is sufficient to mimic this inhibition of cell spreading. Forced expression of mGBP-2 is also sufficient to down-regulate MMP-9 expression in these cells. Restoration of MMP-9 by ectopic expression is able to rescue the defect in cell spreading. To determine which region(s) of mGBP-2 was required to inhibit cell spreading, a variety of point mutations and truncations were generated for mGBP-2. The carboxy terminal region, containing α-helices 6 through 13 but lacking the amino terminal GTP binding domain, was sufficient to inhibit cell spreading. While GTPase activity was not required, the addition of the geranylgeranyl isoprenoid to the carboxy terminus was required to inhibit

cell spreading. A single amino acid change in the CaaX motif of mGBP-2 that prevents lipid addition abolished inhibition of cell spreading. Taken together we have demonstrated a mechanism for IFN-γ-mediated changes in cell interaction with fibronectin that begins with the transcriptional induction of mGBP-2 and proceeds through the mGBP-2-mediated inhibition of MMP-9 expression. Work is currently underway to identify the mechanism(s) by which mGBP-2 inhibits MMP-9 expression.

**Synatxin 6, Vamp4, and Vti1b Complex Regulates MMP-9 Secretion during the Invasion of Breast Cancer Cells**

J. Jing,[1] A. A. Peden,[2] R. Prekeris[1]; [1]Cellular and Developmental Biology, UCHSC, Aurora, CO, [2]Wellcome Trust/MRC Building, Cambridge Institute for Medical Research, Cambridge, United Kingdom

Matrix metalloproteinases (MMPs) are family of endopeptidases that capable of cleaving extracellular matrix (ECM) molecules. The degradation of ECM plays an important role in regulation of cell motility and metastasis. MMP-9 is the members of gelatinase sub-family and mainly hydrolyze the components of basement membrane, such as gelatin and collagen type IV. MMP-9 is secreted by tumor, immune, and stroma cells, and is known for its role in tumor growth and metastasis. However, while the transcriptional regulation and activation of MMP-2 and MMP-9 are well understood, we know little about the mechanisms of their secretion. Several protein families , including SNAREs, have emerged as key regulators of protein secretion. SNARE proteins are divided in two subfamilies, VAMPs (also known as R-SNARE) and syntaxins (also known as Q-SNARE). The formation of stable core protein complex between VAMP and syntaxins was shown to be required for membrane fusion and specificity of protein secretion. Here we use siRNA-based screen to identify the SNARE proteins that mediate MMP-9 secretion. From all SNAREs tested only syntaxin 6 and VAMP4 inhibited MMP-9 secretion from MDA-MB-231 breast cancer cells. Using immunoprecipitation approaches we have shown that in MDA-MB-231 cells syntaxin 6 and VAMP4 form a protein complex, which includes Vti1B, another member of SNARE protein family. We also used zymopraphy in situ to show that syntaxin 6, VAMP4, and Vti1B complex is required for MMP-9 dependent gelatin degradation. Finally, we demonstrate that syntaxin 6 or VAMP4 down-regulation inhibits MDA-MB-231 cell invasion, while having minimal effect on cell motility. Thus, we propose that VAMP4, synatxin 6 and Vti1B sore complex is required for the fusion of MMP-9 transport vesicles with plasma membrane and subsequent secretion of MMP-9 to exrtracellula space.

**MMP-3-induces Epithelial-mesenchymal Transition by Stimulating the Expression of the Splice Variant Rac1b**

D. C. Radisky,[1] D. D. Levy,[1] L. E. Littlepage,[2] H. Liu,[1] C. M. Nelson,[1] J. E. Fata,[1] D. Leake,[3] E. L. Godden,[3] D. G. Albertson,[2] M. Nieto,[4] Z. Werb,[2] M. J. Bissell[1]; [1]Lawrence Berkeley National Laboratory, Berkeley, CA, [2]University of California, San Francisco, San Francisco, CA, [3]Dharmacon, Inc., Lafayette, CO, [4]Instituto de Neurociencias de Alicante, San Juan de Alicante, Spain

We have previously investigated stromelysin-1/matrix metalloproteinase-3 (MMP-3), a stromal enzyme upregulated in many breast tumors, and found that MMP-3 can cause epithelial-mesenchymal transition (EMT) and malignant transformation in cultured cells. We have now identified the molecular pathways by which MMP-3 exerts these effects. We show that exposure of mouse mammary epithelial cells to MMP-3 leads to induction of a highly activated splice isoform of Rac1 known as Rac1b, and that expression of this protein stimulates increased mitochondrial production of reactive oxygen species (ROS). We find that the Rac1b-induced ROS are necessary and sufficient to stimulate expression of the transcription factor Snail and to induce EMT. Analysis of response to TGFbeta in this model system reveals that the EMT programs triggered by MMP-3 and TGFbeta are fundamentally and functionally distinct. These findings identify a novel pathway in which a component of the breast tumor microenvironment alters cellular structure in culture and tissue structure in vivo, leading to abberant cellular motility and malignant transformation.

**The Matrix Metalloproteinase, MMP-3, Mediates Rapid Membrane Blebbing in Human Breast Epithelial Cells**

J. E. Fata,[1] Z. Werb,[2] M. J. Bissell[1]; [1]Life Sciences Division, Lawrence Berkeley National Lab, Berkeley, CA, [2]Dept. of Anatomy, University of California, San Francisco, San Francisco, CA

Cell contraction and membrane blebbing are evolutionarily conserved events that occur during the execution phase of apoptosis. Several members of the TNF-ligand superfamily, which are associated with the promotion of a number of pathological processes, including inflammation and cancer are also capable of inducing membrane blebbing in some cell types. The majority of these ligands are transmembrane bound but can be shed from the cell surface through proteolytic processing where soluble ligands can act as antagonists, as in the case of FAS ligand, or agonists, as seen with TNF-alpha. Here we provide evidence that the matrix metalloproteinase, MMP-3/stromelysin-1 induces rapid membrane blebbing in serum starved or cyclohexamide-treated MCF10A human breast epithelial cells. MMP-3-mediated membrane blebbing is associated with reorganization of the actin cytoskeleton, upregulation of both p53 and p38 MAP kinase activity, and loss of cell surface E-cadherin. A broad-spectrum MMP inhibitor completely abolishes these reactions. To understand the signalling cascade initiated by MMP-3, we asked whether factors down-stream of TNF-superfamily signalling were involved. We show that inhibitors against JNK and caspase-3, and RNAi reduction of MKK7, a known activator of JNK inhibit membrane blebbing. Moreover, stable expression of a dominant negative FADD (dnFADD), a downstream effector of several TNF superfamily ligands, renders MCF10A cells resistant to membrane blebbing. Together these findings indicate that MMP-3 induces cell membrane blebbing through a TNF-superfamily signalling pathway and provides an impetus to further explore this protease in inflammation and cancer. J.E.F. (jefata@lbl.gov) is supported by the Dept. of Defence BCRP (DAMD17-03-1-0486). This work was also partially supported by the Dept. of Energy to M.J.B. (DE AC03 76SF00098).

**Overexpression of MMP-16 in *Xenopus* Causes Defects in Morphogenetic Movements During Gastrulation**

L. A. Walsh, S. Damjanovski; Biology, University of Western Ontario, London, ON, Canada

Matrix metalloproteinases (MMPs) are a family of highly homologous endopeptidases that cleave and remodel the extracellular matrix (ECM). Degradation of the ECM and the basement membrane is a critical component of tumor invasion and metastasis. Recently, there has been compelling evidence suggesting MMP-2 specifically can be correlated with the metastatic potential of many tumors. Once activated by other

proteases such as MMP-16, MMP-2 cleaves a broad spectrum of ECM constituents. Little is known however, about how these enzymes function during development when ECM remodeling is high. The overexpression of MMP-16 and the *in vivo* activation of MMP-2 were examined during *Xenopus* laevis development. Embryonic stage 1 embryos microinjected with MMP-16 mRNA show dose-dependant defects in blastopore closure during gastrulation. Phenotypic effects at stage 25 range from a shortened axis to severe defects in morphology. Histological sections of stage 25 embryos revealed the presence of all major tissue types. Somites however, appeared misaligned. This in part may contribute to the observed axis defects. Overexpression of MMP-16 did not affect marker gene expression in notochord, neural, endodermal and muscle tissues, suggesting phenotypes were not due to changes in cell fate specification but rather changes in morphogenic movements during gastrulation. Zymography confirmed the overexpression of MMP-16 mRNA resulted in increased gelatinase activity which suggests increased activation of MMP-2. Here we show that activation of MMP-2 can result in phenotype defects when upregulated. We also show that although the balance of MMP activity may not directly affect cell fate specification, it is still critical to ensure proper morphogenetic movements in *Xenopus* development.

**Microenvironmental Regulators of Metastasis: Role of Matrix- and Mechanotransduction in Control of MT1-MMP Expression**

M. Barbolina,[1] E. Ariztia,[2] M. S. Stack[1]; [1]Cell and Molecular Biology, Northwestern University, Chicago, IL, [2]Obstetrics and Gynecology, New York University Medical Center, New York, NY

Epithelial ovarian carcinoma is the leading cause of death from gynecologic malignancy. Due to difficulties diagnosing ovarian cancer in early stages, most patients present when metastasis had already occurred. Thus, it is important to understand mechanisms of invasion and develop strategies to prevent tumor cells from spreading. The metastatic phenotype is characterized by disruption of cell-cell contacts and loss of extracellular matrix (ECM) constraints due to upregulation of ECM-degrading matrix metalloproteinases (MMP) and alterations in matrix- and mechano-transduction. We previously showed that metastatic ovarian cancer cells interact with interstitial collagens via α2β1- and α3β1-integrins, resulting in increased expression of membrane type 1-MMP (MT1-MMP). The goal of our research was to establish the role of epigenetic factors, particularly matrix status, in the transcriptional regulation MT1-MMP. We used real-time RT-PCR, western blotting and zymography to monitor changes in MT1-MMP and MMP2 levels in ovarian cancer cell lines cultured a) on 2D vs 3D collagen I; b) in a synthetic 3D Hydrogel (BD PuraMatrix); c) under conditions of static strain. Our results indicate an upregulation of MT1-MMP protein and activity following 3D collagen culture or static strain. Corresponding to the increased protein levels, an 8-fold increase in MT1-MMP mRNA was detected following 4 h of collagen culture using RT-RT-PCR. Upregulation of the transcription factors Egr-1 and -2 (20- and 3-fold, respectively) was observed at 2 h of collagen culture, suggesting that these factors participate in transcriptional control of MT1-MMP. These data implicate signal transduction through collagen binding integrins in control of MT1-MMP expression. As we have previously demonstrated that MT1-MMP co-localizes with α2β1 and α3β1 integrins at the cell-matrix interface, these results provide additional data in support of the hypothesis that matrix status influences matrix degrading potential.

2581

**Transforming Growth Factor-β Induces CD44 Cleavage that Promotes Breast Tumor Cell Migration by Up-regulation of MT1-MMP**

Y. Guo,[1] C. Su,[2] H. Wang[1]; [1]Department of Anatomy, Yang-Ming University, Taipei, Taiwan Republic of China, [2]Department of Surgery, Veterans General Hospital, Taipei, Taiwan Republic of China

Transforming growth factor-β (TGF-β), a multifunctional cytokine, is involved in cell proliferation, differentiation, migration, and pathological processes. CD44, a transmembrane receptor for hyaluronic acid (HA), is implicated in various adhesion-dependent cellular processes including cell migration, tumor cell metastasis and invasion. Recent studies have shown that CD44 expressed in cancer cells can be proteolytically cleaved at the ectodomain by the membrane type I matrix metalloproteinase (MT1-MMP), and that CD44 cleavage plays a critical role in cancer cell migration. Here, we demonstrated that TGF-β increases smad2/smad3 phosphorylation and MT1-MMP production in breast tumor cells. Treatment with cycloheximide, an inhibitor of translation, significantly reduced MT1-MMP production. These results suggested that TGF-β has the ability to induce MT1-MMP expression, and this pathway is through phosphorylated smad2/smad3 entering the nucleus to regulate gene transcription of MT1-MMP. Moreover, the induction of MT1-MMP expression by TGF-β is blocked by the specific extracellular regulated kinase-1/2 (ERK1/2) inhibitor PD98059 and by specific phosphoinositide 3-OH kinase (PI3K) inhibitor LY294002. We also found that treatment with SP600125, an inhibitor for c-Jun NH2-terminal kinase (JNK), resulted in a significant inhibition of MT1-MMP production. In contrast, the p38 MAP kinase inhibitor, SB203580, had no significant effect on MT1-MMP production. These data indicated that PI3K, ERK1/2, and JNK are also involved in TGF-β-induced MT1-MMP expression. Furthermore, TGF-β induced MT1-MMP is also able to cleave CD44 and this might promote tumor cell migration resulting in enhanced metastasis.

2582

**A Role of Transmembrane Domain of Tumor Necrosis Factor-α Converting Enzyme (TACE) in Ectodomain Shedding**

X. Li, H. Fan; Physiology, UMDNJ-RWJMS, Piscataway, NJ

TACE is a membrane-anchored metalloprotease that is essential for development and disease. TACE catalyzes regulated release of soluble growth factors and cytokines from their transmembrane precursors. It also cleaves growth factor/cytokine receptors. The primary sequence of TACE consists of an amino-terminal prodomain, a zinc metalloprotease domain, a cysteine-rich/disintegrin domain (CRD), a transmembrane domain (TM) and a cytoplasmic domain. The prodomain inhibits the protease activity by interacting with the enzyme's catalytic center, and is removed in the secretion pathway. We are interested in possible regulatory activities in other noncatalytic domains of TACE. Using transmembrane transforming growth factor-α (TGF-α) as a model substrate, we have previously shown that the cytoplasmic domain is dispensable for TGF-α release from the cell surface, even though the cytoplasmic domain undergoes regulated phosphorylation. In contrast, a point mutation (C600Y) in CRD resulted in complete inactivation of enzyme activity, suggesting an interaction between CRD and the metalloprotease domain. The objective of this current study is to evaluate the role of the TACE TM in ectodomain cleavage. We have substituted the TACE TM with the TMs of prolactin receptor and platelet-derived growth factor receptor. Transfection experiments showed that the chimeric TACE constructs, similar to wild type TACE, were processed to mature form located at the cell surface. However, the chimeras are severely defective in TGF-α cleavage. These results suggest that the TACE TM plays a regulatory role in ectodomain cleavage.

2583

### Comparative Localisation of Angiotensin-Converting Enzymes in Polarised Kidney Cells

F. J. Warner,[1] D. W. Lambert,[2] R. A. Lew,[1] A. I. Smith,[1] N. M. Hooper,[2] A. J. Turner[2]; [1]Biochemistry and Molecular Biology, Monash University, Clayton, Australia, [2]Biochemistry and Microbiology, University of Leeds, Leeds, United Kingdom

Angiotensin converting enzyme (ACE) is a zinc metallopeptidase, which functions as a key regulator of the renin-angiotensin system. ACE2, a homologue of ACE, is an 805 amino acid, type I integral membrane protein, abundant in human heart and kidney. Whilst ACE2 shares ~41% sequence identity to somatic ACE[1] and has the same membrane topology, it has a different catalytic action and different substrates to ACE. The cellular localisation and targeting of ACE2 has not been investigated. ACE2 and ACE were stably transfected into CHO cells and the polarised Madin-Darby canine kidney type II (MDCKII) cell and studied in parallel. In CHO cells, ACE2 and ACE were localised to the cell surface by indirect immunofluorescence. Both proteins expressed in CHO cells were soluble in Triton-X-100 at 4C when separated by sucrose density gradient centrifugation and were not associated with lipid rafts found in detergent-insoluble glycolipid-enriched fractions of cell membrane. In polarised MDCKII cells under steady-state conditions, ACE2 was observed predominantly at the apical surface by cell-surface biotinylation, and immunofluorescence studies. Comparatively, ACE was present on both the apical (45%) and basolateral membranes (55%). Soluble forms of ACE2 and ACE were detected in the medium taken from MDCKII cells by enzyme assays, suggesting ACE2, like ACE, is shed from the cell surface. ACE2 is shed apically, whereas ACE is shed from both surfaces. The level of ACE shed from the apical surface was 2.5-fold higher than that from the basolateral surface after 6 h. This study has demonstrated ACE2 and ACE are cell surface proteins that have distinct localisation patterns, that may determine their roles as ectoenzymes at the cell surfaces of polarised kidney epithelium and the dynamics of the renal renin-angiotensin system. 1. Tipnis S.R. et al. (2000) J. Biol. Chem 275:33238

## Tight Junctions (2584-2604)

2584

### A Role for JAM-A in the Development of Hepatic Polarity

L. T. Braiterman,[1] S. Heffernan,[1] A. Sharma,[1] M. Herman,[1] A. Khalsa,[1] U. Naik,[2] A. L. Hubbard[1]; [1]Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, [2]Biological Sciences, University of Delaware, Wilmington, DE

The WIF-B cell is a well-characterized, polarized rat-human hybrid line with properties similar to hepatocytes *in vivo*. The presence of apical "cysts" that are sealed by functional tight junctions (TJ) between adjacent cells is a hallmark of the mature WIF-B hepatic phenotype. Development of this phenotype is biphasic over 14 days in culture: cells first exhibit a simple columnar epithelial morphology with TJ proteins forming a belt around the cell apex (~6-9 d); later, cells exhibit the hepatic phenotype where TJ proteins form a belt around the apical cyst (~9-14 d). Our current goal is to determine the functional relevance of junctional adhesion molecule (JAM) in the phenotypic switch. By RT-PCR, we determined that JAM-A, B and C are expressed in rat liver hepatocytes while only JAM-A is expressed in WIF-B cells. Therefore, day 9 WIF-B cells were infected with recombinant adenovirus encoding human wild-type (wt) JAM or mutant JAM-A and analyzed 4 days later. Cells over-expressing wtJAM-A exhibited the hepatic phenotype to a much lesser extent than those over-expressing a mutant JAM-A that lacked its PDZ binding motif (4 C-terminal residues). Interestingly, both exogenous JAM-A proteins were found at cell-cell contact sites. While neither E-cadherin nor occludin colocalized with either over-expressed JAM-A, ZO-1 co-localized with wtJAM-A to a greater extent than with mutant JAM-A at these sites. Our data suggest that JAM-A may play a role in the development of hepatic polarity. We are currently assessing the effects of the two JAM-A proteins on 6-10 day WIF-B cells and Caco-2 cells, where the simple epithelial cell morphology predominates.

2585

### Regulation of Epithelial Tight Junction Assembly by AMP-activated Protein Kinase

B. Zheng, L. C. Cantley; Division of Signal Transduction, Beth Israel Deaconess Medical Center and Department of Systems Biology, Harvard Medical School,, Boston, MA

AMP-activated protein kinase (AMPK) is a heterotrimeric serine/therine kinase that plays important roles in maintaining cellular energy balance. The activity of AMPK is modulated both by the cellular AMP to ATP ratio and by upstream kinases. Upon activation, AMPK increases energy supply by stimulating ATP-producing pathways and inhibiting ATP-consuming pathways. Recently, one of the AMPK upstream kinases was identified as LKB1, a homolog of C. elegans and Drosphila Par-4 proteins that are essential to the establishment of cell polarity during embryogenesis. Here we have used MDCK epithelial cells as a model system to investigate whether AMPK, as a substrate of LKB1, plays a role in the regulation of epithelial polarization. We found that AICAR, an activator of AMPK, promoted the assembly of tight junctions as indicated by measurement of trans-epithelial resistance (TER) and immunofluorescence analysis of ZO-1 translocation after calcium switch. Expression of a kinase-dead mutant of AMPK (D157A) inhibited the development of TER and Zo-1 translocation after calcium switch. Furthermore, the levels of AMPK phosphorylation (T172) increased during calcium-induced cell polarization, and this increase was dependent on the kinase activity of LKB1, because expression of a LKB1 kinase dead mutant (K78I) but not the wild-type abolished the increase of phospho-AMPK level. These results together support a role of AMPK in the regulation of epithelial tight junction assembly, and provide an intriguing link between cellular energy status and tight junction assembly in epithelial cells.

2586

### Activation of AMPK is Associated with Tight Junction Formation and Maintenance of Epithelial Polarity

L. Zhang,[1] J. Li,[2] L. H. Young,[2] M. J. Caplan[1,3]; [1]Department of Cell Biology, Yale University School of Medicine, New Haven, CT, [2]Department of Internal Medicine (Section of Cardiovascular Medicine), Yale University School of Medicine, New Haven, CT, [3]Department of Cellular and Molecular Physiology, Yale University School of Medicine, New Haven, CT

AMP activated protein kinase (AMPK), known as a sensor of cellular energy status, is a substrate for LKB1, a kinase capable of polarizing single intestinal epithelial cells. However, it is not clear whether AMPK is also involved in epithelial cell polarization. Using an antibody specific for phospho-Thr172-AMPK, the phosphorylation of AMPK was found to increase 3-fold when MDCK cells regenerate polarity after being depolarized by $Ca^{2+}$ depletion. In repolarizing MDCK cells, 5-aminoimidazole-4-carboxamide ribonucleoside (AICAR), which makes AMPK a

better substrate for LKB1, facilitates tight junction organization under conditions of normal $Ca^{2+}$ concentration, and initiates tight junction assembly in the absence of $Ca^{2+}$. Specifically, under conditions of normal $Ca^{2+}$ concentration, the recruitment of ZO-1, a tight junction protein, to the tight junction region, is faster in the presence of AICAR. In the absence of $Ca^{2+}$, a slow but detectable ZO-1 recruitment to the tight junction region could be observed in the presence, but not in the absence, of AICAR. The activation of AMPK appears to protect epithelial cells at least in part from losing polarity under conditions of energy depletion. The internalization of a basolateral marker Na, K-ATPase could not be detected in the MDCK cells pretreated with AICAR prior to energy depletion induced by 2-deoxy-D-glucose; however, a considerable amount of Na, K-ATPase was internalized in cells that were not pretreated with AICAR before the energy depletion. Taken together, these results suggest that AMPK may contribute to the regulation of epithelial cell polarity.

**PKCζ Activity is Essential for the Establishment of Cell Polarity during the Assembly of Mammary Epithelial 3D- Acini**

L. Thornton, E. McArdle, E. Gilligan, J. Murtagh, F. Martin; Conway Institute for Biomolecular and Biomedical Research, University College Dublin, Ireland

Dispersed primary mouse mammary epithelial cells organize as spherical acini when grown on a laminin-rich ECM. It has been demonstrated that acinus formation begins with the apicobasal polarization of the outer cells of the assembly and subsequent to this, follows cell cycle withdrawal and loss of the internal cells by apoptosis. We have shown that JNK activity is necessary for the establishment of cell polarity and functional acinus formation. We have now investigated the downstream targets of JNK that contribute to the polarisation of the cells in the acini. It is proposed that polarization in an epithelial sheet is established by the generation of an active ternary signaling complex consisting of the atypical PKCζ and two PDZ domain proteins, Par3 and Par6 with resultant activation of PKCζ. We demonstrate that PKCζ is phosphorylated (at Thr410) and active in the early stages of acinus formation in a JNK-dependent fashion. In addition, inhibition of PKCζ activity was sufficient to disrupt the assembly of properly polarized acini. We also show that phospho-[Thr410]-PKCζ distributes with ZO-1 to tight junction sites and is in a complex with Par3 and Par6 in maturing acini; these events can be disrupted by JNK inhibition. In contrast to phospho-PKCζ, the main cellular PKCζ component distributes to a perinuclear location as acini form but this is also dependent on the correct establishment of cell polarity. Furthermore, we show that Par3 co-localises with phospho-PKCζ and ZO-1 to areas of tight junction formation. Finally, we demonstrate that PKCζ activation lies downstream of JNK activation; we therefore propose that JNK activity underpins key molecular events leading to the activation of PKCζ, which is necessary for cell polarisation, a determining event in mammary epithelial acinus assembly.

**A Beta Subunit Specific, Ion-transport Independent Function of the Na,K-atpase is Required for Barrier Junction Formation and Epithelial Morphogenesis in the *Drosophila* Tracheal System**

S. M. Paul, Z. Liang, G. J. Beitel; BMBCB, Northwestern University, Evanston, IL

Although epithelial tubes are essential for the functions of many vertebrate and invertebrate organs, the cellular and molecular mechanisms that control the sizes and shapes of epithelial tubes are poorly understood. Using the Drosophila tracheal (airway) system as a model, we previously demonstrated that the occluding junction in flies, the septate junction (SJ), plays a critical role in epithelial tube size regulation. Mutations in SJ components cause tracheal tubes to become too long and have diameter abnormalities. Importantly, the occluding function of SJ was separable from its tube-size control function. We also unexpectedly found that the Na,K-ATPase localizes to and is required for normal tube-size control and for SJ formation. We now show that the canonical ion pump function of Na,K-ATPase is dispensable for tube-size control and junction formation, thus revealing a novel ion-transport independent function of the Na,K-ATPase. This ion-transport independent activity appears to reside with the beta subunit of the Na,K-ATPase complex since all alpha subunit isoforms tested have tube-size and septate junction activity, but only one of the three beta subunit loci in the Drosophila genome, nrv2, is necessary and sufficient for tube-size control and SJ formation. Chimera analysis between nrv2 and another Na,K-ATPase beta subunit reveals that the unique tube-size and junctional activity localizes to the extracellular domain of nrv2. We will discuss models for the role of Na,K-ATPase in junction formation and of SJs in epithelial morphogenesis, as well as possible evolutionary conservation of these mechanisms.

**Na,K-ATPase is a Novel Member of the Apical Junctional Complex**

S. A. Rajasekaran,[1] S. P. Barwe,[1] S. Ryazantsev,[2] E. E. Schneeberger,[3] A. K. Rajasekaran[1]; [1]Pathology and Laboratory Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA, [2]Biological Chemistry, University of California, Los Angeles, Los Angeles, CA, [3]Molecular Pathology Unit, Massachusetts General Hospital East, Charlestown, MA

Polarized epithelial cells form a permeability barrier between two biological compartments and have a unique structural organization with distinct apical and basolateral plasma membranes separated by tight junctions. Tight junctions not only give rise to the polarized distribution of receptors, ion channels, transporters and pumps, but also regulate the paracellular solute and water flux. They are multiprotein complexes composed of transmembrane proteins that are linked to the actin cytoskeleton through plaque proteins that also serve as adapters for the recruitment of cytosolic signaling molecules to integrate diverse processes such as cell polarity, cell proliferation, and tumor suppression. Na,K-ATPase is a transmembrane protein consisting of a non-covalently linked α- and β-subunit and catalyses an ATP-dependent transport of three sodium ions out and two potassium ions into the cell per pump cycle, thereby generating a transmembrane sodium gradient across the plasma membrane. More recent evidence suggests that Na,K-ATPase also plays a role in a variety of signaling processes in epithelial cells. In a series of earlier studies we have shown that Na,K-ATPase function is necessary to form and maintain functional tight junctions. We now provide evidence that Na,K-ATPase is localized to tight junctions and is in a complex containing PP2A, annexin II and occludin. The enzyme activity of Na,K-ATPase modulates this complex formation in polarized epithelial cells. Together these results suggest that Na,K-ATPase, PP2A, annexin II and occludin form a novel apical junctional complex involved in the regulation of tight junction permeability in epithelial cells.

**The Coxsackie and Adenovirus Receptor (CAR) is an In Vivo Marker for Epithelial Tight Junctions, Potentially Regulating Permeability**

**and Tissue Homeostasis**

E. Raschperger,[1] J. Thyberg,[2] S. Pettersson,[3] J. Fuxe,[4] R. F. Pettersson[1]; [1]Ludwig Institute for Cancer Research, Karolinska Institute, Stockholm, Sweden, [2]Department of Cell and Molecular Biology (CMB), Karolinska Institute, Stockholm, Sweden, [3]Microbiology and Tumor Biology Center (MTC), Karolinska Institute, Stockholm, Sweden, [4]Cardiovascular Research Institute, University of California, San Francisco (UCSF), San Francisco, CA

Cell adhesion molecules are components of epithelial and endothelial tight junctions, a complex membrane structure that is important for paracellular barrier function and cell polarity. One such component is CAR, a transmembrane protein and a member of the CTX family of Immunoglobulin Superfamily (IgSF) molecules. The role of CAR as a virus receptor has been extensively explored in various adenovirus-based gene transfer/therapy studies but its physiological role, however, has remained less clear. CAR associates with tight junctions in cultured epithelial cells and mediates cell-cell adhesion, and during development, CAR has been shown to be essential for normal cell differentiation and tissue maturation. Here we show that CAR is exclusively expressed in epithelial cells lining the body cavities, such as the gastrointestinal tract, the respiratory system, the bile ducts, the urinary system etc. In all tissues examined, CAR specifically co-localized with the tight junction markers ZO-1 and occludin. No CAR expression was detected in the vasculature, not even in brain capillaries, where endothelial tight junctions are well developed and form the blood brain barrier. A mutant form of CAR, lacking the intracellular tail, was mislocalized in cells when transgenically expressed in mice. Instead of being targeted to tight junctions this mutant CAR protein was diffusely localized over the plasma membrane, confirming the importance of the cytoplasmic portion of CAR for its correct localization and function. Moreover, the expression pattern of CAR in different epithelial cell layers correlated positively with the degree of tight junction maturity and inversely with permeability. Thus, we conclude that CAR, in adult tissues, restrictively localizes to epithelial tight junctions where it may participate in the regulation of epithelial permeability and tissue homeostasis.

**Occludin Phosphorylation and Regulation of Vascular Permeability**

J. M. Sundstrom,[1] B. A. Stanley,[2] D. A. Antonetti[1]; [1]Cell and Molecular Physiology, Penn State College of Medicine, Hershey, PA, [2]Section of Research Resources, Penn State College of Medicine, Hershey, PA

**Objective:** Our objective is to better understand the mechanisms which modulate vascular permeability in health and disease. Recent research has begun to define the molecular mechanisms in diabetic retinopathy which lead to enhanced vascular permeability. VEGF is elevated in the eye in diabetes and acts through protein kinase C to cause the phosphorylation of a transmembrane tight junction protein, occludin, on multiple sites. Preventing this phosphorylation with PKC inhibitors reduces VEGF induced vascular permeability. Therefore, mapping these phosphorylation sites is a critical step in understanding the pathophysiology of increased vascular permeability in diabetic retinopathy. **Methods**: Bovine retinal endothelial cells (BREC) were treated with VEGF for 15min, occludin was immunoprecipitated and separated by SDS-PAGE. Occludin bands were excised, digested with trypsin, and analyzed by MALDI TOF mass spectrometry to identify sites of occludin phosphorylation. Phosphopeptides were identified based on mass accuracy, repeat observations, identification in multiple overlapping fragments, presence in VEGF treated and gel shifted (hyperphosphorylated) occludin bands. Finally, conservation of serine and threonine residues and kinase consensus motifs were used to identify potential phosphorylated residues. **Results**: Six putative phosphopeptides were identified within occludin. This data led to the successful creation of a phospho-specific antibody to Ser490. Immunoblotting and immunocytochemistry experiments have confirmed that Ser490 is phosphorylated in vivo and that VEGF stimulation of BREC increase Ser490 phosphorylation. **Conclusion**: To our knowledge, this is the first demonstration of site specific occludin phosphorylation within cells and provides further evidence that occludin phosphorylation is associated with alterations in vascular permeabilily. Ser 490 is located within the cytoplasmic coiled-coil domain of occludin known to interact with ZO-1 and phosphorylation of this site may alter this interaction. Future experiments, including mutational analysis, will identify the funcitonal significance of occludin phosphorylation.

**Glucocorticoids Increase Barrier Properties of Retinal Endothelial Cells Through Transactivation of Tight Junction Genes**

E. A. Felinski, D. A. Antonetti; Cellular & Molecular Physiology, Penn State College of Medicine, Hershey, PA

Tight junctions provide the barrier between adjacent epithelial and endothelial cells that allows compartmentalization of tissues. In brain and retina, tight junctions between endothelial cells of blood vessels create the blood-brain and blood-retinal barrier. Breakdown of the retinal tight junction complex, and formation of leaky blood vessels, is problematic in several disease states including diabetic retinopathy. Glucocorticoids have been shown to restore and/or preserve the endothelial barrier to paracellular flux, although the mechanism remains unclear. Previous work has shown an increase in content of the tight junction protein occludin in cultured bovine retinal endothelial cells upon glucocorticoid treatment, co-incident with an increase in the barrier properties of cell monolayers. The objective of this study was to determine the mechanism by which glucocorticoids induce the expression of endothelial tight junction proteins. Glucocorticoids increased the expression of endothelial caludin-5 as well as occludin, decreased the expression of claudin-1 and did not change the content of ZO-1. Glucocorticoids increased the promoter activity of the occludin and claudin-5 genes in primary retinal endothelial cells using luciferase reporter constructs for each promoter. The glucocorticoid-mediated increase in occludin protein content and endothelial barrier properties was reversed with both the chemical glucocorticoid receptor (GR) antagonist RU486 and siRNA specific for GR. The GC responsive element has been mapped to a 450 bp occludin promoter fragment and neither this sequence nor the claudin-5 promoter contains a canonical glucocorticoid response element (GRE). These data suggest a mechanism for glucocorticoid induction of vascular endothelial barrier properties that involves up regulation of the genes for transmembrane tight junction proteins occludin and claudin-5 and that the GR is required for this process possibly functioning through the stimulation of a transacting factor that directs occludin and claudin-5 gene transcription.

**Side-by-side and Head-to-head Interaction of Claudin-5 in *Vitro* and in *Vivo***

I. E. Blasig,[1] L. Winkler,[1] N. Zuleger,[1] M. S. Bal,[1] H. Wolburg,[2] G. Krause,[3] K. Gast,[4] J. Piontek[1]; [1]Signal Transduktion, Forschungsinstitut für molekulare Pharmakologie, Berlin, Germany, [2]University Tuebingen, Tuebingen, Germany, [3]Forschungsinstitut für molekulare Pharmakologie,

Berlin, Germany, [4]University Potsdam, Potsdam, Germany
Claudin-5 is known to tighten the paracellular cleft of brain capillary endothelial cells against solutes ≤800 Da and, hence, the blood-brain barrier (BBB). However, the interaction mechanism is unknown and was studied in this investigation. The recombinant segment of the second extracellular loop (2ECL) was detected as dimer by size-exclusion chromatography. The dimer is concentration dependent and sensitive to arginine. Thus, occludin may self-associate via itsthe second extracellular loop may contribute to claudin-5 self-association. We hypothesize that, in the BBB, the dimerization is involved in the attraction of the cell membranes of two adjacent cells (head-to-head interaction) and/or in the strand formation within the cell membrane of one cell (side-by-side interaction). To study the 'side-by-side' hypothesis tight junction-free HEK cells were cotransfected with the fluorescent fusion proteins claudin-5-CFP and claudin-5-YFP. Fluorescence resonance energy transfer (FRET) between the fluorophores demonstrated 'side-by-side' interaction. The FRET signal was not prevented by the mutations of the 2ECL tested so far which would not support 'side-by-side' association of claudin-5 via its 2ECL. Coimmunostaining of mixed cultures of claudin-5-FLAG and claudin-5-YFP showed enrichment of the staining in cell-cell contact areas which was abolished after mutations within the 2ECL. The latter finding indicates that the 2ECL of claudin-5 might contribute to the 'head-to-head' association of claudin-5 between the cells and, consequently, to the paracellular tightness. In general the results makes a contribution to a better understanding of the molecular structure and function of the major tightening protein of the BBB claudin-5.

2594

**Extracellular Domains of Claudin-7 Affect the Paracellular Chloride Conductance in LLC-PK1 Cells**

M. Alexandre, Y. H. Chen; Anatomy and Cell Biology, East Carolina University Brody School of Medicine, Greenville, NC
Tight junctions form selective paracellular diffusion barriers regulating the passage of ions and solutes across epithelia. Claudins are the major structural and functional components of tight junctions and are considered the best candidates for forming paracellular channels. Our recent study demonstrated that overexpression of claudin-7 in LLC-PK1 cells affected the ionic charge selectivity through a concurrent decrease in the paracellular conductance to $Cl^-$ and an increase in the paracellular conductance to $Na^+$. To investigate the importance of the extracellular domains of claudin-7 in the paracellular charge selectivity, we created claudin-7 mutants by reversing the negative charge to a positive charge of selected amino acids located on the extracellular domains using the site-directed mutagenesis method. Claudin-7 mutants were expressed in cultured LLC-PK1 cells and assessed for transepithelial electrical resistance (TER) and dilution potentials. Expression and localization of claudin-7 mutants were determined by immunoblotting and immunofluorescence microscopy. Ectopically expressing of claudin-7 mutants did not change the expression and localization of endogenous tight junction proteins. However, TER and dilution potential measurements revealed that the paracellular $Cl^-$ conductance was significantly increased on the cells expressing claudin-7 mutants compared to that of control cells. This result indicates that the extracellular domains of claudin-7 are critical in determining the paracellular $Cl^-$ permeability in kidney epithelial cells.

**Permeability Barrier Dysfunction in Transgenic Mice Overexpressing a Cytoplasmic Tail Deletion Mutant of Claudin 6**

K. Turksen, T. Troy; Ottawa Health Research Institute, Ottawa, ON, Canada
A defective epidermal permeability barrier (EPB) in premature birth remains a leading cause of neonatal death as a result of its associated complications, which include poor temperature stability, infection by microorganisms through the skin and the outflow of water. Recently we defined a crucial role for Claudins (Cldns), a new superfamily of tight junctional molecules, in the formation of the EPB by engineering transgenic mice with Claudin 6 (Cldn6) overexpressed in the suprabasal layers of epidermis via the involucrin (Inv) promoter. Homozygous mice overexpressing Cldn6 exhibit a perturbation in the epidermal differentiation program leading to a defective EPB and dehydration-induced death within 48 h of birth [Turksen, K., Troy, T.C., 2002. Permeability barrier dysfunction in transgenic mice overexpressing Claudin 6. Development 129, 1775-1784]. To further address the role of Cldns in epidermal differentiation and formation of the EPB, we have initiated a structure function analysis by generating a transgenic mouse overexpressing a cytoplasmic tail deletion mutant of Cldn6 under control of the Inv promoter. Like their full length Cln6 overexpressing counterparts, the tail deletion mutant mice are also born with an incomplete EPB; however, barrier dysfunction is less severe with some animals surviving up to ~21 days postnatally. Tail deletion transgenics lack hair and histological analysis shows epidermal hyperproliferation. Epidermal differentiation anomalies and barrier dysfunction were manifested biochemically by the aberrant expression of late epidermal differentiation markers, including K1, filaggrin, loricrin, transglutaminase 3, and involucrin. Also the expression profiles of other Cldns in the epidermis are modified. These results provide new insight into the importance of the cytoplasmic tail of Cldn6 in epithelial differentiation as well as EPB formation and function. Supported by the March of Dimes Birth Defects Foundation (USA).

**Gap Junctional Intercellular Communication Participates in the Barrier Function of Tight Junctions of Brain and Lung Capillary Endothelial Cells**

H. Fujita, H. Chiba, K. Nagasawa, T. Kojima, N. Sawada; Department of Pathology, Sapporo Medical University School of Medicine, Sapporo, Japan
Gap-junction plaques are often observed with tight-junction strands of vascular endothelial cells, but the molecular interaction and functional relationships between these two junctions remain obscure. We herein showed that gap-junction proteins connexin40 (Cx40) and Cx43 were colocalized and coprecipitated with tight-junction molecules occludin, claudin-5 and ZO-1 in porcine blood-brain barrier (BBB) endothelial cells. Blockers of gap junctional intercellular communication (GJIC) 18β-glycyrrhetinic acid and oleamide did not influence expression of Cx40, Cx43, occludin, claudin-5, junctional adhesion molecule (JAM)-A, JAM-B, JAM-C and ZO-1, nor their subcellular localization in the porcine BBB endothelial cells. In contrast, these GJIC blockers inhibited the barrier function of tight junctions in cells, determined by measurement of transendothelial electrical resistance and paracellular flux of mannitol and inulin. 18β-glycyrrhetinic acid also reduced the barrier property in rat lung endothelial cells expressing doxycycline-induced claudin-1, but not changed interaction between Cx43 and either claudin-1 or ZO-1, as well as their expression levels nor subcellular distribution. These finding suggest that signaling molecules passed through Cx40- and/or Cx43-based gap-junction channels promote the endothelial barrier function without altering expression and localization of tight-junction components analyzed.

**Activation of p21$^{CIP1/WAF1}$ Gene Expression and Inhibition of Cell Proliferation by Overexpression of Hepatocyte Nuclear Factor-4α**

N. Sakai, H. Chiba, T. Itoh, M. Osanai, T. Kojima, N. Sawada; Department of Pathology, Sapporo Medical University School of Medicine, Sapporo, Japan

The F9 murine embryonal carcinoma cell line provides an attractive system for studying epithelial differentiation and antiproliferative processes. We have recently established F9 cells expressing doxycycline-inducible hepatocyte nuclear factor (HNF)-4α, and shown that HNF-4α triggers the gene expression of tight-junction molecules, occludin, claudin-6 and claudin-7, as well as formation of functional tight junctions and polarized epithelial morphology (Exp. Cell Res. 286, [2003] 288 ). Since these events were very similar to those induced by retinoids, we investigated whether HNF-4α, like retinoid receptors, was involved in the control of cell proliferation. We herein show that HNF-4α up-regulates expression of the p21 gene, but not the p15, p16, p18, p19 or p27 gene, in a p53-independent manner, and inhibits cell growth in F9 cells. Similar results were observed in rat lung endothelial cells, in which expression of HNF-4α is conditionally induced by doxycycline. Furthermore, we demonstrate, by reporter assay, that HNF-4α significantly elevates the transcriptional activity of the p21 promoter. Since, HNF-4α is expressed not only in the liver but also in organs containing epithelial cells, such as kidney, intestine, pancreas and stomach, it might also play critical roles in the regulation of epithelial morphogenesis and proliferation in these organs.

2598

**Behavior of Tight-Junction, Adherens-Junction and Cell-Polarity Proteins during HNF-4α-Iinduced Epithelial Polarization**

H. Chiba,[1] S. Satohisa,[1] M. Osanai,[1] S. Ohno,[2] T. Kojima,[1] N. Sawada[1]; [1]Department of Pathology, Sapporo Medical University School of Medicine, Sapporo, Japan, [2]Department of Molecular Biology, Yokohama City University School of Medicine, Yokohama, Japan

We previously reported that expression of tight-junction molecules occludin, claudin-6 and claudin-7, as well as establishment of epithelial polarity, was triggered in mouse F9 cells expressing hepatocyte nuclear factor (HNF)-4α. Using these cells, we examined in the present study behavior of tight-junction, adherens-junction and cell-polarity proteins, and elucidated the molecular mechanism behind HNF-4α-initiated junction formation and epithelial polarization. We herein show that not only ZO-1 and ZO-2, but also ZO-3, junctional adhesion molecule (JAM)-B, JAM-C and cell-polarity proteins PAR-3, PAR-6 and atypical protein kinase C (aPKC) accumulate at primordial adherens junctions in undifferentiated F9 cells. In contrast, CRB3, Pals1 and PATJ appeared to exhibit distinct subcellular localization in immature cells. Induced expression of HNF-4α led to translocation of these tight-junction and cell-polarity proteins to beltlike tight junctions, where occludin, claudin-6 and claudin-7 were assembled, in differentiated cells. Interestingly, PAR-6, aPKC, CRB3 and Pals1, but not PAR-3 or PATJ, were also concentrated on the apical membranes in differentiated cells. These findings indicate that HNF-4α provokes not only expression of tight-junction adhesion molecules, but also modulation of subcellular distribution of junction and cell-polarity proteins, resulting in junction formation and epithelial polarization.

2599

**Cyclin D1 is Transcriptionally Down-regulated by ZO-2 via an E box**

M. Huerta,[1] B. Muñoz,[1] R. Tapia,[2] L. Gonzalez-Mariscal,[2] E. Lopez-Bayghen[1]; [1]Genetica y Biol. Mol., Cinvestav-IPN, Mexico, Mexico, [2]Fisiología, Biofísica y Neurociencias, Cinvestav-IPN, Mexico, Mexico

ZO-2 is a membrane-associated guanylate kinase (MAGUK) protein present at the tight junction (TJ) of epithelial cells. While confluent monolayers have ZO-2 at their cellular borders, sparse cultures conspicuously show ZO-2 at the nuclei. In accordance with the tumor suppressor role proposed for ZO-2, recent data indicates that cyclin D1 levels are down regulated by ZO-2. Concomitantly a diminishing in cell growth and a cell cycle arrest was observed. We further explore the mechanisms underlying the ability of ZO-2 to modulate cyclin D1 gene transcription. To test if ZO-2 modulates cyclin D1 gene transcription, we co-transfected MDCK cells with full length ZO-2 and a reporter plasmid containing cyclin D1 promoter driving luciferase gene (pXP2-CD1). ZO-2 down regulates cyclin D1 promoter both in sparse and confluent monolayers. We also performed RT-PCR assays to analyze the mRNA cyclin D1 levels in cells that over-expressed ZO-2. The results show ZO-2 diminishes mRNA levels in a dose-dependent manner. Since ZO-2 has several characteristic domains, amino, middle and carboxyl regions were over-expressed, in order to explore their role in cyclin D1 promoter regulation. We observed that the amino fragment is a strong repressor and additionally found that the carboxyl region, which concentrates at the cytoplasm also represses cyclin D1 promoter. Moreover we performed deletion analyses and reporter gene assays employing constructs driven by the cyclin D1 promoter and evaluated its activity under ZO-2 influence. We found that ZO-2 negatively regulates cyclin D1 transcription in a manner dependent on the E box of the cyclin D1 promoter.

**In Epithelial Monolayers the Tight Junction Protein ZO-2 Inhibits Cyclin D1 Expression and Cell Proliferation**

R. Tapia, S. Islas, L. Gonzalez-Mariscal; Physiology, Biophysics and Neuroscience, CINVESTAV, Mexico DF, Mexico

In epithelial MDCK cells, the overexpression of ZO-2 generates a down regulation of cyclin D1 (CD1) protein. Since the latter mediates the progression through G1/S stages of the cell cycle, we analyzed the effect of ZO-2 transfection on monolayers previously synchronized by serum deprivation. In these cells the amount of CD1 protein is higher in sparse than in confluent cultures. A flow cytometric analysis of cells stained with propidium iodide, revealed that the overexpression of ZO-2 induced in synchronized cultures, a blockade at the Go/G1 stage of the cell cycle. Moreover, cells transfected with ZO-2 displayed a significantly lower incorporation of 3H-thymidine, than wild type cells and monolayers transfected with the empty vector. This inhibition of cell proliferation is not accompanied by an increase in apoptosis or necrosis, determined by trypan blue exclusion and an annexin V fluorescence assay. To explore if the degradation of CD1 could be due to an increased degradation of the protein, we evaluated the effect of ZO-2 transfection in cultures treated with the proteosoma inhibitor MG132. In these monolayers we observed no further decrease in CD1 content, thus suggesting that the decreased expression of CD1 generated by ZO-2 overexpression is not related to an increased proteosomal degradation of CD1. Taken together these results suggest that ZO-2 plays a role in cell proliferation by inhibiting CD1 protein expression.

2601

**ZO-2 Downregulation Alters the Gate and Fence Functions of the Tight Junction and Modifies the Monolayer Morphology**

S. Hernandez,[1] B. Chavez,[2] L. Gonzalez-Mariscal[1]; [1]Physiology, Biophysics and Neurociences, CINVESTAV, Mexico DF, Mexico, [2]Experimental Pathology, CINVESTAV, Mexico DF, Mexico

MDCK cells transfected with ZO-2 siRNA, display 45% decrease in ZO-2 mRNA and 65% reduction in ZO-2 protein, with no effect on cell viability or cell proliferation evaluated by trypan blue exclusion and 3H-thymidine incorporation. In these monolayers the expression of the TJ proteins claudin-1 and ZO-1 remained unchanged, while that of occludin diminished by 70%. The culture exhibited a transepithelial electrical resistance similar to that found in control and mock transfected monolayers. In contrast cultures transfected with ZO-2 siRNA showed an increased paracellular flux of 70 kDa dextran, indicating that the gate function of the TJ had been altered. When a fluorescent sphyngolipid was added to the apical surface of the cells, the lipid probe remained at the mucosal side of control and mock transfected cultures. Instead in ZO-2 siRNA treated cells, the fluorescent lipid probe appeared also at the upper portion of the lateral membrane, indicating that the fence function of the TJ had been affected. To further explore the impact of ZO-2 knock down on cell adhesion, the number of cells forming aggregates was observed in a hanging drop assay. ZO-2 siRNA transfected cells displayed a transient decrease in the number of cell aggregates. Semithin sections of ZO-2 siRNA transfected cells showed a profound widening of the intercellular space and frequent growth of cells on top of each other. TEM images reveal the appearance of markedly dilated lateral spaces in ZO-2 siRNA treated cells. Taken together these results indicate that the diminished expression of ZO-2 modifies the gate and fence function of the TJ as well as the monolayer morphology.

2602

**Microtubules Regulate Disassembly of Epithelial Tight and Adherens Junctions**

A. I. Ivanov, I. C. McCall, A. Nusrat, C. A. Parkos; Pathology and Laboratory Medicine, Emory University, Atlanta, GA

Epithelial tight junctions (TJ) and adherens junctions (AJ) regulate cell-cell adhesion, paracellular permeability and cell polarity. TJ and AJ are anchored on cytoskeletal structures such as actin microfilaments and microtubules (MT). While the role of F-actin in junctional biogenesis has been extensively studied, a little is known about the involvement of MT in TJ and AJ formation and disassembly. The role of MT is TJ/AJ disassembly was investigated in epithelial cells that lose cell polarity as a result of an extracellular calcium depletion. Calcium depletion of SK-CO-15 colonic epithelial cells induced disruption and internalization of TJ and AJ and reorganization of perijunctional actin microfilaments into contractile F-rings. MT were observed to accumulated inside of such F-actin rings. Depolymerization of MT with nocodazole significantly attenuated junctional disassembly and F-actin ring formation. MT stabilization with either docetaxel or pacitaxel did not prevent TJ/AJ disassembly but attenuated contraction of F-actin rings and prevented accumulation of internalized junctional proteins into an apical cytosolic compartment. Calcium depletion affected neither the balance between stable (acetylated) and instable (tyrosinated) MT nor phosphorylation status of major microtubule-stabilizing protein tau. Pharmacological inhibition of MT motors kinesins with adenylylimido-diphosphate or aurintricarboxilic acid attenuated formation of F-actin rings and junctional disassembly in calcium depleted cells. The kinesin-1 was specifically enriched at TJ/AJ in polarized SK-CO-15 cells and also colocalized with internalized TJ/AJ proteins in calcium-depleted cells. We conclude that MT play a role in disassembly of TJ/AJ during calcium depletion by regulating formation of contractile F-actin rings and endocytosis of junctional proteins.

2603

**Human T Lymphocyte Trafficking across the Lung Epithelium**

J. C. Porter, A. Hall; Lab of Molecular Cell Biology, University College London, London, United Kingdom

Lung disease is the single greatest cause of morbidity and mortality worldwide, often occurring as a result of uncontrolled inflammation. One pathway for clearing leukocytes from the lung, and so limiting inflammation, is across the bronchial epithelial barrier into the large airways; so called egression or transepithelial migration (TEM). We have developed an assay of leukocyte TEM from basal-to-apical surfaces of the bronchial epithelium, and have used this system to define the adhesion molecules and signaling pathways involved. Bronchial epithelial (BE) cells are cultured as standard or inverted monolayers on Transwell™ filters, allowing access to apical and basal surfaces. The presence of tight junctions is confirmed by microscopy, measurements of trans-epithelial resistance and permeability to dextran. T-lymphocytes, labelled with a fluorescent dye, are placed on one side of the epithelial monolayer. After 90 minutes lymphocytes recovered from the other side of the monolayer can be counted. We show that stimulated BE cells produce a polarised gradient of the T cell chemoattractant CXCL11, from the apical surface. Although very few (<5%) of T cells move across a monolayer of epithelial cells in the absence of a chemotactic gradient, 10-60 % of the T cells migrate in response to CXCL11. Analysis of the adhesion molecules required for TEM shows that LFA-1, CD47 and CD29 on the T cells interact with ICAM-1, CD47 and VCAM-1 on the epithelial cell respectively. We also show that T cell adhesion, even in the absence of migration leads to an increase in epithelial permeability. This permeability change is not sufficient for TEM, and additional epithelial cytoskeletal signaling events are required. We are focusing on the role of the epithelial cytoskeleton, and the Rho-GTPases in co-ordinating these events.

2604

***In vivo* Evidence that Tight Junctions are Functionally Disrupted by Attaching and Effacing Bacteria**

J. A. Guttman,[1] Y. Li,[1] M. E. Wickham,[1] W. Deng,[1] A. W. Vogl,[2] B. B. Finlay[1]; [1]Michael Smith Laboratories, University of British Columbia, Vancouver, BC, Canada, [2]Department of Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, Canada

The human attaching and effacing (A/E) pathogens, enterohemorrhagic *Escherichia coli* (EHEC) and enteropathogenic *E. coli* (EPEC), have long been implicated in the disruption of tight junctions *in vitro*. Within the chromosome of various A/E bacteria is a conserved pathogenicity island called the locus of enterocyte effacement (LEE), which encodes a syringe-like type-III secretion system and effector proteins that are essential for tight junction alteration. Recently, a naturally occurring murine model of these diseases has been developed that uses *Citrobacter rodentium* for infection. We have used this model to investigate whether colonic tight junctions are disrupted *in vivo* during A/E infection. Following 7day oral infections with 4-5X$10^8$ bacteria, the distribution of claudins-1, -3 and -5 in the distal colon was altered when evaluated by immunolocalization. Staining normally found along the lateral sides of the colonocytes was now found in the cell cytoplasm while levels of the proteins in the colon remained unchanged. Moreover, molecular tracers penetrated between cells and into the epithelium in infected tissue, but did not do so in controls where the tracer was confined to the lumen of the colon. This functional disruption of tight junctions is dependent on the LEE encoded effector

protein EspF, but not Map or EspG as suggested by *in vitro* EPEC infections. It also is dependent on the presence of bacteria attached to the colonocytes because mice, which eventually clear the infection, retain normal claudin-3 localization. We conclude that functional disruption of colonic tight junctions occurs in mice during infection with *Citrobacter rodentium* and that this is due partly to an altered distribution of claudins.

## Structure & Function of Membrane Proteins II (2605-2617)

2605

### Membrane Protein Alteration in Thalassemic Red Blood Cell (RBC)

M. S. Soriano,[1,2] H. G. Baylon,[3] A. Caviles,[4] M. D. Enriquez,[1,2] F. F. Natividad[1]; [1]Research and Biotechnology Division, St. Luke's Medical Center, Manila, Philippines, [2]College of Science, De La Salle University, Manila, Philippines, [3]Blood and Marrow Transplant Unit, St. Luke's Medical Center, Manila, Philippines, [4]Dr. Fe Del Mundo Medical Center Foundation, Manila, Philippines

Thalassemia, a disease of imbalance between alpha (α) and beta (β) globin chain synthesis, can result to cell membrane damage and premature RBC destruction. The erythrocyte (RBC) membrane is composed of four peripheral proteins: spectrin, the major protein that interacts with actin, protein 4.1 and ankyrin which play an essential role in determining the shape and deformability of RBC. Disruption of interaction among these components may cause loss of structural and functional integrity of the RBC. This study aims to differentiate the membrane protein content between thalassemic and hematologically normal RBC. Specifically, it looked at the assembly of spectrin in the RBC plasma membrane. Eight thalassemic and five normal peripheral blood samples were processed to isolate plasma, cell lysate and membrane proteins or ghost proteins. Protein concentrations were determined using the Bradford Assay. Spectrin distribution was compared using immunofluorescence assay. The mean protein content in plasma, cell lysate and membrane protein of normal RBC are: 0.56430 ug/ml (± 0.070774), 0.65360 ug/ml (± 0.041165) and 0.24252 ug/ml (± 0.065998) respectively, while in thalassemic RBC mean protein content are: 0.58051 ug/ml (± 0.047102), 0.68788 ug/ml (± 0.077435) and 0.15764 ug/ml (± 0.195612) respectively. Results showed no pronounced difference in total protein content of plasma and cell lysate in hematologically normal and thalassemic RBC (t=0.500, p=0.627, t=0.903, p=0.386 respectively). On the other hand, the total membrane protein of thalassemic RBC is lower than that of normal RBC but not statistically significant (t=-0.925, p=0.375). The spectrin assembly in thalassemic RBC exhibited clumping or uneven distribution while in normal RBC there was a uniform distribution. It is believed that this uneven spectrin distribution in the plasma membrane of thalassemic RBC affects the stability, flexibility and shape of RBC.

### Novel Insights into Binding Properties of Cytoskeletal Proteins 41R and 41G with CD44 in HeLa Cells

P. Gascard,[1] W. Nunomura,[2] M. Parra,[1] Y. Takakuwa[2]; [1]LBNL UC Berkeley, Berkeley, CA, [2]Biochemistry, Tokyo Women's Medical University, Tokyo, Japan

[Introduction] We have reported that the 30kDa domain of $4.1R^{80}$ interacts with CD44, and that these interactions are regulated by $Ca^{2+}$ and calmodulin (CaM). The 135kDa 4.1R isoform ($4.1R^{135}$) and 4.1G have an additional polypeptide, referred to as headpiece (HP), upstream of the 30kDa domain. Preliminary data suggest that the HP region of 4.1R regulates $4.1R^{135}$ interaction with membrane proteins but that it is not the case for 4.1G. In order to verify this hypothesis, we investigated the impact of HP on the binding affinity of two chimera proteins, 4.1RHP+4.1G30kDa (RHPG30) and 4.1GHP+4.1R30kDa (GHPR30), to CD44 and on the distribution of these chimera in HeLa cells. [Materials and Methods] HeLa cells were cultured in RPMI medium containing 10% FCS. Specificity of antibodies to 4.1R, 4.1G, 4.1N and 4.1B has been previously characterized (*Kidney Int.* 63:1321). Antibody to CD44 was obtained from Ancell Co. Ltd. RHPG30 and GHPR30 were expressed as GFP fusion proteins in HeLa cells. Protein-protein interactions were measured using the IAsys system. [Results] (1) Immunoblotting and immunocytochemistry analyses revealed that HeLa cells expressed $4.1R^{135}$, 4.1G and 4.1N but not 4.1B; (2) both $4.1R^{135}$ and 4.1G distributed at the cell-cell contact of HeLa cells; (3) both RHPG30 and GHPR30 chimera proteins bound to CD44cyt with similar affinity ($K_{(D)} \sim 10^{-7}$M); (3) both chimera interacted with CaM with similar affinity ($K_{(D)} \sim 10^{-7}$M) in a $Ca^{2+}$-independent manner; (4) $Ca^{2+}$/CaM decreased the binding affinity of both chimeras to CD44 from $\sim 10^{-7}$ M to $\sim 10^{-6}$M; (5) GFP-GHPR30 distributed at a much higher extent to cell-cell contacts than GFP-RHPG30 in transfected HeLa cells. [Conclusion] The results support that HP in $4.1R^{135}$ and 4.1G may specifically regulate binding of their respective 30kDa domain to plasma membrane.

### Role of the Headpiece Region on Cytoskeletal Proteins 41R and 41G Interactions with Red Cell Membrane Proteins

W. Nunomura,[1] P. Gascard,[2] M. Parra,[2] M. Narla,[3] Y. Takakuwa[1]; [1]Biochemistry, Tokyo Women's Medical University, Tokyo, Japan, [2]LBNL UC Berkeley, Berkeley, CA, [3]NYBC, New York, NY

[Introduction] We have reported that the 30kDa domain of $4.1R^{80}$ interacts with Band3 and Glycophorin C (GPC), and that these interactions are regulated by $Ca^{2+}$ and calmodulin (CaM). The 135kDa 4.1R isoform 4.1R ($4.1R^{135}$) and 4.1G have an additional polypeptide, referred to as headpiece (HP), immediately upstream of the 30kDa domain (R30 and G30). Preliminary data suggest that the HP region of 4.1R regulates $4.1R^{135}$interaction with membrane proteins but that it is not the case for 4.1G. To clarify the function of HP, we compared the binding profiles of two chimera proteins, 4.1RHP+4.1G30kDa (RHPG30) and 4.1GHP+4.1R30kDa (GHPR30), to various red cell membrane proteins. [Materials and Methods] Recombinant proteins were expressed as GST fusion proteins except full length $4.1R^{135}$ and 4.1G which were expressed as non-tagged recombinant proteins. CaM was purified as previously described (*JBC*(2000) **275,** 6360). Protein-protein interactions were measured using the IAsys system. [Results] (1) All chimera proteins bound to cytoplasmic domains of Band3 and GPC with similar affinity ($K_{(D)} \sim 10^{-7}$ M) to R30 and G30; (2) RHP30 and GHP30 bound to CaM with a higher affinity ($K_{(D)} \sim 10^{-8}$ M) than chimera proteins ($K_{(D)} \sim 10^{-7}$ M), (3) RHP30 and GHP30 binding to CaM was $Ca^{2+}$-dependent, while binding of RHPG30 and GHPR30 was independent; (3) $Ca^{2+}$/CaM reduced the binding affinity of RHPG30 to Band3cyt and GPCcyt but not that of GHPR30. [Conclusion] Our results support that HP in $4.1R^{135}$ and 4.1G may specifically regulate their respective 30kDa domain binding to membranes. **Functional Analysis of Zebrafish (*Danio rerio*) Protein 41R Binding to Membrane Proteins and Calmodulin**

W. Nunomura,[1] K. Murata,[2] Y. Takakuwa[1]; [1]Biochemistry, Tokyo Women's Medical University, Tokyo, Japan, [2]Animal Science, UC Davis, Davis, CA

[Introduction] We have reported that the binding profiles of 30kDa domain of human protein 4.1R (H•R30) with membrane proteins, Band3, Glycophorin C (GPC) and p55. A complex of $Ca^{2+}$/ and calmodulin (CaM) regulated 4.1R interactions with those membrane proteins (*JBC* (2000) **275:** 24540). The amino acid sequence of zebrafish (ZF, *Danio rerio*) 30kDa domain of 4.1R (ZF•R30) was 59% conserved that of human. In this study, we studied on the ZF•30 binding to membrane proteins and CaM. [Materials and Methods] Expression of recombinant proteins, H•R30, ZF•R30 (cDNA was gift from Prof. Zon, LI, Dana-Farber Cancer Institute, Boston), cytoplasmic tails of Band 3 (Band 3cyt), GPC (GPCcyt) and p55 of human, and purification of CaM were performed according to previous reports (*JBC* (2000) **275:** 24540). $PIP_2$ was obtained from Sigma. Inside-out-vesicles (IOV) was prepared from human erythrocytes. Protein-protein interaction was measured using IAsys based on the resonant mirror detection method. [Results] (1) ZF•R30 co-precipitated with IOV; (2) The $K_{(D)}$ values of ZF•R30 binding to Band 3cyt and GPCcyt were ~$10^{-6}$ M and ~$10^{-7}$ M, respectively; (3) The $K_{(D)}$ value for ZF•R30 binding to CaM was ~$10^{-7}$ M in the presence and the absence of $Ca^{2+}$; (4) $Ca^{2+}$/CaM did not reduce the binding affinity of ZF•R30 to Band3cyt and GPCcyt; (5) $PIP_2$ inhibited CaM binding to H•R30 but not ZF•R30 in the absence of $Ca^{2+}$. [Conclusion] Our results suggest that $Ca^{2+}$/CaM does not affect on ZF•R30 binding to membrane proteins regardless of $Ca^{2+}$ level. **Functional Characterization of Cytoskeletal Protein 41R Interaction with Na+/H+ Exchanger NHE1**

W. Nunomura,[1] S. P. Denker,[2] B. A. Watts,[3] V. Calinisan,[4] S. Grinstein,[5] J. Orlowski,[6] C. Brugnara,[7] N. Mohandas,[8] D. W. Good,[3] P. Gascard[4]; [1]Biochemistry, Tokyo Women's Medical University, Tokyo, Japan, [2]UCSF, San Francisco, CA, [3]Medicine and Neuroscience and Cell Biology, UTMB, Galveston, TX, [4]Genome Biology, LBNL, Berkeley, CA, [5]Cell Biology, Hospital for Sick Children, Toronto, ON, Canada, [6]Physiology, McGill University, Montreal, PQ, Canada, [7]Laboratory Medicine, Children's Hospital Boston, Boston, MA, [8]Red Cell Physiology, New York Blood Center, New York, NY

We have previously shown that three members of the family of cytoskeletal 4.1 proteins exhibit segment-specific expression in mouse kidney (Ramez et al., Kidney Int. 2003, 63:1321). In particular, 4.1R expression is restricted to the thick ascending limb (TAL). Strikingly, 4.1R null mouse red blood cells (RBCs) display a dramatic increase in NHE1 activity that may result from a loss of regulation of NHE1 by an unidentified phosphatase (De Francheschi et al., Blood 2004, 104:167a). Here we characterize 4.1R/NHE1 interaction in vitro, assess the impact of the absence of 4.1R on ion transport in medullary TAL tubules (MTALs) and investigate potential mechanisms accounting for NHE1 hyperactivity in 4.1R null RBCs. Pull down and IAsys-based resonant mirror detection binding assays show that 4.1R interacts with NHE1 cytoplasmic domain (KD~100-200nM). This interaction involves primarily a Glu-Glu-Asp motif in 4.1R Four.1/Ezrin/Radixin/Moesin (FERM) domain and two positively charged clusters in the juxta-membrane region of NHE1 cytoplasmic domain. Inhibition of basolateral NHE1 by amiloride or nerve growth factor induces cytoskeleton remodeling that secondarily inhibits transepithelial bicarbonate absorption in MTALs (Watts et al., J. Biol. Chem. 2005, 280:11439). This regulation is similar in wild type and 4.1R null mouse MTALs, arguing against a role for 4.1R in controlling NHE1-induced transport regulation in the TAL. Last, we show that 4.1R null and wild type mouse RBCs express similar levels of the phosphatase “Calcineurin Homologous Protein” (CHP), thus ruling out that NHE1 hyperactivity in 4.1R null RBCs results from a lack of CHP. Studies are under way to unveil possible tissue-specific differences in 4.1R/NHE1 protein complex organization. This work was supported by NIH grant DK56355 to PG and by Grants-in-Aid for Scientific Research from the Ministry of Education of Japan 12680702 and 15570123 to WN.

**The Immunochemical Analysis of the Zebrafish (*Danio rerio*) Protein 41R Isoforms**

K. Murata,[1] W. Nunomura[2]; [1]Animal Science, University of California, Davis, Davis, CA, [2]Biochemistry, Tokyo Women’s Medical University, Tokyo, Japan

[Introduction] Human protein 4.1R (H•4.1R) has been identified as the major component of the erythrocyte membrane cytoskeleton. The $NH_2$ terminal 30kDa (FERM) domain of 4.1R binds to the membrane skeletal proteins and calmodulin. H•4.1R has been also found in nonerythroid cells as multiple alternatively spliced forms, however the functions of these molecules have not been clearly identified yet. The primary structure of 4.1R in zebrafish (ZF) (ZF•4.1R) includes the putative functional domains corresponding to FERM and C-terminal (CTD) domains of H•4.1R (*Development* (2002) **129**, 4359). In this study, to understand the function of 4.1R, we used ZF as the model animal and investigated on the expression and localization pattern of ZF•4.1R as the beginning. [Materials and methods] The blood, liver, ovary, and heart samples were obtained from the anesthetized ZF. The synthetic peptides conjugated with bovine serum albumin (BSA), CEHLNLLERDYFGLV (pep5) and CMGLMDENGKTILLRTQEEIFA (pepCTD) of ZF•4.1R (*Development* (2002) **129**, 4359) were immunized with rabbits. The western blot analysis was performed with these antibodies. [Results] In the erythrocytes, both antibodies detected 150, 80, 75, 25kDa proteins. A 40kDa protein in the liver and heart, and a 25kDa protein in the ovary were detected with both antibodies. Interestingly, a 65kDa protein was detected in the ovary, liver and heart with the anti-pepCTD but not with anti-pep5. Anti-pep5 detected 130kDa protein in the liver and 30kDa protein in the ovary but anti-pepCTD did not. [Conclusion] Our data suggest that zebrafish may have multi-isoforms of 4.1R. **Structural Analysis of Sarcoglycans Reveals Functional Domains Essential for Their Interaction and Plasma Membrane Targeting**

J. Chen, W. Shi, Y. Zhang, Y. M. Chan; Sigfried and Janet Weis Center for Research, Geisinger Clinic, Danville, PA

Mutations in sarcoglycans (SG) have been reported to cause autosomal-recessive limb-girdle muscular dystrophies (LGMD). In skeletal and cardiac muscle, four sarcoglycans (α, β, γ, δ) are assembled into a complex on the sarcolemma via a stepwise pathway that is dependent on the formation of the β/δ-SG core. In this study, we present a detailed structural analysis of sarcoglycans. Our results from proteolysis and co-

immunoprecipitation indicate that their extracellular regions consist of two distinctive functional domains. Deletion studies demonstrate that the N-terminal half of the extracellular domain is primarily involved in sarcoglycan interaction. On the other hand, the C-terminal half regions of β-SG, γ-SG and δ-SG are critical for plasma membrane localization. This domain consists of a highly conserved sequence and an EGF-like repeat motif that are thought to stabilize the tertiary structure of sarcoglycans. Mutations within these structural feat ures often affect sarcoglycan complex assembly and/or localization in our heterologous expression system. In addition, region near the transmembrane domain is essential for both sarcoglycan interaction and targeting to the cell surface. Finally, we provide evidence that the β/δ-SG core associates with the C-terminus of dystrophin. Our results therefore generate important information on the structure of the sarcoglycan complex and the molecular mechanism underlying sarcoglycan mutations in LGMD.

**Characterization of the Binding Site of Small Ankyrin 1, a Protein of the Sarcoplasmic Reticulum, for Obscurin, a Protein that Surrounds Sarcomeres in Striated Muscle**

M. A. Ackermann,[1] A. Kontrogianni-Konstantopoulos,[2] R. J. Bloch[2]; [1]Biochemistry and Molecular Biology, University of Maryland, Baltimore, School of Medicine, Baltimore, MD, [2]Physiology, University of Maryland, Baltimore, School of Medicine, Baltimore, MD

The proteins that organize the intracellular membranes of cells are not well understood. Here, we consider how the membranes of the sarcoplasmic reticulum, (SR), become organized around the contractile apparatus in striated muscle. We hypothesize that two novel binding partners, small ankyrin 1 (sAnk1, ~17 kDa), concentrated in the network SR, and obscurin (~800 kDa), concentrated at the periphery of the M-lines and Z-disks of each sarcomere, mediate this organization. Obscurin has been shown to bind sAnk1 at its nonmodular, C-terminal region. sAnk1 binds to obscurin through a portion of its cytoplasmic sequence (amino acids 61-130), that is partly homologous to the sequence conserved in larger isoforms of ankyrin. We are characterizing the binding site on sAnk1 for obscurin by site-directed mutagenesis and binding assays. We mutated a set of charged amino acids to alanines in a potential amphipathic α-helical region of the conserved portion of sAnk1, and then measured the binding of the mutated proteins in blot overlays and by surface plasmon resonance. Single mutations (K100A, K101A, R104A, K105A, and R108A) reduced binding of the cytoplasmic portion of sAnk1 to the C-terminal region of obscurin in blot overlays. The K100A/ K101A double mutation reduced binding further (80% reduction as seen with surface plasmon resonance), and mutating 4 of these residues eliminated binding completely. Our results suggest that these five charged amino acids contribute to the interaction between sAnk1 and obscurin. Further characterization of their binding sites will provide an understanding of the interaction between sAnk1in the SR and obscurin at the periphery of the contractile apparatus.

2613

**Obscurin Modulates the Organization of Sarcomeres and the Sarcoplasmic Reticulum**

A. Kontrogianni-Konstantopoulos,[1] D. H. Catino,[1] J. C. Strong,[1] S. Sutter,[2] D. W. Pumplin,[3] M. W. Russell,[2] R. J. Bloch[1]; [1]Physiology, University of Maryland, Baltimore School of Medicine, Baltimore, MD, [2]Pediatrics and Communicable Diseases, University of Michigan Medical School, Ann Arbor, MI, [3]Anatomy and Neurobiology, University of Maryland, Baltimore School of Medicine, Baltimore, MD

Obscurin (~800 kDa) is a multidomain protein composed of tandem adhesion modules and signaling domains. Obscurin is not present within sarcomeres but intimately surrounds them, primarily around the M-line and Z-disk, where it is appropriately positioned to participate in their assembly and integration with other sarcoplasmic elements. Consistent with this, obscurin interacts with diverse proteins located in distinct subcellular compartments, including small ankyrin 1 (sAnk1), an integral component of the network sarcoplasmic reticulum (SR), titin and sarcomeric myosin. We used small inhibitory RNA (siRNA) technology to reduce the levels of obscurin in primary cultures of skeletal myotubes, to study its role in myofibrillogenesis and the organization of the SR. siRNA-treated myotubes showed a specific and dramatic reduction in the ~800 kDa form of obscurin by reverse transcription-polymerase chain reaction, immunoblotting and immunofluorescence. M-lines and A-bands, but not Z-disks or I-bands, were severely disrupted when the synthesis of obscurin was reduced. sAnk1 also failed to align around the middle of sarcomeres in myotubes infected with siRNA targeted to obscurin. Myosin and myomesin levels were significantly reduced in treated myotubes, but α-actinin was not, suggesting that down-regulation of obscurin destabilizes proteins of the M-line and A-band but not of the Z-disk. Our findings suggest that obscurin is required for the assembly of the M-line and A-band and for the regular alignment of the network SR around the contractile apparatus. Supported by grants from the NIH (RO1 HL075093 to MWR; RO1 HL064304 to RJB) and the Muscular Dystrophy Association (to AK-K, MWR and RJB).

**Lactoferrin Inhibits Trophoblast Proliferaton via Its Receptor**

V. Lopez; Nutrition, UC Davis, Davis, CA

Inflammation and infection are known to result in pregnancy complications. Lactoferrin (Lf) is an iron (Fe) binding protein that increases during infection and binds to its GPI-anchored receptor, LfR, however its biological function has yet to be determined. Fe bound to Lf results in a protein conformational change, which may play an important role in the dynamics of how Lf interacts with its receptor activating downstream signals. We hypothesized that Lf decreases trophoblasts proliferation via MAPK signaling through LfR, which is dependant upon Lf conformation. BeWo cells (human trophoblasts) were treated with Fe-saturated- (holo) Lf or Fe-unsaturated (apo) Lf. LfR localization was visualized with confocal microscopy. Activated MAPK was measured by Western analysis and cell proliferation by the MTT assay. We demonstrated that apoLf binds with higher affinity to LfR compared to holoLf. The binding of apoLf resulted in immediate LfR clustering. Consequently, MAPK was immediately inactivated and cell proliferation was inhibited. In contrast, holoLf resulted in delayed LfR clustering and MAPK inactivation, and cell proliferation was also reduced. These data confirm the differential cell response to apo- and holoLf. These effects also indicate an inhibitory effect on trophoblast proliferation. In conclusion, Lf may have different roles in the placenta depending on its Fe-saturation (conformation) and this potentially could play a role in infertility associated with inflammation and infection. Supported by NIH HD43240.

**Non-muscle Myosin Heavy Chain IIA and Lck Are Involved in CD38 Internalization**

U. Kim, S. Rah, K. Park, M. Im; Biochemistry and Institute of Cardiovascular Research, Chonbuk National University Medical School, Jeonju,

Republic of Korea
CD38 activation in lymphokine-activated killer (LAK) cells involves IL-8-mediated PKG activation and results in an increase of long-lasting intracellular $Ca^{2+}$ concentation ($[Ca^{2+}]_i$) that is critical for migration of LAK cells. However, our previous study has indicated that CD38 is not phosphorylated directly by PKG. In this study, we have examined molecular mechanism of CD38 activation in LAK cells and Jurkat T cells. Non-muscle myosin heavy chain IIA (MHCIIA) was identified as a CD38-associated protein during IL-8 signaling by MALDI-TOF analysis. The IL-8-dependent association of MHCIIA with CD38 was inhibited by an inhibitor of PKG, and the association of both proteins was significantly increased by the treatment with membrane-permeant cGMP, 8-pCPT-cGMPS. Moreover, IL-8-induced formation of cyclic ADP-ribose (cADPR), increase of $[Ca^{2+}]_i$, and migration of LAK cells were substantially inhibited by the treatment with an inhibitor of MHCIIA, blebbistatin. IL-8 treatment of LAK cells resulted in CD38 internalization that was blocked by pre-treatment with blebbistatin. During CD38 internalization, CD38 was colocalized with MHCIIA as well as Lck in LAK cells. Supporting the observations, levels of CD38, MHCIIA, and Lck in lipid rafts were significantly increased by OKT-3 treatment of T cells compared to the control. A synthesized cell permeable peptide $CD38^{11-20}$, cytoplasmic juxtamembrane domain inhibited OKT-3-induced formation of cADPR, increase of $[Ca^{2+}]_i$, and cell proliferation. These findings indicate that CD38 activation in IL-8 or T cell receptor signaling pathway involves the internalization of CD38 and that the internalization is mediated by the interaction with MHCIIA and Lck via cytoplasmic domain of CD38.

### Elucidating the Structural Role of Dnm1 in Mitochondrial Fission

J. A. Mears,[1] E. Ingerman,[2] M. Marino,[1] J. Nunnari,[2] J. E. Hinshaw[1]; [1]LCBB, NIDDK/NIH, Bethesda, MD, [2]Section of Molecular and Cellular Biology, University of California, Davis, Davis, CA

Dynamin family members are large GTPases involved in many cellular processes including budding of transport vesicles, cytokinesis, pathogen resistance and division of organelles. The structure of classical dynamin from humans has been solved using cryo-electron microscopy. Furthermore, the GTPase and pleckstrin-homology domains of the protein are clearly defined in the structure, and a detailed model has been developed for these regions. Our group is currently interested in characterizing the structural features of several dynamin family members to better understand how this family of proteins can accomplish such varied tasks. Therefore, we are studying Dnm1 (homologous to Drp1/Dlp1 in humans), which regulates mitochondrial fission in yeast and self-assembles at sites of mitochondrial membrane constriction. We have shown with electron microscopy that Dnm1 self-assembles *in vitro* into spiral structures in the presence of nucleotide and absence of lipid. It also decorates lipid in the presence or absence of nucleotide, and the resultant Dnm1 tube forms a helical structure similar to classical dynamin. However, the diameter of Dnm1 tubes (between 100 and 200 nm) is much larger than seen with classical dynamin (40 and 50 nm). This larger diameter is consistent with distinct constriction sites observed during mitochondrial fission *in vivo*. Using a variety of microscopic methods, we are working towards determining a high-resolution structure of Dnm1 to better understand how the protein sequence and architecture affects the size and function of dynamins during membrane fission.

### Serotonin Regulates the Plasma Membrane Expression of Serotonin Transporter Protein Via Its Interactions with Rab4

F. Kilic,[1] V. Lupashin,[2] P. van der Sluijs[3]; [1]Department of Biochemistry and Molecular Biology, University of Arkansas for Medical Sciences, Little Rock, AR, [2]Department of Physiology, University of Arkansas for Medical Sciences, Little Rock, AR, [3]Cell Biology, University Medical Center, Utrecht, The Netherlands

Serotonin (5HT) is a platelet-stored vasoconstrictor that also acts as a neurotransmitter. Alterations in the levels of 5HT in the nervous system, or blood plasma are associated with a number of neuropsychiatric disorders, or major heart and kidney diseases, respectively. The actions of 5HT are mediated by different types of receptors, and terminated by a single 5HT transporter (SERT). Although both substrates and inhibitors are capable of regulating transporter distribution in cells, the mechanism by which 5HT can accomplish this task has remained elusive. We first showed that the plasma membrane expression of SERT is regulated by 5HT in a concentration-dependent manner. We investigated the impact of 5HT on other proteins those also interact with SERT. It has been reported that a small GTPase, Rab4 is modified with 5HT covalently at the phosphate binding domain. This modification stabilizes Rab4 at its constitutively active, GTP-bound form which interacts downstream with effector molecules, resulting in actin-myosin cytoskeleton rearrangement and stimulation of membrane trafficking of small vesicles. We have found that Rab4-GTP was co-immunoprecipitated with SERT and that recycling of SERT involves the action of Rab4. Pretreatment with 5HT at high (≥50 μM) concentrations increased SERT-Rab4 co-localization at intracellular compartments. We propose that 5HT controls the density of SERT on the plasma membrane by enabling its interactions with Rab4, and that this interaction regulates membrane trafficking and plasma membrane expression of SERT.

## Membrane Domains (2618-2635)

### Short-Range Dynamics of Lipid Domains in Model Biomembranes

D. J. Mudaliar, R. P. Walvick, A. A. Heikal; Bioengineering, Pennsylvania State University, University Park, PA

Cellular plasma membranes are heterogeneous, dynamic and complex systems that regulate numerous biological processes. Due to the coexistence of a variety of lipid molecules with different melting temperatures and acyl chain lengths as well as proteins, biomembranes exist as different lipid domains characterized by different physical and biochemical properties. Gel phase lipids have rigid, ordered acyl chains while fluid phase lipids are marked by higher levels of unsaturation and higher freedom of motion of acyl chains. An intermediary lipid phase (rafts), which is rich in sphingolipids and cholesterol, has been implicated in important membrane functions. The long-range (microsecond to seconds) biophysical properties of these domains have been investigated in model systems using fluorescent probes that are inherently specific to the lipid phases. Here, we present a new approach for investigating short-range (picoseconds to nanoseconds) lipid-lipid and lipid-tag interactions, at high spatial and temporal resolution, in giant unilamellar vesicles (GUVs) that mimic biomembranes. We have employed two-photon fluorescence polarization and lifetime imaging microscopy for quantitative imaging of the excited-state dynamics and rotational diffusion of fluorescent markers (DiI-C12,

Bodipy-PC, and Alexa-Cholera toxin B) in different lipid domains. We have also developed image processing and data analysis algorithms for modeling these short-range dynamics, which are extremely sensitive to the surrounding environment and molecular conformations, to understand their correlation to lipid domains. For example, the polarization anisotrpy decays of these probes were modeled as wobbling-in-cone motion that quantifies the spatial restriction on the probe exerted by different lipid domains. These results will help filling the current gap of molecular, short-range knowledge of lipid domains in model membrane systems and, ultimately, will be used to correlate lipid phases to the biological functions of biomembranes.

2619

**Patterning Complexity into Biomimetic Lipid Membranes: Toward Understanding Raft Dynamics**

K. Vats, M. Kyoung, E. D. Sheets; Chemistry, Pennsylvania State University, University Park, PA

The relationship between the structure of biomembranes and their biological functions remains elusive, particularly with respect to cholesterol-rich microdomains or “rafts”. We are exploiting a combination of microlithography and quantitative fluorescence microscopy to systematically probe the molecular interactions that lead to lipid domain formation as well as domain dynamics. Complexity is built into supported bilayers by patterning domains via a polymer lift-off approach. We find that the complex bilayers, composed of fluid phase dilauroylphosphatidylcholine (di12:0 PC; $T_m$ = -1°C) and gel phase dipentadecanoylphosphatidylcholine (di15:0 PC; $T_m$ = 33°C), retain their patterns and form a single continuous bilayer, as assessed by quantitative fluorescence microscopy. Using fluorescence correlation spectroscopy (FCS), we observe that fluid phase lipids retain typical diffusion coefficients ($D$ = $10^{-9}$-$10^{-8}$ $cm^2/s$) whether they are deposited as conventional unpatterned, single-component bilayers or as patterned complex bilayers. In addition to FCS, we are combining single particle tracking with imaging to probe the molecular dynamics associated with lipid domains and interfaces at high spatial and temporal resolution. We are also characterizing these patterned membranes with liquid atomic force microscopy to further confirm the results from the fluorescence measurements about the continuity of the biomimetic membranes. Our results with the initial composition of di12:0 PC and di15:0 PC suggest that our approach will allow us to form chemically well-defined domains *within* the context of another chemically well-defined lipid composition, independent of whether lateral phase separation would result in conventional model membranes. Ultimately, we will follow the dynamics of domains and individual lipids within this milieux as a function of cholesterol content to understand how these physical interactions in cholesterol-rich rafts control biological function.

**The Search for Membrane Microdomains (Lipid Rafts) in *Ascidia ceratodes* Sperm Cells**

D. Diaz, R. A. Koch; Biological Science, California State University, Fullerton, CA

Contact between sperm and egg cells initiates reciprocal activation of metabolic and signaling reactions within both gametes. During activation, ascidian sperm cells undergo a morphological change termed mitochondrial translocation. Sperm-egg interactions in ascidians involves events such as adhesion, signaling, and cytoskeletal remodeling that require *N*-acetylglucosaminidases, G-protein coupled receptors, surface-mounted proteases, and integrins. In order for intra-/extracellular activity of all cells to take place, a platform to facilitate protein gathering and assembly must exist. The structure that is becoming more accepted as being this platform is a microdomain at the surface of the cell termed a lipid raft. These lipid rafts are distinguished by having concentrated aggregates of sphingolipids, cholesterol (Ch) and signaling proteins and being non-ionic detergent insoluble. In order to determine if these structures exist in ascidian sperm, the fluorescent labels, filipin and Alexa 555-conjugated cholera toxin (CTX) were used to label cholesterol and sphingolipid domains. These structures were viewed using epi-fluorescence and analyzed using the NIH computer software, ImageJ. Experiments were conducted at 4 °C, 15 °C and 25 °C to ensure that temperature was not influencing labeling behavior (results were not significantly different). Analysis of digital micrographs revealed that high concentrations of Ch and sphingolipids, consistent with the presence of microdomains, increased in number and intensity following sperm activation. Labeled patches translocated with mitochondrial movement. Experiments to study the behavior of microdomains following activation by the G-protein activator, mas-7, and integrin-clustering antibody, mAB-12G10, and possible disruptive effects of methyl-β-cyclodextrin are in progress. Our evidence supports the preliminary conclusion that lipid rafts play a role in signaling processes involved in ascidian sperm activation (Funded by NIH Grant 2R25-GM-56625).

**ABCA1 Expression Disrupts Raft Membrane Microdomains Through its ATPase-Fueled Functions**

Y. Landry,[1] M. Denis,[1] S. Nandi,[1] S. Bell,[1] A. M. Vaughan,[2] X. Zha[1]; [1]Ottawa Health Research Institute and University of Ottawa, Ottawa, ON, Canada, [2]Department of Medicine, University of Washington, Seattle, WA

ATP binding cassette transporter A1 (ABCA1) is an ATP-fueled transporter known to facilitate efflux of both phospholipids and cholesterol to extracellular acceptors, such as apoA-I. How ABCA1 mediates cholesterol export is largely unknown at present. Upon transient induction of ABCA1 expression in BHK cells, we observed the disruption of caveolae-rich plasma membrane lipid rafts. ABCA1-expressing cells also had a higher percentage of non-rafts on the plasma membrane, which was not due to cholesterol redistribution or alterations in cellular free cholesterol content. These observations suggest a re-organization of the plasma membrane by ABCA1. As a member of ancient ABC transporter families, ABCA1 is thought to flip phosphatidylserine (PS) from the inner to outer leaflet of the plasma membrane by hydrolyzing ATP. This raised the possibility that, by flipping PS, ABCA1 may disrupt lipid-lipid interactions, leading to an increase in the non-raft pool of the plasma membrane. This process should then depend on ABCA1’s ATPase activity. To test this hypothesis, we expressed an ABCA1 mutant, A937V, which lacks ATPase activity. This mutant can effectively traffic to the plasma membrane, but is unable to flip PS or export cholesterol. In BHK cells expressing the A937V mutant, we observed that caveolae-rich microdomains remained intact, similar to mock cells. In addition, there was no increase in the non-raft pool by this mutant, in contrast to wild type ABCA1. We thus conclude that ABCA1 re-organizes the plasma membrane by actively countering lipid ordering through an ATPase-fueled function, and speculate that this membrane re-organization is one pre-requirement for cells to efflux cholesterol. Our observations may imply that, in live cells, the microdomains are actively maintained by many events at any given time and that the overall process is likely far from equilibrium, contrary to artificial liposomes.

**Giant Plasma Membrane Vesicles Derived from Mammalian Cells Show Large-Scale Fluid/Fluid Phase Separations and Protein Sorting**

A. T. Hammond,[1] T. Baumgart,[2] P. Sengupta,[1] W. W. Webb,[3] D. Holowka,[1] B. Baird[1]; [1]Chemistry and Chemical Biology, Cornell University, Ithaca, NY, [2]Chemistry, University of Pennsylvania, Philadelphia, PA, [3]Applied and Engineering Physics, Cornell University, Ithaca, NY

We have developed a method for producing giant plasma membrane-derived protein-rich membrane vesicles (GPMVs) that show a pronounced capacity for lateral phase separation. Such large-scale separations may represent exaggerated examples of the lateral membrane heterogeneities that occur in cellular membranes and are hypothesized to act as a mechanism for regulating the interactions of certain classes of membrane proteins. This hypothesis makes the assumption that proteins possess intrinsic properties that allow them to respond to differences in their local membrane environment. We have tested this assumption for a set of proteins involved in the signal cascade of the immune-cell receptor Fc-epsilon-RI from mast cells. Membrane proteins, including both transmembrane and lipid-anchored proteins, do in fact respond to the differences in membrane environment and partition preferentially into one or the other of the coexistent fluid phases. This partitioning is observed by fluorescence microscopy and can be compared to the distribution of fluorescent lipid analogs included in the vesicles, which are collected from RBL mast cells that have been chemically induced to shed these plasma membrane vesicles. The lipid and protein composition of these vesicles is highly complex, and similar but not identical to the RBL cell plasma membrane. A surprising finding is that inner leaflet proteins anchored to the plasma membrane by saturated acyl chains preferentially partition into the less ordered phase of these GPMVs. These vesicles lack an underlying actin cytoskeleton and have lost some of the leaflet asymmetry characteristic of a plasma membrane. These factors may influence the observed phase partitioning and the size of the coexisting domains. Because of the importance of receptor crosslinking in mast cell signaling, the effects of crosslinking signaling molecules in these phase-separated membranes are being examined.

**Newly Biosynthesized Sterols Are Located in a Lipid Raft Domain and Serve as an Important Pool for ABCA1-Mediated Cellular Sterol Efflux**

Y. Yamauchi,[1] P. C. Reid,[1] S. Yokoyama,[2] C. C. Y. Chang,[1] T. Y. Chang[1]; [1]Biochemistry, Dartmouth Medical School, Hanover, NH, [2]Graduate School of Medical Sciences, Nagoya City University, Nagoya, Japan

We monitored the fate of endogenously synthesized sterols in normal and Niemann-Pick type C cells with respect to their intracellular trafficking, cellular distribution, and efflux. The results show that biosynthesized precursor sterols quickly leave the endoplasmic reticulum (ER) for the plasma membranes, and then move back to the ER, to be converted to cholesterol. The retrograde transport of precursor sterols is largely independent of NPC1 and NPC2 proteins. However, long after biosynthesis (more than 24 hours), small but significant amounts of the precursor sterols finally accumulate in the late endosomes/ lysosomes of the NPC1 and NPC2 mutant cells, but not those of the normal cells. We then analyzed the cellular distribution of newly synthesized sterols in normal cells by using sucrose density gradient centrifugation after treating cells with non-ionic detergents. The results show that most of the newly synthesized sterols are localized in a detergent-insoluble lipid raft domain. This domain is also enriched in the protein ABCA1, which plays an important role in cellular lipid efflux. Our results reveal that newly synthesized sterols are enriched in a lipid raft domain, and serve as an important pool for ABCA1 mediated cellular sterol efflux.

**Domain Formation and $PIP_2$ Segregation in Biomimetic Monolayers**

I. Levental,[1] J. Solon,[2] P. Janmey[2]; [1]Department of Bioengineering, University of Pennsylvania, Philadelphia, PA, [2]Department of Physiology, University of Pennsylvania, Philadelphia, PA

The discovery of sphingolipid and cholesterol-rich detergent-resistant membrane (DRM) fractions in mammalian cells has led to significant inquiry into the structural and functional arrangement of lipids in the plasma membrane. Lipid rafts, as the original DRMs were termed, have been found to be rich in signaling and adhesion molecules, as well as structural and scaffolding proteins. Other lateral heterogeneities containing microdomains of important phospholipids, such as polyphosphoinositides (PPI), have been postulated to be critical for localization and activity of membrane active enzymes. The objective of this study was to develop a system to mimic the non-ideal mixing behavior of biologically-relevant lipids and determine the effect of this behavior on the lateral distribution of $PIP_2$. We have used a Langmuir monolayer as a model system to show liquid-liquid phase separation in mixtures of bio-derived lipids. Specifically, we have observed domain formation in mixtures of 1-palmitoyl, 2-oleyl phosphatidylcholine (POPC), L-α phosphatidic inositol 4,5-phosphate ($PIP_2$), and cholesterol. Domains were visualized using fluorescence microscopy by addition of a fluorescent contrast agent. It was found that mixtures of SOPC, cholesterol, and $PIP_2$ form two immiscible liquid phases. One phase was found to be rich in phospholipids, in particular $PIP_2$. At low cholesterol concentrations (<50mol %), the two phases mixed upon compression at pressures much lower than those speculated to be relevant for biological membranes (~5mN/m). However, at higher cholesterol concentrations, the lateral heterogeneity of the monolayer persisted to much higher pressures, and were not made miscible before collapse of the monolayer (~40mN/m). We conclude that these monolayers are a reasonable model of lipid demixing (i.e. lipid raft and domain formation) in the plasma membrane, and that $PIP_2$ is preferentially excluded from the cholesterol-rich phase, which is analogous to the DRM fractions of biochemical experiments.

2625

**Transient Coupling of Lipid-anchored Raftophilic Molecules in the Inner and Outer Leaflets of the Cell Membrane as Detected by High-speed, Simultaneous Two-color, Single-molecule Tracking**

I. Koyama-Honda,[1,2] K. Ritchie,[3] T. Fujiwara,[1,2] E. Kajikawa,[3] R. Iino,[3] H. Murakoshi,[1,2] A. Yoshimura,[4] T. Kobayashi,[3] A. Kusumi[1,2]; [1]Institute for Frontier Medical Sciences, Kyoto University, Kyoto, Japan, [2]Membrane Mechanisms Project, JST-ICORP, Kyoto, Japan, [3]Department of Biological Science, Nagoya University, Nagoya, Japan, [4]Institute for Bioregulation, Kyushu University, Fukuoka, Japan

Coupling of lipid-anchored molecules between the outer and inner leaflets of the bilayer of the cell membrane is one of the key issues in the studies of raft-mediated signal transduction by GPI-anchored receptors. We addressed this issue by observing the recruitment of H-Ras or Lyn (inner leaflet) to artificially-induced small clusters of a ganglioside GM1 or a GPI-anchored protein CD59 in the outer leaflet in live HeLa cells, using a high-speed, dual-color, single-molecule tracking technique at a time resolution of 6.5 ms. After stimulation in the outer leaflet, i.e., crosslinking by

secondary antibodies of CD59 tagged by Alexa633-anti-CD59 antibody or of GM1 labeled with Alexa633-cholera toxin B, dynamic recruitment of GFP-H-Ras or Lyn-GFP in the inner leaflet to GM1 or CD59 clusters located in the outer leaflet was observed. Clustering of outer-leaflet molecules induced transient colocalization of single molecules of GFP-H-Ras or Lyn-GFP, lasting ~200 ms, in a cholesterol-dependent manner. Meanwhile, crosslinking of a non-raft phospholipid in the outer leaflet did not induce colocalization of inner-leaflet molecules. These results suggest that the engagement of raftophilic molecules in the outer leaflet can recruit beneath their clusters raftophilic molecules in the inner leaflet for short periods (~200 ms), which might explain why immunofluorescence colocalization experiments of fixed cells generally report low and/or variable levels of colocalization. Coupling between the inner and outer leaflets by interdigitating lipids in the raft may be weak, but might be sufficient to induce such transient recruitment of the inner-leaflet molecules. Such a coupling between two leaflets may be responsible for the signal transduction across the bilayer or may assist the signal transduction of raft-associated transmembrane proteins.

### Transbilayer Distribution of a Fluorescent Sterol in Living Cells

M. Mondal, F. R. Maxfield; Biochemistry, Weill Medical College of Cornell University, NY, NY

Cholesterol is an important constituent of mammalian cell membranes and plays a significant role in signaling and membrane trafficking. It is most abundant in plasma membranes and in the endocytic recycling compartment. The transbilayer distribution of sterols is poorly characterized. We have used quantitative fluorescence imaging in living cells to study the transbilayer distribution of dehydroergosterol (DHE), a naturally occurring fluorescent cholesterol analog that mimics many of the properties of cholesterol. Addition of a water soluble quencher, trinitrobenzene sulphonic acid (TNBS), which doesn't cross the bilayer during the time scale of our experiment, shows only 10% quenching of DHE fluorescence on the plasma membrane of the TRVb1 cells. When TNBS was microinjected inside the cells, almost all the DHE fluorescence in the plasma membrane and in the endocytic recycling compartment was quenched within seconds. Similar quenching was found when TNBS was added to cells after permeabilization. Our results indicate that most DHE in the plasma membrane and in the endocytic recycling compartment is in the cytoplasmic leaflet. Since DHE shares many properties with cholesterol, including its distribution among cellular organelles and the ability to form detergent resistant, raft-like membranes, these results raise the possibility that most plasma membrane cholesterol is in the inner leaflet and not in the sphingolipid-rich outer leaflet.

### Two-dimensional Surfactants and Lipid Raft Organization

M. J. Saxton,[1] A. Oldham,[2] P. F. Almeida[2]; [1]Dept of Biochemistry and Molecular Medicine, University of California, Davis, CA, [2]Dept of Chemistry, University of North Carolina, Wilmington, NC

One of the main questions about lipid rafts is why liquid-ordered (Lo) domains in model lipid mixtures are large enough to be observed by light microscopy but domains of the raft phase in cell membranes are submicroscopic. We consider the existence of 2D surfactants in cell membranes and propose experimental tests. These hypothetical molecules would have a "raftophilic" face and a "raftophobic" face. They would tend to bind to the raft-nonraft interface, and to disperse rafts as a microemulsion. The presence of 2D surfactants suggests an organized raft structure in which purely raftophilic species are in the Lo phase, purely raftophobic species are in the liquid-disordered (Ld) phase, and 2D surfactants are at the interface. Candidate species include lipids and GPI-linked proteins with one saturated and one unsaturated acyl chain; acylated proteins with raftophilic and raftophobic chains; and proteins, either peripheral or transmembrane, with raftophobic and raftophilic faces. These species would be permanent 2D surfactants; a less permanent form would be a complex of a raftophilic and a raftophobic species crosslinked by an external ligand. Alternatively, raft size could be determined by a monotopic protein replacing the inner leaflet of the membrane. Preliminary data in majority-Lo mixtures of POPC/sphingomyelin/cholesterol, obtained using fluorescence resonant energy transfer between two probes that partition preferentially into the Ld phase, show a decrease in energy transfer upon addition of the amphipathic peptide mastoparan or annexins A4 and A5, if POPC is the minor component. This decrease is consistent with the possibility that these proteins cause a reduction in Ld domain size. Supported by NIH grants GM-038133 (MJS) and GM-059205 to the University of Virginia (PFA).

### Microbial Glycosylated Phosphatidylinositol Targets Plasma Membrane Lipid Rafts to Interfere with $Ca^{2+}$ Signaling and Membrane Trafficking in Macrophages

I. Vergne, H. Lee, J. Chua, V. Deretic; Molecular Genetics and Microbiology, University of New Mexico School of Medicine, Albuquerque, NM

*Mycobacterium tuberculosis* is a facultative intracellular pathogen which survives in macrophages by blocking the maturation of phagosomes in which it resides, into fully degradative phagolysosomes. A heavily glycosylated phopshatidylinositol product of *M. tuberculosis*, termed lipoarabinomannan (MtLAM) has been shown to participate in the arrest of phagosome maturation (Fratti et al., (2001), J. Cell. Biol). MtLAM inhibits a $Ca^{2+}$/ hVPS34PI3K cascade, essential for phosphatidylinositol 3-phosphate generation on phagosome thus inhibiting phagolysosome biogenesis (Vergne et al., (2003), J.Exp.Med.). The objective of this study was to determine the mechanism of MtLAM action on signaling and consequently on phagosome maturation. Using detergent-based raft isolation method, we show that MtLAM associates mainly with rafts in macrophages. This association leads to a reorganization of the rafts and to alterations of raft-dependent- signaling events, such as translocation of sphingosine kinase to plasma membrane. Our data suggest that *Mycobacterium tuberculosis*, by shedding lipoarabinomannan, affects processes involved in signaling and trafficking by targeting rafts.

### Nanoscale Signal Transduction Across the Plasma Membrane

Y. Chen, B. Yang, K. Jaconson; Department of Cell and Developmental Biology, UNC at Chapel Hill, Chapel Hill, NC

Previous unpublished studies indicate that cross-linking GPI-anchored cell surface molecules, such as CD59, stabilizes the short-lived "cluster" rafts and increases the size of rafts (K. Suzuki, et al., Biophys. J. Annual Meeting Abstracts, 2002 : 348a) by SFK-mediated attachment of the cluster to the cytoskeleton. Here we use single particle tracking to detect the dynamics of these longer-lived rafts. To achieve optimal cross-linking, we incubated C3H fibroblast cells first with biotinylated anti-Thy1 antibodies, then anti-biotin antibody-coated colloidal gold particles, after which

anti-mouse IgG antibodies were added. Under these conditions, transient anchorage of gold-labeled Thy-1 was observed for periods ranging from 300 ms to 10 seconds. Cholesterol depletion and addition of Src family kinases (SFKs) inhibitors PP2 abolished transient anchorage, suggesting the involvement of both cholesterol and SFKs in cross-linking dependent transient anchorage. Further proof of the involvement of SFKs was obtained from Src, Yes, Fyn defective (SYF) cells, in which transient anchorage was not detected. Caveolin-1 knockout cells showed reduced transient anchorage by 1/3, suggesting the partial participation of caveolin-1. Another GPI-anchored protein, CD73, a 5'-ectonucleotidase, exhibited qualitatively similar behavior in IMR-90 human fibroblasts, indicating that these cross-linking induced effects are general. In addition, in PI3 kinase inhibited IMR-90 cells, short-period transient anchorage (less than 1 second) increased sharp and no long-period anchorage occurred. In addition, short-range directed motion occurred, possibly implicating motor-driven transport. (Supported by NIH GN 41402)

2630

**Lateral Heterogeneity in the Distribution of Lipids and Proteins in Plasma Membranes of Live Cells and Isolated Membrane Vesicles Detected by Fluorescence Resonance Energy Transfer and Confocal Microscopy**

P. Sengupta, A. Hammond, T. Baumgart, D. Holowka, B. Baird; Chemistry & Chemical Biology, Cornell University, Ithaca, NY

We have utilized fluorescence resonance energy transfer (FRET) between carbocyanine lipid analogues in the plasma membrane of RBL mast cells to investigate lateral distributions of lipids and to develop a general method for quantitative measurements of lipid heterogeneity in live cell membranes. FRET measured as fluorescence quenching of long chain donor probes such as DiO-C18 is greater with long chain, saturated acceptor probes such as DiI-C16 than with equimolar concentrations of unsaturated or shorter chain acceptors. Sucrose gradient analysis of plasma membrane-labeled, Triton X-100 lysed cells shows that proximity measured by FRET correlates with the extent of probe partitioning into detergent-resistant membranes. These and other FRET data are consistent with nanometer scale phase separations of lipids in the outer leaflet of the plasma membrane. In addition, sucrose gradient analysis of plasma membrane vesicles indicate that membrane heterogeneity is present even in the absence of the membrane-associated cytoskeleton, as proteins and lipids show differential distribution following detergent lysis. Giant plasma membrane vesicles exhibit large scale liquid order (Lo) and liquid disorder (Ld) phase separation, with napthopyrene (an order preferring probe) and Rhodamine-DOPE (a disorder preferring probe) exhibiting complementary partitioning. Partitioning of putative raft proteins such as GPI-anchored Thy-1 and non-raft proteins such as CD43 were complementary in the phase separated vesicles, with Thy-1 preferring the ordered phase. These results demonstrate that Lo/Ld phase separations coexist in compositionally complex plasma membranes, and the cytoskeleton and associated proteins appear to play an active role in preventing large scale phase separation in live cell membranes.

**Imaging of Viral Diffusion Reveals Insights into the Dynamics of the Plasma Membrane**

C. J. Burckhardt,[1] I. F. Sbalzarini,[2] J. A. Helmuth,[2] H. Ewers,[3] P. Koumoutsakos,[2] U. F. Greber[1]; [1]Institute of Zoology, University of Zürich, Zürich, Switzerland, [2]Institute of Computational Science, ETH Zürich, Zürich, Switzerland, [3]Institute of Biochemistry, ETH Zürich, Zürich, Switzerland

The dynamic organization of the plasma membrane and its receptors has been a long standing puzzle in cell biology and signal transduction. Answering this question is essential to understand how signals from the outside are transmitted to the inside of a cell. Despite years of work to determine how proteins bind each other in a particular signal transduction pathway, the available data do not explain how these proteins meet to interact specifically and successfully. Viral particles are excellent tools to tackle the functional organization of the plasma membrane. Most of the more than 50 human Adenovirus (Ad) serotypes use the Coxsackie virus B Ad receptor (CAR) or the membrane-cofactor CD46 for cell attachment. The entry of the species C Ad serotypes Ad2 and Ad5 involves CAR binding and activation of alpha v integrin coreceptors, clathrin-mediated viral uptake and the induction of macropinocytosis engulfing large amounts of membranes and fluids. In contrast, the functional interactions between CAR and the integrin coreceptors on the cell surface are largely unknown. We will present our recent data documenting surface movements of fluorescently labeled Ad2 using total internal reflection fluorescence microscopy at 50 Hz acquisition frequencies. The data reveal a dynamic structure of the plasma membrane with confined viral motilities owing to CAR, slow directional movements and fast processive movements mediated by activated integrin receptors.

2632

**Clustering of Chemotactic Receptors in E coli with Altered Morphologies**

D. Weibel, I. Schneider, E. Garner, R. D. Vale, S. Khan; The Physiology Course, Marine Biological Laboratory, Woods Hole, MA

E. coli possess a sophisticated signal transduction machinery that involves receptor-mediated binding of extracellular attractants and repellants and an intracellular relay mechanism that control the rotation of the flagellar motor. The signal transduction components are concentrated at one pole of the bacteria. This high degree of spatial order is thought to be important producing a high degree of cooperativity that is necessary for sensing shallow gradients of attractants/repellants. However, the mechanism that produces this pole clustering is unknown. Here, we have visualized a receptor-GFP fusion protein (TAR-GFP) and examined conditions that might affect its clustering. We chemically depolymerized the bacterial actin MreB, which produces spherical instead of rod-shaped cells, and found that receptors remained clustered. We also produced long filamentous bacteria by inhibiting septation, confirming that additional receptor clusters formed along the length of the rods, and these nonpolar clusters often appeared to have regular spacing. Finally, we observed small microclusters of TAR-GFP that diffused rapidly in the membrane. We propose these microclusters might be precursors of larger receptor clusters and that clustering reflects a self-assembly process that does not require the bacterial cytoskeleton and occurs in cells with dramatically different shapes.

2633

**Characterization of Septin7 and Novel Proteins of Compacted Myelin Identified Through Multi-Dimensional Protein Identification (MudPit)**

A. D. Roth, A. Ivanova, D. R. Colman; Montreal Neurological Institute, McGill University, Montreal, PQ, Canada

Axonal ensheathment by myelinating cells produces sections along axons with different electrical resistances: low resistance nodes of Ranvier and myelin-surrounded high resistance internodes. This arrangement allows action potentials to "jump" from one node to the next, resulting in faster

transmission along axons of smaller diameter and lower metabolic costs when compared to non-myelinated axons. Myelin formation, deposition and maintenance is dependent on the establishment of two structurally and biochemically discernible domains: a) compact myelin: multilamellar stacks of plasma membrane sheets, and b) non-compact myelin: cytoplasmic channels that border the compact myelin domains, attach them to the cell body and participate in anchoring the myelin sheath to the axonal membrane. In order to identify proteins involved in the organization of these domains we took advantage of the high lipid content of compact myelin to cleanly separate it from other neural membranes. Proteins were characterized by reverse-phase HPLC coupled to Electro-Spray Double Mass Spectrometry ("MudPit"). 122 proteins were detected and classified: 9 were classic myelin markers including proteolipid protein and myelin basic protein, (which together make up 75% of CNS myelin proteins). The rest of the proteins were: 20% known plasma membrane, 54% cytosolic and 19% mitochondrial. We focused on the septin family of small GTPases because of their involvement in formation of diffusion barriers in mammalian cells and confirmed the presence of Septins 7 and 8 in CNS and PNS myelin. We show that Septin7 is distributed through cytoplasmic channels of myelinated tracts (CNS and PNS) and that its levels increase as sciatic nerves mature. We propose that this protein may be involved in the formation of the sharp border between compacted and non-compacted myelin.

2634

**Partitioning of the Endoplasmic Reticulum during Cell Division**

M. K. Rantanen, H. Vihinen, E. Jokitalo; Electron Microscopy Unit, Institute of Biotechnology, Helsinki, Finland

Partitioning of the major subdomains of the endoplasmic reticulum (ER) - the nuclear envelope (NE), rough and smooth ER - in animal cells during cell division is poorly understood. Electron microscopic data suggests partial fragmentation of the membranes in some cell types. On the other hand, light microscopy shows that after NE breakdown (NEBD) some of NE components disperse into ER which remains continuous throughout the cell division. It is not known, however, whether NE proteins spread evenly throughout ER, or, whether ER network organization itself changes during cell division. NE and peripheral ER of interphase and mitotic Chinese hamster ovary cells were studied with light and electron microscope. Live cells carrying either NE or total ER labels were imaged in three dimensions with the confocal microscope. Three-way-junctions representing the degree of ER networking and tubule lengths of ER profiles in confocal optical sections were quantified. Similarly labelled fixed cells were used to model ER structures by 3D electron tomography. In confocal images, ER of the dividing cells appeared tightly networked and quantification showed there were more three-way-junctions and short tubules than in interphase cells. The labelling pattern of the NE protein lamin B receptor resembled that of total ER labelling after NEBD to the end of anaphase. After that it accumulated on NE surrounding the chromosomes. Electron tomography revealed the continuity of ER in dividing cells. It also confirmed dispersion of the NE label into ER after NEBD. However, the distribution of this label was not homogeneous: stained and unstained ER tubules were directly continuous with each other. These observations suggest the ER organization of the dividing cells is different from that of interphase cells, which may be required to ensure even distribution of ER to both daughter cells.

2635

**mRNA Mis-targeting to ER Subdomains Disrupts Correct Protein Deposition in Rice Endosperm Cells**

H. Washida,[1] A. Sugino,[1] A. J. Crofts,[1] N. Crofts,[1] M. Satoh,[2] M. Ogawa,[3] T. Kumamaru,[2] H. Satoh,[2] T. W. Okita[1]; [1]Institute of Biological Chemistry, Washington State University, Pullman, WA, [2]Faculty of Agriculture, Kyushu University, Fukuoka, Japan, [3]Department of Life Science, Yamaguchi Prefectural University, Yamaguchi, Japan

RNA localization is utilized for the synthesis of distinct classes of storage proteins and their efficient packaging within separate endomembrane compartments in developing rice endosperm cells. Prolamine RNAs are targeted to the spherical protein body ER which bounds the newly assembled prolamine polypeptides whilst glutelin RNAs are enriched on adjacent cisternal ER. Following translocation into the ER lumen, glutelin precursors are routed via the Golgi to the protein storage vacuole (PB-II). This relationship between RNA and protein localization within the endomembrane system exists for all RNAs examined to date with one exception. *in situ* RT-PCR and confocal microscopy analysis revealed that the 26 kD α-globulin mRNA is localized to PB-ER but the protein is not retained within this subdomain. Instead, it is rapidly exported to the Golgi and transported to PB-II. Analysis of RNA targeting mutants in rice provides the cellular basis for this unique relationship between globulin RNAs and their coded proteins. When globulin or glutelin RNAs co-exist on the same ER subdomain due to mis-localization of one of the RNAs, normal protein export from the ER and transport to PB-II are disrupted. Both globulin and glutelin proteins are observed in large dilated ER structures and at the cell's periphery. Hence, localization of globulin and glutelin RNAs to separate ER subdomains is essential for PB-II biogenesis and suggests that globulin and glutelin proteins are transported to PB-II by separate pathways.

## Exocytosis: Regulated Secretion (2636-2651)

2636

**Caveolin-1 is a Novel Regulator of Cdc42 and Targets Granules to Active Fusion Sites in Pancreatic β-Cells**

A. K. Nevins, D. C. Thurmond; Biochemistry and Molecular Biology, Indiana University School of Medicine, Indianapolis, IN

Insulin exocytosis is a tightly regulated process whereby upon stimuli intracellular granules translocate and fuse to the plasma membrane via SNARE proteins. However, the specific targeting of granules to active sites of exocytosis in a stimulus-dependent manner remains unknown. Recent studies have suggested that caveolae function as microdomains for cellular signaling and regulation of SNARE-mediated vesicle/granule exocytosis in numerous cell types. To investigate the potential requirement for caveolae in regulated insulin granule exocytosis from pancreatic β-cells, we studied interactions amongst the resident caveolar protein Caveolin-1 (Cav-1), Cdc42 and SNARE proteins and compared these structural interactions with their functional importance in glucose-stimulated insulin secretion. Subcellular fractionation analyses of MIN6 β-cells revealed Cav-1 distribution in both the plasma membrane and insulin granule fractions. Co-immunoprecipitation analyses revealed that Cav-1 associated with Cdc42-VAMP2 bound insulin granules in a glucose-dependent manner. Cav-1 interacted preferentially with GDP-bound GST-Cdc42 in pulldown analyses, and mutation/deletion of the Cav-1-scaffolding domain ablated this interaction. Sequence analysis of Cav-1 revealed a guanine nucleotide dissociation inhibitor (GDI) motif in the scaffolding domain and treatment of cells with GGTI-2147, a geranylgeranylation inhibitor resulted in a significant loss of Cdc42-Cav-1 binding. Functionally consistent with a role for Cav-1 as a Cdc42 GDI, siRNA-mediated depletion of endogenous Cav-1 increased basal insulin secretion by ~40%. Moreover, in Cav-1-depleted cells expression of the wild-type Cav-1 but not the

Cav-1 scaffolding domain mutant (F92A/V94A) compensated for the depletion and restored basal secretion. Taken together, these data support a model whereby Cav-1 interacts with the Cdc42-VAMP2 bound insulin granule complex and may contribute to the specific targeting of granules to active sites of exocytosis organized by caveolea and suggests that Cav-1 acts as a guanine nucleotide dissociation inhibitor to maintain basal secretion.

2637

**A Synapsin IIb Site 1 Phosphorylation Mutant Blocks Retention but not Insulin-Stimulated Release of GluT4 Vesicles**

J. M. Muretta, I. Romenskaia, C. C. Mastick; Biochemistry, University of Nevada, Reno, Reno, NV

Intracellular retention of GluT4 under basal conditions is a key mechanism for controlling glucose metabolism in adipocytes. However, the proteins regulating this process remain unknown. In neurons, the synapsin family of phosphoproteins are proposed to regulate synaptic vesicle (SV) traffic. Synapsins cluster SVs by binding to both vesicles and other synapsin molecules. Phosphorylation at serine 9/10 decreases their affinity for SVs, and is proposed to be a mechanism for stimulated release of the tethered vesicles. Synapsin 1 is expressed in liver epithelial cells and pancreatic β-cells, as well as in neurons. We found that adipocytes express synapsin IIb (protein and mRNA). Over-expression of phosphorylation mutant synapsin IIb (S10A) caused GluT4 vesicles to redistribute into perinuclear clusters. Unexpectedly, however, it also increased the amount of GluT4 at the plasma membrane (PM) 3-4 fold in basal cells. The surface content of the transferrin receptor (TfR) was unchanged. The GluT4 at the PM continually exchanged with the GluT4 in the perinuclear clusters under basal conditions. Furthermore, the GluT4 translocated out of the perinuclear clusters in response to insulin, with a further 2.5-fold increase at the PM. In control cells, insulin increased PM GluT4 6.5-fold. Insulin also increased PM TfR 2.5-fold, which was unaffected by S10A synapsin. After insulin stimulation, the levels of GluT4 at the PM, as well as its rates of exocytosis and endocytosis were the same in control cells and in cells over-expressing either WT or S10A synapsin. Additional data suggest that expression of S10A synapsin in adipocytes redistributes GluT4 from specialized storage compartments into the endosome where it co-localizes with TfR. We propose that synapsin may have a general function in recycling proteins from the endosome back into specialized compartments (i.e. GluT4-vesicles and SVs).

**Small GTPase RNAi Screen of Insulin-mediated Insertion of GLUT4 into the Plasma Membrane of 3T3L1 Preadipocytes**

M. N. Teruel,[1] M. Kim,[1] A. Tengholm,[2] A. Salmeen,[1] T. Meyer[1]; [1]Molecular Pharmacology, Stanford University School of Medicine, Stanford, CA, [2]Medical Cell Biology, Uppsala University, Uppsala, Sweden

The glucose transporter GLUT4 is a primary mediator of glucose uptake in muscle and fat tissue, and its insulin-triggered translocation from intracellular vesicles to the plasma membrane is likely relevant for attacking diseases such as diabetes and obesity. The molecular mechanisms that control GLUT4 trafficking still need to be elucidated. Using the Dicer method [1], we constructed a library of siRNA against 430 mouse small GTPases, GEFs, and GAPS. We co-transfected this library into 3T3L1 preadipoctes together with cDNA encoding YFP-GLUT4 with an HA-tag inserted in the first extracellular loop. We measured the amount of plasma membrane inserted GLUT4 before and after insulin stimulation by using a fluorescently-labelled antibody to the HA-tag [2]. Imaging was carried out in 96-well and 384-well format using an Axon ImageXpress automated epifluorescence imaging system. We have identified a number of small GTPases, GEFS, and GDIs with potential roles in different steps of GLUT4 transport, insertion, and recycling. [1] Myers et al. (2003) Nat Biotechnol. 21:324-8. **Examination of Complexin Function during SNARE-mediated Fusion In Vitro**

J. Schaub, J. Liao, J. A. McNew; Biochemistry and Cell Biology, Rice University, Houston, TX

The specific assembly of cognate SNARE proteins drives the fusion of synaptic vesicles with the presynaptic plasma membrane in neurotransmission. Syntaxin1A and SNAP25 form a t-SNARE complex localized to the plasma membrane that specifically pairs with the v-SNARE, VAMP2/synaptobrevin, located on the synaptic vesicle. We have been characterizing fusion driven by neuronal SNARE proteins and the accessory proteins involved in this process, specifically the neuronal regulatory proteins called complexins. The complexin isoforms are proteins found in the cytosol of neurons that bind to the assembled neuronal SNARE complex; however, the functional consequences of this association have yet to be determined. We utilize an in vitro fusion assay using reconstituted syntaxin1A/SNAP25 and VAMP2 to determine the effects of complexin on neuronal SNARE mediated fusion. When Drosophila melanogaster complexin, expressed in E. coli and purified by affinity chromatography, is added to fusion reactions containing mammalian neuronal SNAREs fusion activity is modestly, but reproducibly decreased. However, the addition of complexin to fusion reactions containing the homologous yeast plasma membrane SNARE proteins Sso1p/Sec9c;Snc2p does not inhibit fusion. Order of addition experiments suggest that complexin must be present as the v-t SNARE complex forms for inhibition to occur, in agreement with the observation that complexin binds primarily to the assembled ternary SNARE complex.

**Assembly and Disassembly of the SNARE Complex Revealed at nm-Resolution**

A. M. Jeremic,[1] A. S. Quinn,[2] W. J. Cho,[1] D. J. Taatjes,[2] B. P. Jena[1]; [1]Department of Physiology, Wayne State University School of Medicine, Detroit, MI, [2]Department of Pathology and Cell Imaging Facility, University of Vermont, Burlington, VT

Target membrane proteins, SNAP-25 and syntaxin (t-SNAREs) and secretory vesicle-associated protein (v-SNARE), are part of the conserved protein complex involved in membrane fusion process. Results from our previous studies demonstrate that t-SNAREs and v-SNARE, when present in opposing bilayers, interact in a circular array to form conducting pores. The size of SNARE supramolecular complex formed is directly proportional to vesicle diameter. To further understand the dynamics and structural arrangement of SNARE complex following membrane fusion, the role of NSF (N-ethylmalemide-sensitive factor) in SNARE complex disassembly was explored. High-resolution imaging using atomic force microscopy (AFM) of single SNARE complexes formed on lipid membrane reveals distinct rings, each measuring a few nanometers in diameter. Addition of recombinant NSF and ATP to the incubation mixture results in rapid disassembly of the SNARE complexes. To further confirm this disassembly, immunochemical studies were performed. Immunoblot analysis demonstrates complete disassembly of SNARE complexes upon

addition of NSF and ATP. NSF alone, or NSF in the presense of the non-hydrolyzable ATP analog AMP-PNP, had no significant effect on the SNARE complex ($p>0.05$, n=4, Student's *t*-test), suggesting an enzymatic and energy-driven process. To further explore the effect of NSF on SNARE-mediated lipid-lipid interactions, real-time light scattering measurements of interacting t-SNARE and v-SNARE reconstituted vesicles in solution were performed. Similar to AFM and immuno blot studies, addition of NSF and ATP to the t/v-SNARE-vesicle mixture led to a rapid and significant increase in intensity of light scattering ($p<0.01$, n=3, Student's *t*-test), suggesting disassembly of the SNARE complex and dissociation of vesicles. These results demonstrate that NSF works downstream to the membrane fusion event, allowing rapid retrieval of secretory vesicles from the fusion site. Supported by NIH grants (BPJ).

**Soluble Forms of SNAP-25 Reveal Specific SNARE Interactions and Dynamic SNARE Function in Secretion**

L. Wang, M. A. Bittner, M. W. Allersma, R. W. Holz; Pharmacology, University of Michigan, Ann Arbor, MI

Syntaxin, SNAP25, and synaptobrevin/VAMP form a core complex which plays an essential role in exocytosis. The steps in core complex formation are unknown. We investigated the ability of the two SNARE motifs of SNAP25 to bind VAMP2 and syntaxin1a in cells. The SNAP25 constructs were labeled with GFP variants and transiently expressed in Hek293T cells. In the absence of other transfected SNAREs, the N- and C-termini of SNAP25 (SN1 and SN2, respectively) had a diffuse cytosolic localization with little or no plasma membrane binding. Transiently expressed VAMP2 and syntaxin1a were localized to the plasma membrane as well as to other cellular membranes. In co-transfection experiments, SN1 colocalized with syntaxin on cellular membranes including the plasma membrane but not with VAMP. SN2 colocalized with either VAMP2 or syntaxin1a. When transiently expressed in chromaffin cells, SN2 was predominantly cytosolic, but with some binding to the plasma membrane in ~20% of the cells. In contrast, transiently expressed GFP-SNAP25 (full length) predominantly localized to the plasma membrane in chromaffin cells. Permeabilization resulted in the rapid loss (within seconds) of Cit-SN2 but not GFP-SNAP25. GFP-SNAP25 and Cit-SN2 (both with a mutation to render them resistant to botNT/E) protected nicotinic agonist-induced secretion from inhibition by the toxin. Thus, SN2 domains in both constructs can function in SNARE reactions leading to fusion. However, in permeabilized cells, GFP-SNAP25 but not Cit-SN2 rescued $Ca^{2+}$-dependent secretion, consistent with their abilities to remain in permeabilized cells. Conclusion: SNARE complex formation is a dynamic process, in which SN2 captures VAMP during formation of the core SNARE complex.

2642

**Cdc42 and Actin Control Polarized Expression of TI-VAMP-vesicles to Neuronal Growth Cones and Their Fusion with the Plasma Membrane**

T. Galli,[1] P. Alberts,[1] R. Rudge,[1] C. Gauthier-Rouvière,[2] T. Eirinopoulou[3]; [1]Cell Biology, Institut Jacques Monod, Paris, France, [2]Rho GTPases, Adhesion and Skeletal Muscle, CRBM-CNRS FRE 2593, Montpellier, France, [3]Inserm u536, Institut du Fer-à-Moulin, Paris, France

Tetanus neurotoxin Insensitive-Vesicle Associated Membrane Protein (TI-VAMP)-mediated fusion of intracellular vesicles with the plasma membrane is crucial for neurite outgrowth, a pathway not requiring tetanus neurotoxin-sensitive synaptobrevin-dependent exocytosis. Yet, it is not known how the TI-VAMP membrane trafficking pathway is regulated or how it is coordinated with the cytoskeletal dynamics that guide neurite outgrowth from the growth cone. Here, we demonstrate that TI-VAMP, but not synaptobrevin 2, concentrates in the peripheral, F-actin-rich region of the growth cones of hippocampal neurons in primary culture. Its accumulation correlates strictly with and depends upon the presence of F-actin as shown by the effect of actin sequestering drugs. Expression of a dominant-positive mutant of Cdc42, a key regulator of cell polarity, stimulates formation of F-actin- and TI-VAMP-rich filopodia outside the growth cone, an effect not seen when expressing Rac1 or RhoA dominant-positive mutants. Furthermore, we report that Cdc42 directly activates actin-dependent exocytosis of TI-VAMP-containing vesicles by imaging pHLuorin-tagged TI-VAMP. Collectively, our data indicate that Cdc42 and regulated assembly of the F-actin network control the accumulation and exocytosis of TI-VAMP-containing membrane vesicles in growth cones and suggest that membrane trafficking and actin remodeling are coordinated in neurite outgrowth.

2643

**Nucleotide-dependent Dissociation of Secretory Vesicles from the Plasma Membrane**

W. Cho, A. Jeremic, B. P. Jena; Department of Physiology, Wayne State University School of Medicine, Detroit, MI

Exocytosis is a fundamental cellular process that involves fusion of membrane-bounded secretory vesicle with fusion pores or porosomes and the expulsion of intravesicular contents. However, the fate of secretory vesicles following content discharge is less clear. In this study, we examined the dissociation of synaptic vesicles (SV) at the presynaptic membrane. To study SV turnover at the nerve terminals, high-resolution imaging of isolated synaptosomal membrane with docked synaptic vesicles were carried out using atomic force microscopy (AFM). Role of ATP-ase NSF, and the GTP-ase dynamin on SV-associated synaptosomal membrane was investigated. Exposure to ATP or GTP resulted in partial detachment of docked SV from the synaptosomal membrane. Simultaneous addition of ATP and GTP, however, led to significant release of the docked vesicles ($p<0.01$, n=4, Student's *t*-test). Addition of non-hydrolyzable ATP and GTP analogs had no significant effect on the dissociation of vesicles, suggesting an energy-dependent enzymatic-coupled process. Quantitative biochemical analysis of isolated synaptosomal membrane and synaptic vesicle fractions further confirmed detachment of docked SV upon addition of ATP and GTP. Similar results were also obtained using isolated plasma membranes of exocrine pancreas, suggesting a universal mechanism in the dissociation of secretory vesicles from the cell plasma membrane. Finally, immunoprecipitation studies using specific SNAP-25 antibody followed by western blot analysis, confirm the association of NSF and dynamin with SNAREs. Therefore, close proximity of NSF and dynamin to the SNARE complex along with their ability to efficiently dislodge secretory vesicle from fusion site suggests their role in cell secretion. Supported by NIH grants (BPJ).

**Structural and Functional Insights into the Exocyst Protein Sec6p**

S. V. S. Mylavarapu, J. A. Saporita, M. Munson; Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA

In eukaryotic cells, small membrane-bound vesicles transport membrane and luminal cargo between intracellular organelles and to the cell surface.

Polarized exocytosis at specific sites on the plasma membrane requires a conserved, eight-subunit protein complex called the exocyst. Exocyst assembly at sites of secretion is essential for tethering the vesicle to the plasma membrane, prior to SNARE-mediated membrane fusion; it may also play a direct role in the SNARE complex regulation. The exocyst shares functional homology with tethering complexes that operate in other intracellular trafficking pathways. Moreover, its sequence conservation suggests a fundamentally important exocytic function in all eukaryotes. However, the structure, mechanisms of action, subunit organization and specific functions of the exocyst are unknown. Molecular characterization of the exocyst subunits individually and in combination is imperative for elucidation of the exocyst's function. Towards this end, we have biochemically and structurally characterized the yeast exocyst subunit Sec6p. Sec6p forms stable homodimers both *in vitro* and *in vivo*. Its N-terminal domain contains the dimerization region and interacts with the t-SNARE Sec9p. The C-terminal half of Sec6p is monomeric in solution and forms an independently folded structural domain (6CT). We have recently determined the crystal structure of this 6CT domain. 6CT is organized into three distinct helical bundles, with prominent solvent-exposed loops. Using structure-based sequence alignments, we identified a patch of highly conserved surface residues on one face of the structure. These residues likely mediate interactions with Sec6p's binding partners *in vivo*; studies are in progress to identify these partners. We have introduced site-specific mutants of these residues individually and combinatorially into yeast, to elucidate their physiological importance for Sec6p's function. The results from these studies will provide a framework for understanding the function of the exocyst at the molecular level.

**Measurement of the Diameter of the Exocytotic Fusion Pore in the Pancreatic Acinar Cell**

J. A. Pickett, J. M. Edwardson; Department of Pharmacology, University of Cambridge, Cambridge, United Kingdom

In the pancreatic acinar cell, acetylcholine stimulates the fusion of zymogen granules with the apical plasma membrane, leading to the secretion of digestive enzymes. Exocytosis is inhibited by clostridial neurotoxins, highlighting the involvement of SNAREs in this process. Exocytotic membrane fusion in the acinar cell has several unusual characteristics, including the extraordinary stability (several minutes) of the fused granule, and the occurrence of compound exocytosis. We have used fluorescent membrane-impermeant dyes of various sizes to estimate the diameter of the exocytotic fusion pore. A lysine-fixable, 3,000 molecular weight (MW), Texas Red-dextran conjugate was used as an extracellular tracer for fused zymogen granules. Following acetylcholine stimulation, Texas Red-dextran labeled many exocytotic structures at the apical plasma membrane. The diameter of the open fusion pore was assessed by looking for co-localization of Texas Red-dextran (3,000 MW) with fluorescein-labeled dextran conjugates of various sizes: 3,000 MW (diameter ~2.5 nm), 70,000 MW (~11 nm), 500,000 MW (~28 nm), and 2,000,000 MW (~54 nm). All of the fluorescein-labelled dextran conjugates co-localized with Texas Red-dextran in the lumen of fused zymogen granules, but to varying extents. In particular, some, but not all, of the Texas Red-dextran positive granules were also positive for the 500,000 and 2,000,000 MW fluorescein dextrans. There was no difference between the labeling of primary or secondary fused zymogen granules. Our results show that the exocytotic fusion pore in the pancreatic acinar cell has a diameter exceeding 50 nm, suggesting that the pore radially expands to a stable state after the initial SNARE-dependent interaction between the two membranes.

**Role of Calpain-10 as a Calcium Sensor in Exocytosis**

E. Aganna,[1] C. Marshall,[1] G. A. Hitman,[1] J. Burrin,[2] M. D. Turner[1]; [1]Diabetes and Metabolic Medicine, Queen Mary, University of London, London, United Kingdom, [2]Molecular Endocrinology, Queen Mary, University of London, London, United Kingdom

OBJECTIVE The molecular control of exocytosis by Ca2+-sensors in stimulus-secretion coupling is poorly defined. We present new data detailing calpain-10's contribution to these events. METHODS We examined the functional consequence of calpain-10 (CAPN10) overexpression and inhibition upon insulin secretion from INS-1 pancreatic beta-cells. We went on to compare CAPN10 expression profiles in INS-1 cells and two pituitary cell-lines, corticotropes (AtT20) and lactotropes (GH3), with their respective secretory profiles. RESULTS INS-1 basal secretion remains unaltered regardless of CAPN10 expression level. There is however a marked increase in stimulus-dependent regulated secretion that correlates with the extent of overexpression within physiological boundaries. Insulin secretory granule exocytosis is mediated by soluble N-ethyl maleimide sensitive fusion protein attachment receptor (SNARE) proteins. The t-SNAREs SNAP-25 and syntaxin 1 both co-immunoprecipitate with a ~ 54kDa membrane-associated calpain-10 isoform, indicating that calpain-10 is directly bound to the exocytotic granule fusion machinery. Furthermore there is a Ca2+-dependent partial proteolysis of SNAP-25 during exocytosis, which like regulated secretion itself is similarly sensitive to pharmacological calpain inhibition. Western analysis revealed a differential expression pattern between the 3 cell-lines, with the ~ 54 kDa calpain-10 isoform similarly expressed in the membrane fraction of both INS-1 and GH3 cells, but markedly reduced in AtT20 cells. This observation is consistent with secretion results, where calpain protease inhibitor similarly surpresses regulated secretion from both INS-1 and GH3 cells, but not AtT20 cells. CONCLUSION We hypothesise that calpain-10 is a Ca2+-sensor that mediates exocytosis in multiple endocrine cells. However it is not essential for exocytosis in all endocrine cells, thereby suggesting the participation of multiple Ca2+-sensors in stimulus-secretion coupling.

**Calcium Signals Associated with 1,25D-Regulated Exocytosis in Osteoblasts**

P. Biswas, L. P. Zanello; Biochemistry, University of California-Riverside, Riverside, CA

The hormonally active form of vitamin D, 1α,25dihydroxy vitamin $D_3$ (1,25D), is considered a bone anabolic hormone. Osteoblasts produce and secrete a variety of bone matrix proteins. 1,25D increases bone matrix production by acting at the cell nucleus. In addition, 1,25D rapidly stimulates secretion of bone materials via nongenomic mechanisms initiated at the plasma membrane of bone cells. The present study investigates molecular pathways involved in 1,25D-regulated exocytosis in primary calvarial osteoblasts and osteosarcoma ROS 17/2.8 cells. Regulated type of secretion occurs as a rapid fusion of vesicles to the plasma membrane in response to a specific electrical or chemical stimulus. We found a rapid (seconds) exocytotic response triggered by nanomolar concentrations of 1,25D. Single exocytosis events were monitored in real time with confocal microscopy performed on live osteoblasts. Secretory granules were stained with 3 μM quinacrine. In addition, 1-100 nM 1,25D promoted a significant (2-fold) capacitance increase in single primary osteoblasts, as measured with patch-clamp techniques. Nifedipine (2 μM) and DIDS (200 μM) significantly reduced 1,25D-promoted capacitance changes, suggesting that this is associated with $Ca^{2+}$ and $Cl^-$ channel activation. Elevation

of cytoplasmic $Ca^{2+}$ by 10 nM 1,25D was measured with flow cytometry in large populations ($10^7$ cells) of ROS 17/2.8 cells labeled with the cell permeable $Ca^{2+}$-sensitive dye Fluo 3-AM. We conclude that a Ca signal is therefore likely to be the transducer of the hormonal stimulus into an electrical signal coupled to a rapid exocytotic response in osteoblasts. The anabolic effects of 1,25D can therefore be explained in part at the nongenomic level as a rapid promotion of exocytosis of bone materials by the hormone.

**Rab27a and its Effector JFC1 Regulate Exocytosis in Human Neutrophils**

J. L. Johnson, D. B. Munafo, B. A. Ellis, S. D. Catz; Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA

Neutrophils play a central role in innate immunity by combating bacterial infections. Neutrophils kill microorganisms using microbicidal products that they release into the phagosome or the extracellular space. Mature neutrophils contain four types of exocytosable storage organelles: azurophilic granules [that contain myeloperoxidase (MPO)], specific granules, gelatinase granules and secretory vesicles. Since the uncontrolled release of the contents of these organelles is potentially harmful, granule exocytosis must be tightly regulated. However, the secretory machinery utilized by neutrophils is poorly characterized. The objective of this work is to characterize the role of Rab27a and JFC1 in the regulated secretion of neutrophils. Here, we show that JFC1 and Rab27a are highly expressed in human neutrophils. While Rab27a distribution is restricted to the membrane fraction after cell fractionation, JFC1 is distributed between the membrane fraction and the cytosol. Colocalization of endogenous JFC1 and Rab27a was observed by immunofluorescence analysis. Furthermore, when a two-layer Percoll gradient was used to separate the subpopulations of granules, JFC1 and Rab27a were mainly associated with the tertiary granules ($\gamma$ fraction) which are enriched in MMP-9 and cytochrome b558. A small proportion of the MPO-positive granules (~5%) were also detected in this fraction. The introduction of the plasma membrane binding domain (C2A domain) of JFC1 into permeabilized neutrophils significantly decreased exocytosis, however, neither Rab27a nor JFC1 integrated to the phagolysosome when neutrophils were exposed to opsonized particles, suggesting that the granules implicated in cargo release towards the surrounding milieu are molecularly and mechanistically different from those involved in their release towards the phagolysosome. Finally, the expression of JFC1 and Rab27a in HL-60 promyelocytic cells is dramatically increased when they are differentiated to neutrophil-like granulocytes, thus further supporting a role for these proteins in the secretory machinery of granulocytes.

**Inhibition of the Vacuolar $H^+$-ATPase by Bafilomycin A1 Disrupts Targeting of Soluble and Membrane Proteins to Regulated Secretory Granules**

J. A. Sobota, B. A. Eipper, R. E. Mains; Neuroscience, University of Connecticut Health Center, Farmington, CT

The vacuolar $H^+$-ATPase (V-ATPase) is responsible for establishing and maintaining the pH gradient along the secretory and endocytic pathways. In the regulated secretory pathway, progressive acidification is thought to be important for proteolytic processing of prohormones, aggregation of soluble content, and secretory granule biogenesis. In order to investigate the role of the V-ATPase in targeting of soluble and membrane secretory proteins to granules, the pH gradient in AtT20 corticotrope cells expressing endogenous proopiomelanocortin was dissipated pharmacologically with the selective V-ATPase inhibitor bafilomycin A1. Alkalinization was verified by labeling cells with LysoSensor Green; fluorescence was abolished by 24 hour preincubation with nanomolar concentrations of bafilomycin. Following this treatment paradigm, localization of endogenous and GFP-tagged soluble secretory cargo was evaluated by confocal microscopy; both accumulate in large LAMP-1 positive structures with diameters up to 4μm. Granule membrane proteins similarly accumulate in these structures. The morphology of the trans-Golgi network remains intact. New protein synthesis is required for these effects, as concurrent treatment with bafilomycin and cycloheximide prevents formation of these structures and does not affect existing granules. Cells recover from drug treatment within 4 hours; the content of the enlarged structures is degraded, while newly synthesized secretory proteins are localized in granules. Secretory granules do not form during bafilomycin treatment, and the content of the LAMP-1 positive structures does not undergo regulated secretion. Constitutive secretion remains comparable to untreated cells. Alkalinization by chloroquine and ammonium chloride treatment does not induce these effects on secretory protein trafficking. Since these effects are specific to bafilomycin, we conclude that the V-ATPase, but not necessarily V-ATPase-mediated acidification, is required for proper targeting of newly synthesized soluble and membrane proteins to regulated secretory granules. Supported by DE017094-01, DK32948.

**Modification of ATP Synthase Alpha Is Associated with Stimulated Acid Secretion by Gastric Glands**

L. Zhu,[1] S. Karvar,[1] J. Trinidad,[2] V. Lao,[1] A. L. Burlingame,[2] J. G. Forte[1]; [1]Molecular & Cell Biology, University of California, Berkeley, CA, [2]Department of Pharmaceutical Chemistry, University of California, San Francisco, CA

Drastic morphologic and functional changes occur when gastric parietal cells secrete HCl. When cells are stimulated with histamine, the apical membrane is expanded, recruiting most of the H,K-ATPase-rich tubulovesicles to the apical membrane where active secretion occurs. Another advantage of this material for studying proteomic changes is that the differences between resting and stimulated states can be maintained for extended periods. To get a global view of secretion-related changes, we prepared resting and stimulated gastric glands from rabbit. The quality of the material is ensured by assays of H,K-ATPase trafficking and acid secretion. Whole lysates from resting and stimulated glands were resolved by 2D electrophoresis. From Coomassie blue stained gels, the most pronounced difference between resting and stimulated samples was the pI shift of a 55kd protein. Although the percentage of the shift is different with different preparations, the 55kd protein repeatedly showed an acidic shift upon stimulation. In resting sample, much of the protein has an apparent pI of 8.3; in stimulated sample, the dominant mass was pI 7.7. We cut out the spots at pI 7.7, 8.0 and 8.3 for in-gel digestion and nano-LC-MSMS analysis. Results clearly identified these spots as ATP synthase alpha subunit. Western blot analysis confirmed the above results. Furthermore, ATP synthase shifted to a more basic value upon phosphatase treatment supporting phosphorylation modification. Western blot with anti-phospho-antibodies indicated that ATP synthase alpha is not Tyrosine phosphorylated, but possibly Serine-phosphorylated. We propose that there is a previously unrecognized mechanism of active regulation of ATP synthase, involving modification of the alpha subunit in a way that adds one or more negative charges. Active regulation of ATP synthase may be necessary for parietal cells to meet the energy demand of stimulated acid secretion.

### Function of Parafusin and Its Modifications in Exocytosis

L. Liu, B. H. Satir; Anatomy & Structural Biology, Albert Einstein College of Medicine, Bronx, NY

Parafusin (PFUS), a phosphoglycoprotein involved in $Ca^{2+}$-regulated exocytosis is regulated by phosphorylation and phosphoglucosylation. One of its orthologs *P*arafusin *R*elated *P*rotein 1 (PRP1) in *Toxoplasma gondii* is used here. To investigate the effects of protein modifications in exocytosis, an ortholog assay was developed. Purified recombinant His-tagged PRP1, labeled with $Alexa_{488}$, was electroporated into live *Paramecium* wt and localization observed by fluorescent microscopy. Like PFUS in wt cells, PRP1 localizes to docked secretory vesicles under the cell membrane. When stimulated, PRP1 becoming cytosolic. In a series of RNAi experiments we here test if knockdown of PFUS would result in an effect on exocytosis. A potential $exo^-$ phenotype could be derived from the knockdown in wt cells and reversal could be tested by electroporating PRP1 or PFUS into the $exo^-$ cells in complementation studies. The method chosen is RNA interference by feeding, as outlined in the paramecium database (http://paramecium.cgm.cnrs-gif.fr/RNAi/). We targeted three different regions of the PFUS sequence: the C-terminal (0.8 kb), the N-terminal (1.0 kb) and the entire open reading frame (1.8 kb). As a control we used the empty RNAi vector (LITMUS 28i). Exocytosis was scored after stimulation with trinitrophenol. Initial experiments using RNAi by feeding show that compared to controls after about 3-4 generations of growth roughly half the cells show only release from the anterior and posterior end of the cells (A/P phenotype) while the other half of the cell population is totally inhibited. Overall, exocytosis becomes inhibited with all three RNAi constructs compared to the control. Interestingly, inhibition progresses identically in a specific pattern with all three RNAi's.

## Caveolae (2652-2665)

2652

### Glycosphingolipid Structure and Plasma Membrane Microdomains: Determinants for Caveolar Endocytosis

R. D. Singh,[1] C. L. Wheatley,[1] E. L. Holicky,[1] Y. Liu,[2] D. L. Marks,[1] R. Bittman,[2] R. E. Pagano[1]; [1]Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN, [2]Chemistry and Biochemistry, Queens College of CUNY, Flushing, NY

Caveolae are a subset of plasma membrane (PM) microdomains that are enriched in glycosphingolipids (GSLs) and cholesterol, and are associated with the protein caveolin-1. Caveolae are also involved in the clathrin-independent endocytosis of many membrane components (e.g., GSLs; β1-integrins) as well as some bacteria, viruses, and toxins. We have previously shown that fluorescent lactosylceramide (BODIPY-LacCer) and other GSL analogs are internalized almost exclusively *via* caveolae in human skin fibroblasts and other cell types. The molecular determinant for this selectivity is as yet unknown. We have systematically modified the structure of the GSL head group and sphingosine moiety and studied the endocytosis of these analogs. We found that the stereochemistry of the sphingosine base is critical for GSL uptake *via* caveolae. The two D-isomers of BODIPY-LacCer were taken up exclusively by caveolae while the two L-isomers underwent endocytosis *via* multiple mechanisms. Surprisingly, the non-natural L-*threo*-LacCer stereoisomer inhibited the caveolar internalization of other markers endocytosed by this mechanism. Finally, we utilized the monomer-excimer fluorescence of the BODIPY-analogs to investigate the formation of GSL microdomains at the surface of living cells. We show that only the D-LacCer analogs partition into plasma membrane microdomains induced either by CtxB clustering of endogenous $GM_1$ or by treatment with $C_8$-D-LacCer. Thus, partitioning of BODIPY-D-LacCer stereoisomers into specific microdomains correlated with their ability to be internalized *via* caveolae.

### The PKC Binding Protein SDPR is Involved in Caveolae Invagination

H. K. Zajicek, K. McMahon, K. Luby-Phelps, Y. Ying, Y. Taketani, R. G. W. Anderson; Cell Biology, UT Southwestern, Dallas, TX

Loss of PKCα activity from cells blocks caveolae internalization. Previously, we showed that caveolae contain the PKCα binding protein SDPR (alias SDR, serum deprivation response protein). SDPR binds with high affinity (~100 nM) the regulator domain of PKCα, binding is calcium dependent and it appears to be necessary for localization of PKCα to caveolae. SDPR is also a PKCα substrate. SDPR is a 68 kDa protein that contains a PKCα binding site (aa 145-250), a putative leucine zipper (aa 52-100) and a PEST domain (aa 22-48). Here we report that SDPR appears to be required for caveolae invagination. Knockdown of SDPR RNA by RNA interference caused a loss of invaginated caveolae from the surface of human fibroblasts, as determined by quantitative electron microscopy (EM). Two regions of SDPR where identified that are necessary for its correct targeting to caveolae. The first is the leucine zipper. Immunofluorescence showed that deletion of this region or substitution of critical leucine residues with alanine blocked SDPR targeting to caveolae. The second is a twelve amino acids long (aa 150-161) potential phosphatidylserine (PS) binding site. A truncated SDPR (aa 1-168), which lacks the PKCα binding site, was correctly targeted to caveolae while a peptide that is missing the PS binding site (1-145) did not. To see if peptide 1-168 had a dominant negative affect on caveolae function, human fibroblasts where transfected with either the 1-168 or the 1-145 peptide. Quantitative EM showed a marked loss of invaginated caveolae in the cells expressing 1-168 compared to those expressing 1-145. We conclude that SDPR is a PKCα binding protein in caveolae that regulates caveolae internalization.

2655

### Caveolae-like Endocytosis in the Protozoan Parasite *Entamoeba histolytica*

N. M. León-Sicairos, M. Reyes-Lopez, M. de la Garza; Biologia Celular, CINVESTAV-IPN, México, Mexico

Caveolae are plasmatic membrane invaginations that contain the caveolin protein and cholesterol and are found in most cell types. Caveoale participate in endocytosis and delivered of proteins and lipids to diverse organelles in cells. *Entamoeba histolytica* is a pathogenic protozoan that causes amoebiasis, disease responsible of 100,000 deaths by year worldwide. Endocytosis is an important event in the pathogenicity of *E. histolytica*, however, endocytosis via caveolae in this parasite has not been described. The objective of this study was to determine if *E. histolytica* contains a caveolae-like endocytosis system. **Methods:** Confocal microscopy and flow cytometry were used to immunolocalize the caveolin-like protein and quantify cholesterol; the main markers of caveolae in cells. Also, the participation of caveolae-like in amoebic endocytosis was corroborated and the traffic of caveolae-like cargo in early and late endosomes and lysosomes. Ultracentrifugation was done to obtain caveolae, inmunoprecipitation and immunoblot assays were used to identify caveolin-like protein in amoebas. **Results.** A co-localization between caveolin

and cholesterol in the amoebic membrane was found. In endocytosis experiments using lactoferrin coupled to fluorescein, we found the co-localization of the three markers (caveolin, cholesterol and lactoferrin), inside amoebas, but when amoebas were pre-incubated with filipin, a drug that disrupts cholesterol and then caveolae structure and function, lactoferrin was not endocytosed. Using anti-bodies against early and late endosomal compartments and against lysosomes, we found that caveolin co-localized with these vesicles at different times. **Conclusions:** Vesicles located in the membrane of amoebas are enriched in cholesterol and in a caveolin-like protein of 21 kDa. These vesicles participated in *E. histolytica* endocytosis events, were filipin sensitive, and incorporated the cargo in the route of endosomes/lysosome. With these data we propose the existence of an alternative endocytosis system based in caveoale-like vesicles in *E. histolytica.*

**Prostate Specific Membrane Antigen Associates with Caveolin-1 and Undergoes Caveolae-Dependent Internalization in Microvascular Endothelial Cells**

G. Anilkumar,[1] S. P. Barwe,[1] J. J. Christiansen,[1] S. A. Rajasekaran,[1] D. B. Kohn,[2] A. K. Rajasekaran[1]; [1]Pathology and Laboratory Medicine, University of California, Los Angeles, Los Angeles, CA, [2]Molecular Microbiology and Immunology, University of Southern California, Los Angeles, CA

Prostate Specific Membrane Antigen (PSMA) is a type II membrane protein expressed primarily in the secretory cells of the prostatic epithelium. PSMA expression is increased several fold in malignant disease, with the greatest levels observed in advanced tumors and androgen independent disease. PSMA is absent in most other tissues and cell types, including normal endothelial cells and pre-formed blood vessels, however, expression has been detected in the angiogenic sprouts of tumor-associated neovasculature for most solid cancers examined to date. This pattern of expression implies that PSMA may perform a functional role in angiogenesis and may offer a therapeutic target for the treatment of a broad spectrum of solid tumors. In an attempt to understand the significance of PSMA expression in the neovasculature, we have expressed PSMA in a well-characterized human microvascular endothelial cell line using retrovirus-mediated gene transfer. We have shown earlier that PSMA undergoes endocytosis via a clathrin-dependent mechanism in prostate epithelial cells. In this study, we demonstrate that PSMA associates with caveolin-1, a marker protein for caveolae; and that a substantial fraction of PSMA cosediments with the caveolar fraction, and undergoes internalization via a caveolae-dependent mechanism. The association between PSMA and caveolae in endothelial cells may provide important insight into PSMA function and ways to best exploit this protein for therapeutic benefit.

**A Domain at N-Terminus of Caveolin-1 Controls Rear Polarization of the Molecule in Migrating Endothelial Cells**

X. Sun, D. C. Flynn, J. Liu; Mary Babb Randolph Cancer Center, West Virginia University, Morgantown, WV

Caveolin-1, a caveolar membrane coating protein, plays an important role in signal transduction. Recently, we and others have shown that caveolin-1 polarizes at cell posterior in migrating endothelial cells and that caveolin-1 polarity is critical for endothelial cell migration. In this study, we generated a series of domain deletion mutants of caveolin-1 as GFP-fusion proteins and investigated domain or sequence that was required for caveolin-1 polarization in migrating cells. Our results demonstrate that $Cav_{1-178}$-GFP was polarized to the cell rear in migrating caveolin-1 deficient mouse embryonic fibroblasts (MEFs). In contrast, deletion of aa 1-60 prevented the molecule from polarization and, in turn, some of the mutant were located at the leading edge, suggesting that aa 1-60 were essential for caveolin-1 polarization. Interestingly, deletion of aa 1-60 did not prevent caveolin-1 polarization in HUVECs as well as Cav-1 wild-type MEFs, suggesting that $Cav_{61-178}$-GFP mutant might be interacting with endogenous caveolin-1 during polarization. Consistent with this, $Cav_{61-178}$-GFP and $Cav_{61-178}$-Flag were co-immunoprecipitated with endogenous caveolin-1. Furthermore, $Cav_{61-178}$ was incorporated into light membrane domains and mediated caveolae formation. Our results indicate that aa 1-60 in caveolin-1 were essential for its polarization in migrating cells.

**Recruitment of Caveolin-1 to Focal Adhesions Initiates Focal Adhesion Disassembly at the Trailing Edge of Migrating Cells**

A. R. Beardsley,[1] X. Sun,[1] L. M. Millecchia,[2] M. D. Schaller,[3] K. M. Bailey,[1] J. Liu[1]; [1]Mary Babb Randolph Cancer Center, West Virginia University, Morgantown, WV, [2]Pathology and Physiology Research Branch, National Institute for Occupational Safety and Health, Morgantown, WV, [3]Department of Cell and Developmental Biology, University of North Carolina, Chapel Hill, NC

Cells migrating on a planar surface develop a characteristic front-rear structural asymmetry with coordinate functions. Actin nucleation and lamellipod protrusion takes place at the cell leading edge while de-adhesion and retraction occur at cell posterior. De-adhesion is mediated by the weakening and loss of focal adhesions, but the molecular events precipitating focal adhesion disassembly are largely unknown. Recent studies have demonstrated the polarization of caveolin-1 to the rear of migrating endothelial cells. To better understand the function of polarized caveolin, we used live-cell imaging to observe human endothelial cells expressing caveolin-1 fused to green fluorescent protein (GFP). Time-lapse confocal and differential interference contrast imaging revealed concentration of polarized caveolin into trailing fibers that formed as the cells advanced. Caveolin-1 recruitment was followed immediately by retraction of the trailing fibers into the cell body. Further imaging of cells co-expressing caveolin-1 fused with red fluorescent protein and paxillin-GFP demonstrated that caveolin-1 was recruited specifically to focal adhesions, leading to sliding and disassembly of the adhesions. Furthermore, caveolin-1 ablation caused a defect in cell de-adhesion, as evidenced by an increase in length and persistence of trailing edges in migrating caveolin-1 null fibroblasts relative to wild-type cells. Altogether, the data suggest that polarized caveolin-1 functions to initiate de-adhesion at the cell rear during migration.

2659

**Inhibition of PI 3-kinase and Myosin II Blocks Caveolin-1 Polarity in Migrating Endothelial Cells**

W. Fu, J. Liu; Physiology and Pharmacology, West Virginia University, Morgantown, WV

Endothelial cell migration is a key step towards angiogenesis, a process that is required in a variety of physiological and pathological conditions, such as embryonic development, wound healing, tissue regeneration and tumor growth and metastasis. The precise mechanism of chemoattractant-induced directional movement of endothelial cells is largely unknown. Recently, we have demonstrated that caveolin-1 polarized at the rear of migrating endothelial cells and that loss of caveolin-1 polarity impeded endothelial cell directional movement. To examine signal pathways that

may affect caveolin-1 polarity, we treated human endothelial cells with specific inhibitors for PI 3-kinase such as wortmannin and LY294002. Treatment with wortmannin caused a dose-dependent inhibition of caveolin-1 polarization. At the concentration of 50nM, wortmannin inhibited the number of caveolin-1 polarized cells by 50%. To assess whether myosin II was involved in caveolin-1 polarization, we treated endothelial cells with a specific inhibitor for myosin II, blebbistatin, and show that blebbistatin inhibited the number of caveolin-1 polarized cells by more than 30%. Our results are consistent with the role of PI 3-kinase/Akt signaling in the control of cell polarity, myosin II assembly and chemotaxis.

**Cav-1 Downregulates Cox-2 Expression Level Through Proteasome Degradation Pathway**

S. Chen,[1,2] S. Shyue[2]; [1]National Defense Medical Center, Taipei, Taiwan Republic of China, [2]Institute of Biomedical Science, Taipei, Taiwan Republic of China

We have previously shown that interleukin-1β (IL-1β) induced cyclooxygenase-2 (COX-2) interacted and colocalized with caveolin-1 (Cav-1), the major component of caveolae. Numerous studies suggest that both COX-2 and Cav-1 play important roles in many diseases including tumorigenesis and maintenance of cardiovascular homeostasis. Although the degradation of COX-2 is important in regulation of its enzymatic activity and associates with many diseases status, study related to COX-2 degradation as well as its post-translational regulation remain mostly unknown. In this study, we investigated the effect of Cav-1 related to COX-2 expression and degradation. Although constitutive expressed COX-2 was suggested in HT-29 cells, low level of COX-2 was detected without induction. COX-2 can be induced by IL-1β to high level at 9 to 12 h and declined thereafter. In mock-transfected and control cells COX-2 levels and activities were increased with IL-1β induction. However, overexpression of Cav-1 significantly attenuated COX-2 expression and its activity. Since MG-132, a proteasome inhibitor, reversed the suppression effect of Cav-1, COX-2 degradation is mediated via the proteasome degradation pathway. Besides, COX-2 mRNA was not altered in Cav-1 overexpressed HT29 cells assayed by RT-PCR. These results suggest that Cav-1 plays an important role in regulating COX-2 expression by enhancing COX-2 degradation through the proteasome degradation pathway.

**Roles of Caveolin-1 and ABCA1 on Cholesterol Efflux in Rat Aortic Endothelial Cells**

Y. C. Lin,[1] W. W. Lin,[2] V. C. Yang[1]; [1]Department of Life Science, Tunghai University, Taiwan, Taichung, Taiwan Republic of China, [2]Division of Cardiology, Taichung Veterans General Hospital, Taiwan, Taichung, Taiwan Republic of China

Atherosclerosis is a most common cause of death in the world. Reducing accumulation of cholesterol in the arterial walls can prevent development of atherosclerosis. Caveolae, a small membrane invaginations on the cell surface, and ABCA1, a transmembrane protein, have both been implicated in the HDL-mediated cellular cholesterol efflux. However, the underlying mechanism in cholesterol efflux is still unknown. Our previous study demonstrates that ABCA1 may act as a structural platform between HDL and caveolin-1, the major structural component of caveolae, on the cell surface during cellular cholesterol efflux. In this study, the cholesterol efflux was evaluated by up-regulation and down-regulation of caveolin-1 gene expression in rat aortic endothelial cells (RAECs). For the up-regulation of caveolin-1 in ECs, pCAV-cDNA expression vectors were constructed and transfected into the cells with lipofectamine. The down-regulation of caveolin-1 was carried out by siRNA. The cholesterol efflux was determined in the [$^3$H]cholesterol-loaded ECs after the aforementioned treatments. Our results indicated that the cholesterol efflux increased about 32% in the caveolin-1 up-regulated cells and decreased about 30% in the siRNA-treated cells as compared with controls. We suggest that caveolin-1 is a positive regulator of cholesterol efflux in RAECs. We also found that the probucol, an inhibitor of ABCA1-mediated lipid efflux, could partially inhibit the cholesterol efflux in the caveolin-1 up-regulated cells. Furthermore, the caveolin-1 siRNA-treated cells down-regulated the expression of ABCA1 and disturbed the colocalization of ABCA1 and HDL. According to these results, we suggest that caveolin-1 and caveolae are necessary for the interaction between ABCA1 and HDL during cholesterol efflux.

**Expression of Caveolin-1 in Human T-cells**

H. M. Maldonado,[1] D. Sosa,[1] A. Rivera,[2] W. I. Silva,[3] G. Velazquez[3]; [1]Pharmacology, Universidad Central del Caribe, Bayamon, PR, [2]Physiology, Universidad Central del Caribe, Bayamon, PR, [3]Physiology, University of Puerto Rico, Medical Science Campus, San Juan, PR

Caveolin-1 (cav-1) has been recognized as a scaffolding protein that concentrates, organizes, and in some instances modulates the function of many membrane associated proteins including several signal transduction elements. Although its presence has been established in most cells, expression of this protein in T-cells remains controversial. In a recent report, a key role for cav-1 in T-cell HIV infection has been suggested (Hovanessian et al., Immunity 21:617, 2004). Moreover, several of the signal transduction pathways implicated in T-cell activation have also been associated with cav-1 in many other cells. In this report we present conclusive evidence of the presence of cav-1 in both the leukemic cell line Jurkat as well as human $CD4^+$, $CD8^+$, and $CD19^+$ lymphocytes. Expression of cav-1 mRNA is demonstrated with real time RT-PCR, while expression of the protein is detected with Western Blot and flow cytometry. Furthermore we have also found the typical methyl-β-cyclodextrin sensitive association of this protein with light density detergent resistant membrane fractions (lipid rafts). Immunofluorescent localization of this protein by confocal microscopy revealed the classical granular distribution pattern observed in many other cells. Finally, T-cell activation resulted in a significant up-regulation of cav-1 and a change in distribution pattern of both cav-1 and CD3 in a capping pattern. Supported by grants S06-GM50695, S06-GM08224, and 2G12RR03035 awarded to HMM, WIS, and AR respectively.

**Mechanism of SRBC Targeting to Caveolae**

K. McMahon,[1] H. Zajicek,[1] W. Li,[1] K. Luby-Phelps,[1] M. Peyton,[2] J. Minna,[2] R. G. W. Anderson[1]; [1]Cell Biology, University of Texas Southwestern Medical Center at Dallas, Dallas, TX, [2]Hamon Center for Therapeutic Oncology Research, University of Texas Southwestern Medical Center at Dallas, Dallas, TX

Detergent-free caveolae proteomics identified a small family of C-kinase interacting proteins that are enriched in caveolae. This family includes SDR, SRBC and PTRF. All three members have a similar domain organization consisting of an N-terminal leucine zipper and a PKC binding site. We have focused on SRBC, which was originally isolated as an interacting partner and substrate for PKC delta and has since been shown to

interact with BRAC1. SRBC is downregulated in several lung and breast cancers, suggesting that it may act as a tumor suppressor. Here we demonstrate that SRBC is a caveolar protein that has a high coefficient of correlation with caveolin-1 by immunofluorescence. Tissue distribution of SRBC suggests it is ubiquitously expressed. The SRBC gene produces by alternative splicing, six different protein isoforms. SRBC depends on caveolin-1 for localization to caveolae. When SRBC-GFP alone is introduced into caveolin-1 knockout cells, SRBC-GFP exhibits a diffuse cellular localization. Expressing caveolin-1-Myc together with SRBC-GFP in these cells restores the co-localization with SRBC at the cell surface. Knockdown of caveolin-1 using RNAi causes the loss of SRBC protein suggesting that SRBC may also be stabilized by caveolin-1. Deletion of the leucine zipper domain shifts the localization of SRBC to the cytosol, demonstrating that this domain contains information necessary for targeting SRBC to caveolae. When we monitored SRBC-GFP movement at the cell surface by TIRF, we observed a "kiss and run" like behavior similar to caveolin-1-GFP. Therefore, SRBC appears to be a cytoplasmic signaling protein that is targeted exclusively to caveolae.

### Organelle Type (Na+, K+)/H+ Exchanger NHE7 Partly Associates with Caveolae

P. J. C. Lin, M. Numata; Biochemistry and Molecular Biology, The University of British Columbia, Vancouver, BC, Canada

Acidic luminal pH in intracellular organelles along secretory and endocytic pathways plays crucial roles in vesicular trafficking and signal transduction. Mammalian ($Na^+$, $K^+$)/$H^+$ exchanger NHE7 predominantly localizes to acidic organelles, such as the *trans*-Golgi network (TGN) and endosomes at steady state. Although NHE7 is proposed to be a key regulator of organelle pH and other monovalent cation homeostasis, little is known about its biological function and the regulation mechanisms. Here, we show that NHE7 partly associates with caveolae and heterologous expression of previously reported caveolin-1 dominant negative constructs diminishes the caveolae accumulation of NHE7. We also report a novel dominant negative caveolin-1 mutant that disrupts the NHE7-caveolae association. We found that NHE7 is N-glycosylated in CHO cells and the N-glycosylated form accumulates preferentially to the caveolae fractions. However, inhibition of N-glycosylation by tunicamycin did not dissociate NHE7 from the caveolae fractions. GST pull-down experiments revealed that the cytosolic C-terminus of NHE7 directly interacts with the C-terminal membrane association domain (C-MAD) of caveolin-1. Most of the previously identified caveolin binding proteins bind to the N-terminal caveolae scaffolding domain (CSD). Thus, NHE7-caveolin interaction represents a novel module of caveolin-binding. Potential implications of caveolae/caveolins in NHE7 transporter functions and targeting will be discussed.

### Growth Hormone Receptor Determinants for Lipid Rafts Localization

N. Yang,[1] X. Wang,[2] J. Jiang,[2] S. J. Frank[2]; [1]Department of Cell Biology, University of Alabama at Birmingham, Birmingham, AL, [2]Department of Medicine, University of Alabama at Birmingham, Birmingham, AL

The growth hormone receptor (GHR) is a cell surface receptor that mediates the somatogenic and metabolic effects of GH. GHR signaling is transduced via the receptor-associated cytoplasmic tyrosine kinase, JAK2. The major intracellular signaling systems activated by JAK2 in response to GH include the signal transducer and activator of transcription (STAT) 5 and extracellular signal-regulated kinase (ERK)-1 and -2 pathways. Our previous study suggests that GHR is highly concentrated in the cholesterol-rich microdomains (caveolae and lipid rafts) of the plasma membrane and such subcellular localization of GHR plays important roles in GH signaling. In the current study, we investigate the determinant(s) for targeting GHR to caveolae/lipid rafts. By comparing GHR-expressing JAK2-deficient human fibrosarcoma cells (γ2A-GHR) with those reconstituted with JAK2 (γ2A-GHR-JAK2), we found JAK2 expression had no effect on GHR caveolar localization. We further looked for region(s) required for caveolar localization within GHR itself by reconstituting GHR mutants into GHR-deficient γ2A-JAK2 cells. $GHR_{1\text{-}274\text{-}Myc\text{-}His,}$ which includes extracellular domain (ECD), transmembrane domain (TMD), and four cytoplasmic domain residues with C-terminal Myc and His tags, was similarly concentrated in the caveolae/rafts as wt GHR was. However, $GHR_{239\text{-}620,}$ which lacks most of the ECD but includes the stem region, was markedly less concentrated in the caveolar fraction (about 2.6-fold) than wt GHR and $GHR_{1\text{-}274\text{-}Myc\text{-}His}$ (more than 8.6-fold for each). In addition, two GHR mutants with deletions within stem region, $GHR_{\Delta 237\text{-}243}$ and $GHR_{\Delta 242\text{-}244,}$ also showed similar caveolar enrichment as wt GHR does. These results suggest that GHR caveolar targeting information may reside mainly in the ECD with contribution from the TMD, and the stem region is probably not important in targeting GHR to caveolae/lipid rafts.

## Trafficking in Polarized Cells (2666-2682)

2666

### Rab11a Is Required for Canalicular Biogenesis in WIF-B9 Hepatic Cells

Y. Wakabayashi,[1] P. Dutt,[2] J. Lippincott-Schwartz,[1] I. M. Arias[1]; [1]Cell Bioligy and Metabolism, NICHD, NIH, Bethesda, MD, [2]NIAID, NIH, Bethesda, MD

Hepatocytes polarize by forming functionally distinct sinusoidal (basolateral) and canalicular (apical) plasma membrane domains. Two distinct routes are utilized for delivery of membrane proteins to the canaliculus. Proteins having GPI anchors or single transmembrane domains are targeted to thesinusoidal plasma membrane from where they transcytose to the canalicular domain. In contrast, apical ATP-binding-casette (ABC) transporters, which are required for energy-dependent biliary secretion of bile acids (ABCB11), phospholipids (ABCB4) and nonbile acid organic anions (ABCC2), lack initial residence in the basolateral plasma membrane and traffic directly from Golgi to the canalicular membrane. While investigating mechanisms of apical targeting in WIF-B9 cells, a polarized hepatic epithelial cell line, we observed that rab11a is required for canalicular biogenesis. Knockdown of rab11a or overexpression of rab11a-GDP locked form prevented canalicular biogenesis as did overexpression of myosin Vb motorless tail domain. In nonpolarized WIF-B9 cells, apical ABC transporters colocalized with transcytotic membrane proteins in rab11a-containing endosomes and, unlike the transcytotic markers, did not distribute to the plasma membrane. We propose that polarization of hepatocytes (ie, canalicular biogenesis) requires recruitment of rab11a and myosin Vb to intracellular membranes which contain apical ABC transporters and transcytotic markers permitting their targeting to the plasma membrane. In this model, polarization is initiated upon delivery of rab11a-myosin Vb-containing membranes to the surface which causes plasma membrane at the site of delivery to differentiatate into apical domain (bile canaliculus).

2667

**MAL2 Is a Possible Regulator of Polarized Apical Protein Sorting in Nonpolarized Hepatic Cells**

S. Ramnarayanan, P. L. Tuma; Biology, The Catholic University of America, Washington, DC

We have been investigating polarized membrane trafficking in nonpolarized cells. One current hypothesis proposes that nonpolarized cells are polarized cells waiting to happen; they have the requisite machinery, and thus capacity, for polarized plasma membrane (PM) delivery, but lack the spatial organization of distinct membrane targets. Consistent with this hypothesis, we found that would-be apical proteins were present at the PM in nonpolarized hepatic cells, but were also specifically sorted to a novel compartment containing only other apical proteins and that this sorting was cholesterol and glycosphingolipid dependent. We propose that this sorting from the PM to the novel compartment is the nonpolarized cell's version of transcytosis. To test this hypothesis, we have been examining MAL2, a raft-associated proteolipid and proposed regulator of transcytosis, in nonpolarized, hepatic Fao cells. MAL2 colocalized with apical proteins in the novel compartment, but was absent from the PM. In cells treated with nocodazole, the apical compartment was dispersed and MAL2 redistributed to the PM suggesting that MAL2 may recycle between the apical compartment and the PM, an itinerary shared by apical residents. Treatment with methyl-β-cyclodextrin also led to the PM redistribution of MAL2 further suggesting this recycling is cholesterol-dependent. Actin disruption with latrunculin B led to the intracellular accumulation of MAL2, indicating its itinerary is also dependent on an intact actin network. When overexpressed, MAL2 was present in the apical compartment, but was also present in large intracellular puncta that did not contain apical proteins. MAL2 overexpression also altered the distribution of the apical PM proteins suggesting MAL2 regulates delivery of apical proteins from the PM to the apical compartment. Together, these results suggest that the transcytotic pathway is conserved in nonpolarized Fao cells.

2668

**Membrane Microdomains in Hepatocytes: Potential Target Areas for Proteins Involved in Canalicular Bile Secretion**

J. R. Jefferson,[1] A. Mazzone,[2] P. Tietz,[2] R. E. Pagano,[2] N. F. LaRusso[2]; [1]Chemistry, Luther College, Decorah, IA, [2]Thoracic Diseases Research Unit, Mayo Clinic and Foundation, Rochester, MN

Formation of hepatic bile requires that large volumes of water be rapidly transported across liver epithelia, including hepatocytes. Aquaporins (AQPs), are a family of water channel proteins involved in bile secretion. Three AQPs are expressed in rat hepatocytes: AQP8, AQP9, and AQP0. Upon exposure of hepatocyte couplets to a choleretic agonist (dibutyryl cyclic AMP), AQP8, the most abundant AQP in hepatocytes, is redistributed to the canalicular plasma membrane, while the subcellular distributions of AQP0 and 9 are unaffected. This study investigated the hypothesis that canalicular bile secretion involves the regulated trafficking of vesicles to and from lipid-enriched microdomains within the canalicular plasma membrane. Toward this goal, microdomains were isolated by isopycnic centrifugation, followed by sonication in Triton and centrifugation on a sucrose gradient. A Triton-insoluble, sphingolipid-enriched microdomain fraction at the 5/30% sucrose interface was recovered and found to be enriched in alkaline phosphatase (microdomain-positive marker) and devoid of amino peptidase-N (microdomain-negative marker). Microdomains prepared from both apical and basolateral fractions tested positive for caveolin-1 (a "raft" associated protein) and negative for clathrin (a "raft" negative protein). The apical fraction was enriched in alkaline phosphatase while the basolateral was enriched in Na/K ATPase. Lipid analysis of these isolated microdomains indicated that both apical and basolateral fractions were highly enriched in cholesterol and sphingolipids. Exposure of isolated hepatocytes to glucagon, a choleretic agonist, significantly increased the expression of AQP8 associated with the apical microdomain fractions but had no effect on AQP9 expression in the basolateral microdomain fraction. The data suggest that microdomains represent targets for the exocytic insertion and retrieval of "flux proteins", including AQPs, involved in canalicular bile secretion. This work was supported by the National Institutes of Health Grant DK 24031 and by the Mayo Foundation.

**Mapping Out the Itinerary of the Proteolipid, MAL2, in Polarized Hepatic Cells**

J. G. In, C. A. Cheng, P. L. Tuma; Biology, The Catholic University of America, Washington, DC

Our long term goal is to understand how hepatic cells establish and maintain their polarity. Our focus is to identify regulators of apical plasma membrane (PM) delivery. Unlike simple epithelial cells that directly target proteins from the TGN to the apical PM, hepatocytes use an indirect pathway: proteins are first delivered to the basolateral domain and then selectively internalized and transcytosed to the apical surface. MAL2 has been identified as a regulator of indirect apical delivery and is proposed to function between the basolateral early endosome (BEE) and the sub-apical compartment (SAC). In polarized WIF-B cells, we localized MAL2 to the apical PM, which presented us with a paradox. How can MAL2 function at the BEE when it is present at the apical pole? Upon closer examination, we noticed that MAL2 was also present in sub-apical structures. After incubation at 18°C, MAL2 accumulated in these structures while staining decreased reciprocally from the apical PM, suggesting MAL2 was present in the SAC. MAL2 colocalized with transcytosing apical residents and basolaterally internalized endolyn-78 in sub-apical structures, confirming the presence of MAL2 in the SAC. In cells treated with methyl-β-cyclodextrin or nocodazole, MAL2 redistributed to the basolateral PM indicating this domain as a step in MAL2's itinerary. To determine if MAL2 traversed BEEs, we double labeled MAL2 with internalized transcytosing apical residents or endolyn-78 in cells treated with nocodazole. This treatment inhibits delivery from the BEE to the SAC, leading to the endosomal accumulation of internalized proteins. MAL2 partially co-localized with the accumulated proteins in treated cells indicating that its itinerary includes BEEs. Together, these data indicate that MAL2 is an itinerant protein that traverses transcytotic intermediates consistent with its proposed role in regulating delivery between the BEE and SAC.

**Molecular and Cellular Determinants of the Asymmetric Distribution of the Low-Density Lipoprotein Related Protein, LRP, in Polarized Cells**

M. Donoso,[1] A. Cáceres,[2] C. Retamal,[1] G. Bu,[3] V. Malhotra,[4] A. Gonzalez,[1] J. Cancino,[1] M. P. Marzolo[1]; [1]Depto.Biología Celular y Molecular, Pontificia Universidad Católica de Chile, Santiago, Chile, [2]Instituto de Investigación Médica Mercedes y Martín Ferreyra (INIMEC-CONICET), Córdoba, Argentina, [3]Department of Pediatrics, Washington University School of Medicine, St. Louis, MO, [4]Cell and Developmental Biology Department, University of California San Diego, San Diego, CA

LRP is expressed in several cell types, including polarized cells, neurons and epithelial cells. We have shown that the basolateral distribution of

LRP is determined by two cytosolic tyrosine residues and by the adaptor complex AP-1B (1). Here, we have extended our studies towards the understanding of the molecular and cellular elements that govern the polarized distribution of LRP in two epithelial cell lines and in hippocampal neurons. Besides the role of the tyrosines residues of the first NPxY and the shared NPxY/Yxxϕ motifs, a distal dileucine motif had also a role in the polarized distribution of LRP. All the mutants that changed the receptor´s distribution from basolateral to apical or non-polarized distribution of LRP in epithelial cells, correspondingly changed its distribution from a somatodendritic to axonal or non-polarized in hippocampal neurons. Interestingly, the mutation of the first NPxY motif by replacing by alanine, either the N or the Y, had a completely different effect in the distribution of the receptor, being the N26A mutant completely intracellular, co-localizing with EEA1, in contrast with the apical/axonal distribution of the and Y29A mutant. This motif is the same one recognized by SNX17 (2). By microinjection experiments, we determined that the mutant Y29A traffics directly to the apical domain, while the mutant N26A goes to the basolateral pole, is endocytosed, but unable to recycle back to the cell surface. Finally, we showed that the basolateral distribution of LRP depends on the activity of protein kinase D2, since the receptor´s distribution was reverted to the apical membrane upon expression of a kinase dead mutant, which would affect the LRP exit from the TGN (FONDECYT 1020746; FIRCA TW006456; FONDAP 13980001 ; MIFAB)

**Distinct BFA-Induced Tubulation of Apical and Basolateral Membranes at the TGN**

K. N. Kitt, J. M. Wilson; Cell Biology and Anatomy, University of Arizona, Tucson, AZ

The establishment and maintenance of cell polarity is an active process that requires specific sorting and targeting to the apical and basolateral plasma membrane domains of the cell. Our lab has identified the small GTPase Rab14 as part of the regulatory machinery for apical targeting in polarized cells. We have shown that Rab14 is associated with the *trans*-Golgi network (TGN) and apical endosomes. In addition, expression of Rab14 S25N (inactive mutant) causes the TGN to expand and missort apical cargo. This led us to implicate Rab14 in the process of budding of vesicles from the TGN. However, the role of Rab14 in this process is not understood. To address the possible role of Rab14 in budding from the TGN we utilized Brefeldin-A (BFA). As shown by others, BFA causes Golgi compartments to redistribute into the ER and induces tubulation of the *trans*-Golgi network (TGN), endosomal, and lysosomal compartments. We found that addition of BFA to NRK cells causes extensive tubulation of Rab14 wt and Rab14 Q70L (active mutant) compartments and some tubulation of the portion of the TGN that contains the basolaterally targeted protein TGN38. Importantly, the BFA-induced tubules contain only TGN38 or Rab14. However, no tubulation of Rab14 occurs in NRK cells expressing Rab14 S25N, but tubulation of TGN38 still occurs. These data show that BFA differentially affects domains of the TGN containing apical and basolateral proteins and suggests that inactive Rab14 cannot associate with cytoskeletal elements to allow tubulation. We are currently investigating the possible association of Rab14 with microtubules and/or motor proteins.

2672

**Significance of Cholesterol in IgA-Receptor Transcytosis**

J. P. Leyt, S. Cohen, B. Aroeti; Hebrew University of Jerusalem, Jerusalem, Israel

Cholesterol enriched lipid rafts serve as platforms for a broad range of cellular activities. They typically resist solubilization in Triton X-100 in the cold and buoy in floatation gradients as detergent resistant membranes (DRMs). OBJECTIVE: To explore the significance of cholesterol-rich domains in the post-endocytic trafficking of the dimeric IgA (dIgA)-receptor (dIgA-R) and human transferrin receptor (hTfnR) expressed in polarized MDCK epithelial cells. RESULTS: In steady state, the dIgA-R is largely excluded from DRMs. However, upon 1 min exposure to the ligand at the basolateral surface, a fraction of the receptor was incorporated into DRMs, suggesting that dIgA binding stimulates the incorporation of its receptor into rafts in the vicinity of the basolateral surface. A fraction of the hTfnR was also associated with DRMs. However, hTfn binding had no effect on receptor association with that fraction. Cell surface biotinylation combined with floatation analyses revealed that hTfnR in DRMs originated at the basolateral plasma membrane, diminishing upon receptor internalization into endosomes. Cholesterol depletion of MDCK cells (with mβCD) before ligand internalization resulted in depolarized post-endocytic trafficking of both, dIgA and hTfn. Constitutive transcytosis of the empty dIgA-R was unaffected by that treatment. Interestingly, cholesterol depletion after ligand endocytosis selectively stimulated the kinetics of dIgA transcytosis. Cholesterol enrichment caused selective inhibition of dIgA transcytosis. A brief uptake of dIgA resulted in activation of Rac-1, whereas prolonged chase of the ligand diminished Rac-1 expression. Cholesterol enrichment counteracted those effects. CONCLUSIONS: Our data suggest that cholesterol-rich microdomains at the basolateral surface of MDCK cells are involved in polarized post-endocytic sorting events. Cholesterol in the basolateral surface and endosomes plays a role in polarized sorting of transcytotic dIgA, possibly via a mechanism that involves the activation of Rho and Rac- dependent pathways that control local actin and microtubule stabilization.

**Beta-2-spectrin Localizes to a Novel Microtubule Dependent Intracellular Tubulovesicular Compartment Distinct from the Golgi that is Enhanced by Brefeldin a in Polarized Epithelial Cells**

K. Kizhatil, K. M. Abdi, V. Bennett; Cell Biology, Duke University, Durham, NC

Recently we have shown that beta-spectrin collaborates with the ankyrin-G in lateral membrane formation and that beta-2-spectrin is required for lateral membrane formation in cultured epithelial cells as well as the early mouse embryo[1]. Here we have analyzed beta-2-spectrin localization in human bronchial epithelial cells. We used confocal microscopy coupled with three dimensionl rendering to obtain high resolution light images of the localization of beta-2-spectrin in bronchial epithelial cells. Ankyrin-G and beta-2-spectrin both localize to the lateral membrane in bronchial epithelial cells. However, beta-2-spectrin also is localized independent of ankyrin-G, E-cadherin, and the Na/K ATPase in an intracellular tubulovesicular compartment. This compartment is juxtaposed to the cytoplasmic face of the lateral membrane as well as in an intracellular distribution. Treatment of cells with BFA markedly increased intracellular beta-2-spectrin-labeled structures. Beta-2-spectrin does not co-localize with markers for conventional Golgi, ER, and endosomes. Adducin, a component of the spectrin network, also localizes to intracellular tubulovesicular structures similar to beta-2-spectrin. Disruption of microtubules disperses the beta-2-spectrin compartment and also reduces levels of beta-2-spectrin on the lateral membrane. This study reports discovery of a novel beta-2-spectrin-containing tubulovesicular compartment distinct from Golgi that is enhanced by BFA and requires microtubules. Considering the requirement for beta-2-spectrin for assembly of lateral membranes together with known activities of beta spectrin in binding to phospholipids, the newly described beta-2 spectrin compartment may function in bulk

sorting of lateral membrane lipids.1. Kizhatil, Yoon, and Bennett, ASCB 2005

**The Effects of Chloral Hydrate on Surface Polarity of MDCK Cells**

A. Sandra, C. Overgaard, C. Yeaman; Anatomy & Cell Biology, University of Iowa, Iowa City, IA

The primary cilium, a solitary nonmotile structure projecting from the centriole of all epithelia of the mammalian kidney except the intercalated cells of the collecting duct, serves as a flow sensor in MDCK cells. Removal of the primary cilium by chloral hydrate (CH) treatment abolishes flow sensing in MDCK cells (Praetorius & Spring, J. Membr. Biol. 191:69, 2003). We have treated MDCK cells after reaching confluency (4 days) with 4 mM CH for an additional 3 days. Cells maintained trans-epithelial resistance. In fact, levels averaged approximately 50% higher in the treated cells compared to the non-treated controls. Chloral hydrate treated cells had lost their primary cilia as observed by scanning electron microscopy and fluorescence microscopy in permeabilized cells stained with anti-acetylated tubulin antibody. The microtubule cytoskeleton appeared normal in chloral hydrate treated cells, suggesting that this chemical perturbation can be used to selectively remove the primary cilium. We show that CH treatment of confluent cultures increases cell size, decreases total protein synthesis, but does not significantly affect total protein content. We have also performed cell surface biotinylation experiments to examine steady state localizations of basolateral (E-cadherin) and apical (gp135/podocalyxin) proteins in control and CH-treated cultures. Polarity of gp135/podocalyxin is not significantly affected, but total gp135/podocalyxin accumulation is reduced by > 95%, even though this protein is not present within the cilia. In contrast, neither polarity nor accumulation of E-cadherin is significantly affected by CH treatment. These results suggest that the primary cilium may be specifically linked to gp135 expression, and that its loss leads to changes in cell morphology similar to those promoted by targeted deletion of gp135 reported by others (Meder et al., J. Cell Biol. 168:303, 2005). Supported by NIH DK052617 to C.Y.

**Sec3-Containing Exocyst Complexes Localize to Desmosomes in Polarized Epithelial Cells**

N. Andersen, I. M. Driskell, C. Yeaman; Anatomy & Cell Biology, University of Iowa, Iowa City, IA

The exocyst is a conserved octameric protein complex that functions in targeted delivery of transport vesicles to sites of polarized membrane growth. The last identified subunit of the mammalian complex, Sec3, has been proposed to serve as a spatial landmark for cell polarity in budding yeast. We sought to determine the localization and function of mammalian Sec3 during polarity development in epithelial MDCK cells. In isolated, non-polarized cells polyclonal antibodies label endogenous Sec3 on punctate cytoplasmic structures, but the protein is not associated with plasma membranes. Following induction of E-cadherin-mediated cell-cell adhesion, some Sec3 becomes associated with the basolateral plasma membrane, and colocalizes with desmosomes. This stable localization is distinct from that previously described for Sec6 and Sec8, which are enriched at the zonula adherens (ZA). In order to better understand these localization differences, we compared the immunostaining pattern of 27 different monoclonal Sec6 antibodies. This identified two subsets of antibodies that specifically label Sec6 at either the ZA or desmosomes. The epitopes recognized by these antibodies map to different domains of Sec6. Antibodies to a third exocyst subunit, Sec15, also label desmosomes, suggesting that desmosomes may represent sites of active membrane fusion on lateral plasma membranes. A 200 residue amino terminal domain of Sec3 is ~32% similar to amisyn, a characterized SNARE regulator. In keeping with the localization data, preliminary binding studies show that Sec3NT binds the basolateral t-SNARE syntaxin4 preferentially to the apical t-SNARE syntaxin3. We suggest that distinct Exocyst complexes, characterized by the absence or presence of Sec3, are present at desmosomes and the ZA, and that Sec3 may function to regulate membrane fusion events at desmosomes through interactions with syntaxin4. Supported by NIH GM067002 to C.Y.

**Phosphatidylinositol 3,4,5-trisphosphate Orients the Basolateral Polarity in Epithelial Cells**

A. Gassama,[1] W. Yu,[1] M. Ter Beest,[1,2] K. Mostov[1]; [1]Anatomy, UCSF, San Francisco, CA, [2]The Vontz Center, University of Cincinnati College of Medicine, Cincinnati, OH

Polarity is essential for numerous biological functions including development, migration and differentiation. Epithelial cells are polarized and elaborate a plasma membrane with two distinct domains. The apical domain is specialized for exchange with the lumen and the basolateral membrane maintains contact with adjacent cells and the underlying connective tissue. These two membranes perform different functions and have different protein and lipid composition. How epithelial cells acquire polarity remains a question under intensive study. Phosphatidylinositol (3,4,5)-triphosphate (PIP3) is the major product of Phosphatidylinositol 3-kinase (PI3K) and plays a crucial role in a great number of cellular processes. In polarized MDCK cells, PIP3 is specifically present in the basolateral membrane. Using a lipid shuttle system, PIP3 was added into the apical plasma membrane of polarized MDCK cells. This ectopic localization of PIP3 induces apical membrane protrusions and Akt Phosphorylation. This process required actin polymerisation and activation of Rac 1 and cdc42. Protrusion formation is dependent on the activity of PI3K, suggesting that exogenous PIP3 initiates a positive feed-back loop producing endogenous PIP3 and amplifying the polarization signal. Apical protrusions contained basolateral membrane proteins and excluded apical membrane proteins, indicating that their plasma membrane was transformed from apical to basolateral. Even if we cannot exclude that some of the basolateral proteins found in protrusions are delivered from the Golgi in the biosynthetic pathway, our data indicate that a substantial amount of basolateral plasma membrane components are transcytosed to the apical surface. When MDCK cells are grown in a three- dimensional gel, the cells form hollow cysts lined by a monolayer cells, with their apical surface facing the central lumen. In this system, addition of PIP3 causes formation of basolateral extensions. Our data clearly demonstrate that PIP3 plays a central role in epithelial polarization.

**Requirement for Beta-2-spectrin in Lateral Membrane Formation is Conserved Between Early Mouse Embryo and Cultured Human Bronchial Epithelial Cells**

K. Kizhatil, W. Yoon, V. Bennett; Cell Biology, HHMI and Duke University Medical Center, Durham, NC

Ability of cells to assemble specialized membrane domains is critical for vertebrate physiology. The first formation of polarized membrane domains occurs during compaction of the morula-stage mammalian embryo, and is essential for further development. We previously have

demonstrated that ankyrin-G is required for assembly of lateral membranes in human bronchial epithelial cells (J. Biol. Chem. 179:16706-14, 2004). We now report that ankyrin-G requires interaction with beta-2-spectrin for lateral membrane formation in epithelial cells. Moreover, depletion of beta-2-spectrin by siRNA results in a near complete loss of the lateral membrane without loss of polarity. Exogenous beta-2-spectrin rescues the knockdown phenotype. Beta-2-spectrin is also required for *de novo* lateral membrane biogenesis during cytokinesis. Previous studies have shown that spectrin localizes to sites of cell-cell contact in the early embryo. We show here that beta-2-spectrin is required for formation of lateral membrane in early mouse embryos. Beta-2-spectrin depletion in one cell of a 2-cell embryo by injection of siRNA plasmid into a single blastomere disrupted compaction. Beta-2-spectrin-depleted embryonic cells also fail to complete cytokinesis. Ankyrin-G is co-localized with beta-2-spectrin in embryos. Studies addressing the role of ankyrin-G in embryos are in progress. Together, these results identify beta-2-spectrin as an essential participant in a pathway for assembly of the lateral membrane domain that is conserved between cultured epithelial cells and early embryos.

**Polarized Membrane Trafficking to Pseudopod Tips is Required for Prostate Tumor Cell Motility**

C. E. Overgaard, K. E. Gokay, M. Royer, C. Yeaman; Anatomy & Cell Biology, University of Iowa, Iowa City, IA

Changes in cellular behavior that cause epithelial cells to lose adhesiveness, acquire a motile, invasive phenotype and metastasize to secondary sites are complex and poorly understood. Molecules that function to integrate adhesive spatial information with cytoskeleton dynamics and membrane trafficking likely play important roles in cellular transformation associated with prostate tumorigenesis. The focus of this research project is on specific components of the membrane trafficking machinery (the Exocyst complex and associated SNARE proteins), which are essential for targeted delivery of membrane and secretory proteins to specific plasma membrane sites to maintain epithelial cell polarity. We hypothesize that following loss of E-cadherin expression in prostatic tumor cells, the Exocyst complex responds to distinct spatial cues, assumes a novel localization within protrusive cell extensions, and functions to target the delivery of membrane components required during invasive cell motility. We have determined that several proteins involved in exocytosis (Exocyst, syntaxins3 and 4, Munc18c) are enriched at pseudopod tips of Dunning R3327 prostate carcinoma cells, where they co-localize and co-purify with focal adhesion proteins involved in regulating membrane trafficking and cytoskeleton dynamics (paxillin, b-PIX, GIT1, Nck1/2). These sites are the preferred destination of post-Golgi transport vesicles ferrying biosynthetic cargo, such as a5-integrin and VSVG. We demonstrate that assembly of transport vesicle targeting patches at filopod tips is regulated by two small GTPases (Arf6 and RalA). Interference with expression and activity of these GTPases, or with the Exocyst complex itself, impairs the cargo delivery to the plasma membrane and inhibits cell motility. Overall, we hope that identification of other proteins associated with Exocyst complex at these sites will lead to a deeper understanding of the role that polarized vesicle trafficking plays in cell motility and metastasis. Supported by DOD DAMD17-03-1-0187 to CY.

**Parallel Targeting of the Exocyst Components for Polarized Exocytosis**

X. Zhang, A. Zajac, J. Zhang, W. Guo; Department of Biology, University of Pennsylvania, Philadelphia, PA

The exocyst is an octameric protein complex essential for tethering secretory vesicles at specific domains of the plasma membrane for exocytosis. However, how the exocyst components are targeted to sites of secretion and how they mediate vesicle tethering is unclear. Here we show that distinct mechanisms control the polarization of different components of the exocyst to sites of secretion. The targeting of the exocyst component Sec3p to the bud tip requires its direct interaction with the activated form of Rho GTPases. On the other hand, all the other seven exocyst components (Sec5p, Sec6p, Sec8p, Sec10p, Sec15, Exo70p and Exo84p) are targeted concurrently with the delivery of the secretory vesicles, which depend on polarized actin cables organization. Among these seven components, Exo84p plays a critical role in both the targeting and assembly of this subgroup of exocyst components. Simultaneous disruption of the targeting of Sec3p (at the plasma membrane) and Exo84p (at the vesicle) leads to depolarization of all the exocyst components and results in secretion blocks and cell morphological defects. We further present evidence that vesicle tethering and subsequent SNARE assembly is defective in the double mutants. We propose that this specific targeting mechanism is important for vesicle tethering and polarized exocytosis.

**Tetanus Neurotoxin-mediated Cleavage of Cellubrevin Impairs Epithelial Cell Migration and Integrin-dependent Cell Adhesion**

T. Galli,[1] V. Proux-Gillardeaux,[1] J. Gavard,[2] T. Eirinopoulou,[2] R. Mège[2]; [1]Cell Biology, Institut Jacques Monod, Paris, France, [2]Inserm u706, Institut du Fer-à-Moulin, Paris, France

A role for endocytosis and exocytosis in cell migration has been proposed but not yet demonstrated. Here we show that cellubrevin, an early endosomal v-SNARE, mediates trafficking in the lamellipod of migrating epithelial cells and partially colocalizes with markers of focal contacts. Expression of tetanus neurotoxin, which selectively cleaves cellubrevin, significantly reduced the speed of migrating epithelial cells. Furthermore, expression of tetanus neurotoxin enhanced the adhesion of epithelial cells to collagen, laminin, fibronectin and E-cadherin, altered spreading on collagen, and impaired the recycling of β1 integrins. These results suggest that cellubrevin-dependent membrane trafficking participates in cell motility through the regulation of cell adhesion.

**Axonal Targeting of NgCAM: Testing the Transcytotic Pathway Model**

C. Yap, D. Wisco, J. Cannon, P. Kujala, J. Klumperman, E. Anderson, B. Winckler; Neuroscience, University of Virginia, Charlottesville, VA

Vertebrate neurons are highly polarized cells possessing different processes, namely axons and dendrites. In order to fulfill their distinct functions, axons and dendrites are morphologically and molecularly distinct. Exactly how somatodendritic and axonal membrane proteins accumulate in the correct domains is less than clear, but some sort of targeting mechanisms must exist. We are studying the targeting of the neuronal cell adhesion molecule L1/NgCAM. We proposed previously based on kinetic analysis that NgCAM travels to the axon by an indirect route whereby it is first targeted to the somatodendritic domain, then endocytosed and sorted to the axon from a somatodendritic endosomal compartment. In this work, we first characterize the transport of NgCAM through the endocytic compartments in the somatodendritic domain that accumulate NgCAM, and

secondly, we map the signals required for transcytotic transport. Consistent with NgCAM transcytosis, we provide evidence that 1. NgCAM does not travel to lysosomes after endocytosis, 2. endocytosed NgCAM sorts away from recycling cargo such as transferrin, 3. endocytosed NgCAM in somatodendritic domain highly co-localized with NEEP-21, a neuron-enriched endosomal protein, and 4. the cytoplasmic tail contains multiple signals necessary for transcytotic transport to the axon.

**SARA and Phosphatidylinositiol-3'-phosphate in Disc Morphogenesis and Membrane Trafficking in Mammalian Photoreceptors**

J. Chuang, T. Yeh, C. Sung; Ophthalmogy, Dyson Vision Research Institute, Weill Medical College of Cornell University, New York, NY

The rod photoreceptor is a phototransducing neuron that is highly polarized in both morphology and function. The rod outer segment (ROS), where phototransduction occurs, contains hundreds of membrane discs stacked in an order array. Rhodopsin, the light-absorbing visual pigment of rod cells, is highly concentrated in the ROS. The ROS and its components are continuously and rapidly renewed throughout the lifetime of the animal. The tip of the ROS is regularly phagocytosed by the adjacent retinal pigment epithelium, while at the base of the ROS, new discs are assembled from proteins and lipids synthesized in the cell body (inner segment). Several lines of evidence have clearly demonstrated that the coordination between ROS breakdown and renewal is critical to the health of photoreceptors. We have isolated a FYVE domain-containing protein SARA (Smad Anchor for Receptor Activation) as a rhodopsin C-terminus interacting protein. The FYVE domain of SARA binds specifically to phosphatidylinositiol-3'-phosphate (PI3P), a product of phosphatidylinositiol-3'-kinase (PI3-kinase). Ultrastructural analysis shows that SARA is highly abundant on the vesicles/tubules and sites immediately adjacent to the "nascent" disc membranes in the outer segment portions of axonemes in rodent rod photoreceptors. Suppression of SARA via RNA interference in the rat retina leads to the impairment of ROS targeting of rhodopsin. Overexpression of FYVE domain, which blocks the SARA-PI3P interaction, affects both the ROS distribution of rhodopsin and the disc morphogenesis in transfected rods. Our results, collectively, suggest that SARA and PI3P are critically involved in the membrane targeting of rhodopsin as well as the disc morphogenesis. Finally, our results open discussion for a model explaining the rod disc formation and renewal.

## Developmental Control of Gene Expression (2683-2689)

**Identification of Early TPA-Responsive Genes during Differentiation of HL-60 Cells**

L. Hu,[1,2] C. Tepper,[3] S. Lo,[4] W. Lin[2]; [1]Graduate Institute of Life Sciences, National Defense Medical Center, Taipei, Taiwan Republic of China, [2]Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan Republic of China, [3]Department of Biological Chemistry and Cancer Center Basic Science, University of California-Davis,, Sacramento, CA, [4]Department of Orthopedic Surgery and Center for Tissue Regeneration and Repair, University of California-Davis, Sacramento, CA

Human myeloid leukemia cell line, HL-60, has been widely used as a model of inducible macrophage-like differentiation in response to 12-O-tetradecanoylphorbol -13- acetate (TPA). We would like to study early TPA-responsive genes that might act as key regulators of the differentiation of HL-60 cells. We have adopted a special experimental approach in which the cells are synchronized to reduce heterogeneity and are pretreated with a protein synthesis inhibitor, cycloheximide, to distinguish primary and secondary target genes, and microarrays are used to identify genes showing direct regulation of expression by TPA. 62 genes upregulated, and 14 downregulated, by TPA were identified in this study. A subset of the TPA-upregulated genes was further validated by real-time PCR. Three directly TPA-upregulated genes (*NFIL3*, *SKIL*, and *JMJD3*), not previously reported to be TPA-responsive and involved in HL-60 cell differentiation, were shown to be early responsive targets with or cycloheximide pretreatment. TPA upregulation of *SKIL* and *JMJD3* mRNA levels was dose-dependent and also PKC-dependent, as this effect was blocked by the PKC inhibitor, Go6983. Our results show that our method can identify genes as candidate primary targets of the TPA-induced differentiation program.

2684

**Estrogen Activates the Promoter for the PEMT (phosphatidylethanolamine N-methyltransferase) Gene**

J. Song, S. H. Zeisel, S. Wang, K. A. da Costa; UNC, Chapel Hill, NC

Choline is an essential nutrient for humans; however some part of this requirement can be met by endogenous synthesis from 1-carbon groups catalyzed by phosphatidylethanolamine N-methyltransferase (PEMT). Pre-menopausal women are resistant to dietary choline deficiency, while post-menopausal women and men are not. There is evidence in animal models suggesting that estrogen can increase PEMT activity. The aim of this study was to investigate whether and how the PEMT gene is upregulated by estrogen. PEMT gene transcription was increased in a dose-response manner when cultured primary mouse hepatocytes were treated with various concentrations of 17β-estradiol for 24 hours. This preceded an increase in protein expression and enzyme activity. Transfection studies, in which the human PEMT promoter was linked to a luciferase reporter, demonstrated that estrogen significantly increased promoter activity. This effect was reversed by ICI 182,780, an estrogen antagonist. The human PEMT promoter contains eight putative estrogen response elements (EREs), and Electrophoretic Mobility Shift Assay revealed that a 41 bp segment which contains two putative EREs can bind estrogen receptor complexes. We have previously reported that there is a common single nucleotide polymorphism (SNP) in the PEMT promoter, and that this SNP (rs12325817) increases susceptibility of women to developing signs of choline deficiency. Using EMSA we showed that the SNP is in a region that is estrogen responsive. And the SNP abrogates this responsiveness. This study is the first to explore the underlying mechanism of why premenopausal women are relatively resistant to choline deficiency.

2685

**Human *NR4A2* (Nurr1) *cis*-Regulatory Sequences Identified by Comparative Sequence Analysis and a Functional Screen in Zebrafish**

R. C. Addis,[1,2] R. M. Vinton,[2] S. Fisher,[2] A. S. McCallion,[2] J. D. Gearhart[1]; [1]Institute for Cell Engineering, Johns Hopkins University School of Medicine, Baltimore, MD, [2]McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD

Directed differentiation of stem cells requires an understanding of the mechanisms that control critical gene expression during development. Several genes have been identified as key players in the development of midbrain dopaminergic neurons, the neurons that are destroyed in Parkinson's Disease. *NR4A2* (Nurr1) is essential for the genesis and survival of midbrain dopaminergic neurons, but little is known about the

mechansims by which the transcription of this gene is regulated. Recent reports have demonstrated that evolutionarily conserved non-coding sequences within and flanking a gene are likely to contain *cis*-acting regulatory sequences. We have compared the sequence at the human *NR4A2* locus with its orthologs from multiple vertebrate species to identify non-coding regulatory sequences at this gene. We tested putative regulatory sequences for *in vivo* function by placing them upstream of the *c-fos* minimal promoter driving GFP and inserting this construct into the zebrafish genome using the Tol2 transposase system. Transgenic zebrafish were examined for GFP expression in regions of the central nervous system known to express the zebrafish ortholog of *NR4A2*, as determined by *in situ* hybridization. We report the identification of a conserved non-coding sequence upstream of *NR4A2* exon 1 that is sufficient to drive expression in a pattern that recapitulates much of the zebrafish Nurr1 expression pattern. We have begun experiments using this sequence to drive reporter gene expression in *NR4A2*-expressing dopaminergic neuron precursors derived from embryonic stem cells to facilitate their isolation using flow cytometry. In addition, we aim to identify the transcription factors that bind to this *cis*-acting sequence. Our goal is to efficiently direct the differentiation of embryonic stem cells into dopaminergic neurons via ectopic expression of identified critical transcription factors.

2686

**Nitric Oxide Activates Peroxisome Proliferator-Activated Receptor Gamma through a p38 MAPK Signaling Pathway**

A. Ptasinska, S. Wang, J. Zhang, R. L. Danner; National Institutes of Health, Critical Care Medicine Department, Clinical Center, Bethesda, MD

Nitric oxide (NO) regulates vascular tone, gene expression, platelet aggregation and leukocyte adhesion. Peroxisome proliferator-activated receptors (PPARs) are ligand activated transcription factors that have functions which overlap with those of NO such as the repression of endothelin-1 and vascular adhesion molecules. All three PPARs PPARa, PPARb/d and PPARg are expressed in endothelium. Since both NO and PPARg regulate endothelial function and protect the endothelium from injury, we hypothesized that these signaling pathways may interact with each other in the vasculature. Human-hybrid endothelial cells (EA.hy 926) were exposed to NO donors S-nitrosoglutathione (GSNO) or spermine NONOate. Electrophoretic mobility shift assays using PPAR-response element (PPRE) probe showed that low dose NO exposure (100 microM) increases PPARg binding. The activation of PPARg binding reached a maximum after 30 to 60 minutes of exposure to NO and was sustained for at least 4 hours. NO had no effect on PPARg protein expression level as detected by Western blotting. GSNO or NONOate was found to activate p38 MAPK in EA.hy 926 cells and p38 MAPK inhibitor, SB202190 (0.1 microM), or siRNA knockdown of p38 MAPK were both shown to block the effect of NO on PPARg binding. Using a luciferase-based reporter gene system, NO activated PPRE containing promoter of cyclooxygenase-2 (COX-2) and a PPRE artificial construct. Further, NO was found to induce the expression of PPRE containing genes including COX-2 and diacylglycerol kinase a (DGKa). These results show that NO increases PPARg binding and activates PPRE containing promoters through a p38 MAPK signal transduction pathway. Thus, NO may exert anti-inflammatory and cytoprotective effects in the vasculature through PPARg. This interaction can be used to identify new of PPARg target genes and potentially may lead to new endothelium protective strategies.

**Developmental Expression Profile and Transcriptional Regulation Analysis of Murine Pinin**

S. Leu, P. Ouyang; Department of Anatomy, Chang Gung University, Tao-Yuan, Kwei-Shan, Taiwan Republic of China

Pnn is a multifunctional protein with dual subcellular localization at desmosomes and in nuclear speckles. The involvement of pnn in mouse development and the mechanism underlying the regulation of pnn expression are still unknown. To characterize the role of pnn in mouse embryo development, we monitored distribution patterns and expression levels of pnn in mouse embryos of each developmental stage. With Northern blot and Real-Time RT-PCR, we found that E12.5 embryos displayed the highest expression of pnn and the expression levels then declined gradually till birth. Immunostaining and mRNA in situ hybridization showed that pnn is widely expressed and its expression is detected in as early as 2-cells stage mouse embryo. Tissues with higher expressions of pnn during mouse development include CNS, E12.5 to E14.5 livers, post-E13.5 epidermis, and E16.5 thymus. To investigate the regulatory mechanism for pnn expression, we determined the promoter region of mouse pnn gene and found regions critical for pnn expression regulation. Through luciferase activity assay on truncated pnn promoter fragments, we determined a region 200 to 180 bp upstream of ATG start codon containing an unidentified *cis*-acting element which plays an important role in enhancing the promoter activity of mouse pnn. In addition, we found that the Ets consensus binding site GGAA at 151 to 148 bp upstream of translation start site is essential for basal pnn expression and is regulated by the transcription factor GABP.

**Design of siRNAs that Silence the Pain Gene PKCγ**

M. Lozada Contreras,[1] S. Garraway,[2] C. E. Inturrisi[2]; [1]Industrial Biotechnology, University of Puerto Rico, Mayaguez Campus, Mayaguez, Puerto Rico, [2]Pharmacology, Weill Medical College of Cornell University, NY, NY

RNA interference is a powerful genetic approach for efficiently silencing target genes. One advantage of this technique is the high specificity it offers over pharmacological antagonism in that it cleaves the mRNA of a precise protein. The purpose of this study is to use RNA interference to target PKCγ, a protein kinase that has been identified in neurons of the brain and spinal cord and implicated in the production of persistent pain. Firstly, we designed five 21 base pair small interfering RNAs (siRNA) that target the gene that encodes the mouse PKCγ by using the MIT-Whitehead siRNA design program. Next, the siRNAs were subjected to a NCBI BLAST search which checks the specificity of each siRNA for the targeted gene and identifies similar sequences in other genes. To screen for effective siRNAs, a small hairpin RNA (shRNA) will be constructed from potential siRNAs by the addition of a stem loop structure. The shRNA is then cloned into the pAAV plasmid with a H1 promoter. Subsequently the PKCγ cDNA (mouse) is inserted into the psiCHECK vector, containing the reporter genes renilla luciferase (Rluc) and firefly luciferase. Both plasmids will be co-transfected into HEK 293 cells. Effective shRNAs will cleave the PKCγ cDNA, which will decrease the luminescence of Rluc in comparison to the firefly. Five siRNAs were tested; only three yielded colonies on plates containing selective growth media. Following several restriction digestion analysis, two siRNAs are confirmed to be transfected into HEK 293 cells. Effective shRNA will be incorporated into viral vectors to be injected into animals. A successful PKCγ siRNA will prevent or reduce pain in a mouse model.

**Regulated Cell Differentiation: Expression of the Traits "Mating type" and "Phagotype" in Ciliate *Dileptus anser***

M. Tavrovskaja, S. Vassyanin; Lab.Cytology of the Unicellular Organisms, Institute of Cytology Academy of Scienses of Russia, Saint Petersburg, Russian Federation

Ciliates exhibit cell differentiation by "mating type"(MT)(Sonneborn, 1937). Trait MT is expressed at particular stage of clone life cycle. Cells of *Dileptus anser* preserves some features of parent MT during the first 24 h after completion of conjugation process. Immaturity period (IP) lasts several months. Maturity begins with secretion of gamone. Experiments show dependence of the duration of immaturity period from number cell division. Two types of fading regime has been offered to the cells of the same exconjugant clone-the first provided intensive cell fission (regime I), cells under the second regime practically did not divided (regime II). Maturity testing of the cells in two groups cultivated during the same physically time has demonstrated maturity of divided cells (regime I) and immaturity of undivided cells (regime II). The very high regenerative ability and peculiarity of nuclei structure *D. anser* cells gave us opportunity to shorten IP to a greater extent by growing cells from caudal mini-fragments of operated cells (Tavrovskaya,1981). Clones originated from mini-fragments of the cell had the same MT as not operated cells after maturing.. No shortening of IP has been found in the cells which originated from macro-fragments of operated cells. Another induction-receptor system of Dileptus anser's cells regulates self- identification and intraclonal fade behavior and determinate the trait phagotype (PhT), (Tavrovskaya,1977). Exconjugants preserved parents PhT nearly 24 h after conjugants separation; in 30h of exconjugants life new PhT was expressed. PhT changing occured without exogenic nutrition, prior to somatic nuclei formation and first cell fission. Testing exconjugants and parents clones during 3,5 years has shown stability of the trait PhT and independence PhT and MT systems. .

**Gemin Proteins Are Required for Efficient Assembly of Sm-class RNPs**

K. B. Shpargel, A. G. Matera; Genetics, Case Western Reserve University, Cleveland, OH

Small nuclear ribonucleoprotein (snRNP) biogenesis constitutes a pathway wherein the uridine-rich small nuclear RNAs (UsnRNAs) that mediate pre-mRNA splicing are complexed with proteins, modified and transported to their appropriate subnuclear locales. The survival of motor neurons (SMN) protein, along with Gemins2-7, forms a large oligomeric complex that is necessary and sufficient for the in vivo assembly of Sm proteins onto snRNAs. Following cytoplasmic assembly of the Sm core, both SMN and splicing snRNPs are imported into the nucleus, targeting Cajal bodies for additional snRNA maturation steps before accumulating in splicing factor compartments known as "speckles." In this study, we have analyzed the function of individual SMN complex members by RNA interference (RNAi). Notably, we find that RNAi-mediated knockdown of SMN, Gemin2, Gemin3 and Gemin4 each disrupt Sm core assembly, whereas knockdown of Gemin5 and Snurportin1 had no effect. Assembly activity can be rescued by expression of a GFP-SMN construct that is refractive to RNAi, but not by similar constructs that contain mutations that cause Spinal Muscular Atrophy in humans. Our results also demonstrate that Cajal body homeostasis requires ongoing snRNP assembly by the SMN complex. Perturbation of SMN complex function results in disassembly of Cajal bodies and relocalization of the marker protein, coilin, to nucleoli. Moreover, newly-synthesized SmB proteins fail to accumulate in Cajal bodies or speckles in SMN-deficient cells. Importantly, the work reveals a novel function for Gemin3 and Gemin4 in Sm core assembly and suggests that defects in snRNP biogenesis contribute to SMA pathogenesis.

**Arginine Methylation and Small Nuclear Ribonucleoprotein Biogenesis : Re-examining the Connection**

G. B. Gonsalvez, T. K. Rajendra, A. G. Matera; Genetics, Case Western Reserve University, Cleveland, OH

Post-translational modification of proteins is a common mechanism used by cells to regulate function. One type of post-translational modification, protein methylation, regulates a vast array of cellular functions. Studies have demonstrated that proteins involved in carrying out pre-messenger RNA splicing are dimethylated on specific arginine residues. These splicing factors are called small nuclear ribonucleoproteins (snRNPs) and the enzymes that modify and potentially regulate the assembly of snRNPs are called protein arginine methyltransferases (PRMTs). Under *in vitro* conditions, the snRNP proteins SmB/B', SmD1 and SmD3 can be symmetrically dimethylated by either PRMT5 or PRMT7. It is unknown which of these enzymes, PRMT5 or PRMT7, is responsible for methylating Sm proteins *in vivo*. Furthermore it is unknown whether dimethylation of Sm proteins is required for proper snRNP maturation and splicing. To gain an *in vivo* understanding of this process, we carried out our studies using *Drosophila melanogaster*. We characterized an allele that contained a disruption in the *Dart5* gene, the fruit fly ortholog of human PRMT5. We demonstrate that in the absence of Dart5, Sm proteins are completely un-methylated, indicating that Dart5 is required for Sm protein methylation *in vivo*. Surprisingly, the absence of Sm methylation does not affect the viability of F1 homozygotes. However, *Dart5* is an essential gene as the homozygous mutant animals are sterile. Interestingly, the absence of Sm protein methylation does not adversely affect snRNP biogenesis. These findings suggest that methylation of Sm proteins is required for a non-splicing related function. Consistent with this interpretation, Sm proteins, independent of their role in splicing, are required for the proper localization and integrity of germ granules in *C. elegans*.

**RNAi of *Drosophila* Nopp140 Expression is Analogous to the Human Treacher Collins Syndrome**

Z. Cui, P. DiMario; Biological Sciences, Louisiana State University, Baton Rouge, LA

Nopp140 is a nucleolar protein that functions in pre-rRNA transcription or ribosome assembly. Although its functions have not been precisely determined, Nopp140 interacts with both box C/D and box H/ACA snoRNP complexes, thus suggesting a chaperone function in pre-rRNA processing and ribosome assembly [Yang *et al*. (2000) *Mol. Biol. Cell* **11**:567-577]. By alternative splicing, *Drosophila* expresses potentially two isoforms of Nopp140: the first is homologous to mammalian Nopp140, sharing a conserved carboxy terminus. The second contains a distinctive glycine and arginine rich (RGG) carboxy terminus typically found in vertebrate nucleolin. To further characterize Nopp140 in *Drosophila*, we expressed interfering RNAs in transgenic flies from yeast GAL4 upstream activating sequences when crossed to GAL4 driver lines. Western blot analysis showed a dramatic loss of Nopp140 in larvae induced to express RNAi. Larval imaginal discs and histoblasts give rise to adult structures

(wings, legs, and cuticle) during pupation. These larval tissues are the likely targets for Nopp140 loss; adult phenotypes resulting from Nopp140 loss include shriveled wings, deformed legs, and fused tergites (abdominal stripes of the dorsal cuticle). Phenotypes attributed to the loss of Nopp140 are complex and variable, and they fall within the *Minute* syndrome of *Drosophila* that presumably results from a lack of ribosome production and protein synthesis. The *Minute* syndrome may be analogous to the human Treacher Collins syndrome (TCS). TCS displays craniofacial birth defects that are also complex and variable. TCS results from mutations in the *TCOF1* gene that encodes Treacle, a nucleolar protein very similar to Nopp140 in peptide domain organization [e.g. Valdez *et al.* (2004) *Proc. Natl. Acad. Sci.* **101**:10709-10714]. *Drosophila* should be an ideal model system to examine nucleolar protein function during critical periods in development.

**RNA-dependent Nucleolar Sequestration and Suppression of APOBEC3C Deaminase for Avoiding Random Cytosine-deamination of Genomic DNA**

W. HE,[1] R. Chen,[2] Z. Yang,[1] Q. Zhou[1]; [1]Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA, [2]Xiamen University, Xiamen, China

APOBEC3C is the most widely expressed member of the APOBEC family of proteins that function in diverse biological processes through deaminating deoxycytosine on single-stranded DNA. It is not clear how its activity is regulated so as to prevent the introduction of uncontrolled hypermutations into genomic DNA. Through affinity-purification of proteins that interact with the evolutionally conserved 7SK snRNA, we have identified APOBEC3C as a major 7SK-associated protein. Most of cellular APOBEC3C interact with 7SK in a single complex that also contains the 5S and 5.8S rRNA. Interactions with these RNA species suppress the deaminase activity of APOBEC3C and sequester the protein in the nucleolus. Because the DNA substrate-binding site in APOBEC3C is different from the region required for the APOBEC3C-RNA interaction, we propose that the RNA molecules serve as negative regulators rathar than substrate-competitors in causing the inhibition of APOBEC3C. We discuss the implications of the RNA-dependent regulation of APOBEC3C for the cellular mechanism of preventing deleterious hypermutations caused by this deaminase.

2694

**Initial Characterization of Raver2, a New Member of the HnRNP Family**

B. Kleinhenz,[1] M. Fabienke,[2] H. H. Arnold,[2] B. M. Jockusch,[1] S. Illenberger[1]; [1]Zoological Institute, Cell Biology, Technical University of Braunschweig, Braunschweig, Germany, [2]Cell and Molecular Biology, Institute for Biochemistry and Biotechnology, Technical University of Braunschweig, Braunschweig, Germany

In database searches we identified a novel member of the hnRNP family reminiscent of the previously described raver1 protein. The open reading frame encodes a protein of 625 amino acids. The deduced amino acid sequence revealed highest sequence homology within three RNA recognition motifs and a similar overall organization of functional domains as compared to raver1, prompting us to name the protein raver2. The protein harbours three N-terminal RNA recognition motifs (RRM), two putative nuclear localization signals (NLS) at the N- and C-termini and a central leucine-rich region which may function as a nuclear export sequence. Like raver1, raver 2 displays nucleo-cytoplasmic shuttling in an interspecies heterokaryon assay. However, while raver1 is expressed ubiquitously both in embryonic and adult mouse tissues, raver2 exerts a distinct spatio-temporal expression pattern. During embryogenesis (E8.5) raver2 expression begins in neuroepithelium and continues in dorsal regions of fore-, mid-, and hindbrain. The protein is also expressed in dorsal root ganglia, branchial arches, and the developing limb buds. In adult mice, raver2 is essentially restricted to brain, lung, and kidney. As revealed by immunofluorescence analyses of glia cells and primary neurons, raver2 resides in the nucleus of both cell types, where it co-localizes with the polypyrimidine tract binding protein (PTB) in the perinucleolar compartment, an RNA-dependent structure characterized by the accumulation of PTB. Immunoprecipitation experiments and biochemical analyses demonstrate that raver2 directly binds to PTB. At present, we are investigating, whether raver2 affects PTB-mediated splicing, as has already been implicated for raver1. The different expression patterns, however, imply that both raver proteins have distinct or only partially overlapping cellular functions, possibly during differentiation processes.

2695

**hnRNP A2 Expression is Required for HIV-1 Genomic RNA Trafficking from the Microtubule Organizing Center**

K. Lavesque,[1] M. Halvorsen,[1] L. Chatel-Chaix,[1,2] L. Abrahamyan,[1] V. Poupon,[1] A. Gatignol,[1] A. J. Mouland[1]; [1]Lady Davis Institute for Medical Research/McGill University, Montreal, PQ, Canada, [2]Biochemistry, Université de Montréal, Montreal, PQ, Canada

Few details are known about how the human immunodeficiency virus type 1 (HIV-1) genomic RNA is trafficked in the cytoplasm. We identified heterogeneous nuclear ribonucleoprotein A2 (hnRNP A2) as one of the first host proteins involved in this process such that its interaction with cis-acting sequences of the HIV-1 RNA is important for HIV-1 RNA localization, protein expression patterns and levels of genomic RNA in new virions. In order to further define the role of hnRNP A2 in the fate of HIV-1 genomic RNA in the cytoplasm, we used small interfering (si)RNA to knockdown hnRNP A2 gene expression in HIV-1-expressing HeLa cells. In this study we demonstrate that HIV-1 RNA trafficking from the microtubule organizing center (MTOC) is dependent on the expression levels of hnRNP A2. A 90-95% knockdown of hnRNP A2 expression resulted in the perinuclear accumulation of HIV-1 genomic RNA at the MTOC as shown by fluorescence in situ hybridization and immunofluorescence co-analyses. Kinetic studies that allow us to follow the fate of HIV-1 RNA reveal that the accumulation of genomic RNA at the MTOC occurs very rapidly and that HIV-1 genomic RNA egress within the cytoplasm is dependent on hnRNP A2 expression. Western and RT-PCR results show that HIV-1 Gag expression is not affected by siRNA treatment and the reduction of hnRNP A2 expression does not result in aberrant splicing of HIV-1 RNA. The results from this study demonstrate that the cytoplasmic trafficking of the HIV-1 genomic RNA is mediated directly by the activity of the host cell protein, hnRNP A2. These data also indicate that the MTOC is likely the point of convergence for HIV-1 genomic RNA following its exit from the nucleus.

**Polypyrimidine Tract Binding Protein Blocks the 5' Splice Site Dependent Assembly of U2AF and the Prespliceosomal E Complex**

S. Sharma,[1] A. Falick,[2] D. Black[3]; [1]HHMI, UCLA, Los Angeles, CA, [2]UC, Berkeley, San Francisco, CA, [3]HHMI/MIMG, UCLA, Los Angeles, CA

Polypyrimidine tract binding protein (PTB) controls the splicing of many alternatively spliced exons, including the c-src exon N1. The repression of N1 splicing in non-neural cells requires the binding of PTB to multiple sites surrounding the N1 exon. We show that PTB blocks splicing prior to formation of the pre-spliceosomal Early (E) complex. To understand the nature of the pre-mRNP complexes that direct changes in spliceosome assembly, we purified and characterized the regulatory pre-spliceosomal H complexes that assemble onto N1 exon RNAs. The repressed complex contains PTB and lacks the essential splicing factor U2AF, even though the 3' splice site for the unregulated exon is present and far downstream of the PTB binding sites. In contrast, an H complex that can go on to splice contains U2AF. Immunodepletion of PTB from extracts or mutation of a PTB binding site allows binding of U2AF and splicing derepression. It has been shown by others that assembly of U2AF into the E complex requires an interaction with the U1 snRNP. We find that U2AF binding to the downstream 3' splice site is restored by including an unregulated 5' splice site upstream from the N1 exon. Our results indicate that PTB represses splicing by blocking an interaction of U2AF with the 5' splice site, presumably via the U1 snRNP that is required for U2AF assembly. Thus, rather than simply occluding a binding site for U2AF, this splicing repressor blocks a very specific interaction required for U2AF assembly into the early spliceosome.

2697

**The Paraneoplastic Neurologic Disease Antigen Nova is a Shuttling Protein and May Have Dual Functions in Nucleus and Cytoplasm**

T. Eom,[1] M. Ruggio,[1] R. Darnell[1,2]; [1]Lab of Molecular Neuro-oncology, The Rockefeller University, New York, NY, [2]HHMI, New York, NY

RNA binding proteins are important for the regulation of transcription, alternative splicing, translation and localization of mRNAs. Nova proteins are neuronal KH-type RNA binding proteins and are targeted in paraneoplastic opsoclonus myoclonus ataxia (POMA). It has been known that Nova proteins play a role as a splicing factor in neurons. Immunohistochemical studies have demonstrated that Nova proteins are highly expressed in the nucleus, as well the cytoplasm. Additionally, sucrose gradient fractions revealed that the Nova proteins comigrate with polysomes in mouse brain. These data strongly suggest that Nova proteins may have some functions in the cytoplasm besides being a splicing factor in the nucleus. Moreover, Nova proteins have both a Nuclear Localization Signal (NLS) as well as Nuclear Export Signal (NES). They may direct the bi-directional transport of Nova proteins between the nucleus and cytoplasm and provide different functions in different areas. A new method, CLIP (in vivo cross-linking IP analysis) has identified many in vivo RNA targets of Nova proteins through covalent cross-linking Nova proteins and RNA complexes without any in vitro manipulation. Immunohistochemical and fluorescence in situ hybridization (FISH) studies may define specific expression patterns of these Novas' target genes such as Gephyrin, Girk2 and CamKII g in discrete regions of the developing nervous system by comparing the difference of distribution, stability and protein expression levels of RNA targets in wild type and Nova-null mice. These studies will demonstrate the physical interaction between Nova proteins and RNA targets and the significance of this interaction in neurobiology.

2698

**Homotrimerization of the Trim Protein Pwa33/xnf7 is Required for its Association with Active Transcription Units**

B. Beenders, M. Bellini; Cell & Developmental Biology, University of Illinois at Urbana-Champaign, Urbana, IL

In amphibian oocytes, the TRIM (tripartite motif) protein PwA33/Xnf7 associates with most loops of the lampbrush chromosomes. These loops correspond to active transcription sites of RNA polymerase II, which are visible by light microscopy because of their thick ribonucleoprotein (RNP) matrix. While PwA33/Xnf7 was described as a component of the loop matrix, about half of the nuclear supply of the protein remains free in the nucleoplasm. Fractionation of an oocyte extract by chromatography indicated that the predominant form of PwA33/Xnf7 is a homotrimer. This data was further supported by glutaraldehyde cross-linking of the endogenous and *in vitro* made PwA33/Xnf7. In addition, deletion analyses demonstrated that the putative coiled-coil region of the protein is essential for its trimerization. Finally, we demonstrated that a coiled-coil-deleted PwA33/Xnf7 failed to associate with chromosomes. Together, these data strongly suggest that PwA33/Xnf7 interact with active transcription units as a homotrimer and provide new insights into the structural role of its TRIM motif.

**Uncovering the Mechanism of Effective Diced Pools for RNAi**

D. Gong,[1] J. W. Myers,[2] J. E. Ferrell[3]; [1]Biological Sciences and Molecular Pharmacology, Stanford University, Stanford, CA, [2]Biochemistry, Stanford University, Stanford, CA, [3]Molecular Pharmacology, Stanford University, Stanford, CA

The use of RNA interference (RNAi) for loss-of-function studies has recently gained popularity due to the rapid optimization of techniques for triggering gene silencing in mammalian cells. Generating synthetic siRNAs, and DNA-based vectors as RNAi triggers generally require screening two to four siRNAs before identifying one that is effective for silencing while the rest seem to have little to no effect. Use of Dicer-generated siRNAs (d-siRNAs) bypasses this screening requirement, and is consistently effective for gene silencing (>80% silencing, 80% of the time). Since d-siRNAs consist of presumably large numbers of siRNAs, we explored two possibilities by which diced pools achieve consistent and effective silencing: (i) siRNAs within the pool work in a cooperative fashion regardless of their individual efficacies, or (ii) highly effective siRNAs exist that confer the silencing ability of the pool, despite other ineffective siRNAs around. To address these possibilities, we identified the complexity of a diced pool by cloning, sequencing, then selected a subpopulation of these siRNAs to make small pools to try to reconstitute the efficiency of the original diced pool. We found that a diced pool generated against a 1.3 kb region of our target gene consists of at least 336 unique siRNAs. When we tested 10 of these single siRNAs for silencing, or when different combinations of siRNAs were mixed together as small pools, no single or combination silenced better than the original pool. Our data indicates that individual siRNAs do not exhibit cooperativity. Although we have not identified an siRNA that is better than original pool for silencing, it seems that nature has chosen dicing as a method of generating a large number of siRNAs to ensure that at least some siRNAs will be potent for silencing.

**The Structurally Diverse Protein L23a of *Drosophila melanogaster* is a Functional Member of the L25/L23 Ribosomal Protein Family**

C. L. N. Ross, R. Patel, V. C. Ware; Biological Sciences, Lehigh University, Bethlehem, PA

The ultimate products of the ribosome biogenesis pathway are ribonucleoprotein complexes that function in protein synthesis. Some ribosomal components are remarkably well conserved in structure between species, highlighting their functional significance within the biogenesis pathway. Many ribosomal components are less well conserved or are unique to certain lineages. The utilization of conserved and unique structural

components to construct the protein synthetic machinery is a notable evolutionary feat. The proposed *Drosophila melanogaster* L23a homologue is a structurally unique ribosomal protein compared to the widely studied L25 protein from *Saccharomyces cerevisiae*. The fly L23a protein includes an N terminal extension, creating a protein of 277 amino acids in length compared to 142 amino acids for yeast L25. The ability of fly L23a with an N-terminal extension to replace yeast L25 function was determined by creating a *S. cerevisiae* strain carrying an endogenous L25 chromosomal gene disruption and a plasmid-encoded FLAG-tagged L23a gene. The yeast strain is dependent on the function of a FLAG-tagged fly L23a for survival and growth, demonstrating functional compatibility between fly L23a and yeast L25. Fly L23a-FLAG is incorporated into yeast ribosomes, as demonstrated by affinity purification of ribosomes using an anti-FLAG antibody. Interestingly, in yeast strains that carry both yeast and fly L25/L23a genes, fly L23a RNA is produced but fly L23a protein does not accumulate, suggesting that fly L23a protein is rapidly degraded within these strains and does not compete effectively with endogenous L25 for assembly into yeast ribosomes. *Supported by PA Department of Health Block Grant and Lehigh University.*

### *Lacandonia* Granules during Mitosis

L. F. Jiménez-García,[1] M. L. Segura-Valdez,[1] J. Otero,[1] F. Fernández,[1] A. M. Castrejón,[1] J. Jiménez-Ramírez[2]; [1]Cell Biology, UNAM, Mexico City, Mexico, [2]Comparative Biology, UNAM, Mexico City, Mexico

*Lacandonia* granules are intranuclear ribonucleoprotein particles present and first observed in the nuclei of the plant *Lacandonia schismatica.* They are also observed in other species as *Triuris brevistylis* and *Ginkgo biloba.* These particles contain poly-A RNA and SR proteins and their number changes during development. Here we present additional biological aspects of *Lacandonia* granules. Ultrastructural cytochemical procedures reveal that they are present in all tissues of *L. schismatica* as well as in several other plant species. In addition, analysis of these granules throughout mitosis in three different species indicates that their number decreases as mitosis progresses. At telophase, their number increases again. Taking together, our results show that *Lacandonia* granules are conspicuous ribonucleoproteins in plants and the behavior during mitosis suggests they are not inherited from one cell cycle to the next. ### Isoproterenol Attenuates Wound Healing in Airway Epithelium via cAMP Signaling

B. J. Schnackenberg,[1,2] S. M. Jones,[1,2] C. Pate,[1] B. Shank,[1] L. Sessions,[1] L. M. Pittman,[1] L. E. Cornett,[3] R. C. Kurten[3,2]; [1]Department of Pediatrics, University of Arkansas for Medical Sciences, Little Rock, AR, [2]Arkansas Children's Hospital Research Institute, Little Rock, AR, [3]Department of Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR

β-agonists constitute a major group of medications used to treat the bronchospasms associated with asthma. It has been shown that β-agonists can trans-activate epidermal growth factor (EGF) receptors in a number of cell types. Since EGFRs are involved in wound healing, we hypothesized that β-agonists would have an effect on wound healing. Therefore, the objective of this study was to determine the effects of β-agonists on airway wound healing and the signaling pathways involved. We used human bronchial epithelial (16HBE) cell cultures as a model for airway wound healing. Serum-starved cultures were scrape wounded and cultured in media containing 1% fetal bovine serum (FBS) supplemented with various drugs. Percent wound closure was determined by measuring the wound areas in images collected after 6 hours. Wounds treated with EGF healed quicker than those treated with FBS alone (90% vs. 67% closure, P=0.014) and this stimulation was attenuated by isoproterenol (ISO) (72%, P=0.041). Using Western blot analysis, we show that the attenuation does not occur by directly affecting EGFR activity or ERK signaling. To determine the effects of cAMP on this attenuation, we used the adenylyl cyclase activator forskolin (FOR) to increase cAMP levels. Wounds treated with FBS+EGF+FOR closed slower than those treated with FBS+EGF (61% vs. 93%, P<0.001) or FBS+EGF+ISO (84%, P<0.001). Finally, over-expression of $\beta_2$-adrenergic receptors ($\beta_2$ARs) has been shown to increase cAMP production upon receptor activation. 16HBE cells stably expressing $\beta_2$AR-YFP closed wounds significantly slower when treated with FBS+ISO vs. FBS alone (42% vs. 68%, P<0.001) or when treated with FBS+EGF+ISO vs. FBS+EGF (52% vs. 85%, P=0.013). Based on this data, we conclude that ISO attenuates the EGF-stimulated wound healing in airway epithelium through cAMP-dependent signaling pathways activated by $\beta_2$ARs.

2703

### A Repeated IMP-binding Motif Controls *oskar* mRNA Translation and Anchoring Independently of *Drosophila* IMP

S. Kwon,[1] T. P. Munro,[2] D. St Johnston,[2] B. J. Schnapp[1]; [1]Cell & Developmental Biology, Oregon Health & Science University, Portland, OR, [2]The Gurdon Institute, University of Cambridge, Cambridge, United Kingdom

Zipcode binding protein-1 (ZBP-1) and its *Xenopus* homologue, VERA/Vg1RBP, selectively bind repeated elements in the 3'UTRs of some asymmetrically localized mRNAs. Although the repeated motifs are required for localization of these RNAs, the requirement of ZBP-1/VERA remains unresolved. Here we address the role of ZBP-1/VERA in mRNA localization through analysis of the *Drosophila* homologue, IMP. Using SELEX with the IMP KH domains, we identified the IMP binding element (IBE), UUUAY, and found that this motif occurs 13 times in the *oskar* 3'UTR. IMP co-localizes with *oskar* mRNA throughout oogenesis, and this depends on the IBEs in the RNA, since IMP is de-localized by single nucleotide substitutions in all of the *oskar* IBE motifs. These point mutations do not affect the initial localization of *oskar* mRNA, but prevent its translational activation and anchoring at the posterior pole. Furthermore, mutations to non-overlapping subsets of 3 or 4 of the 13 IBEs also block translation and anchoring completely. However, *oskar* mRNA is localized and translated normally in germline clones of an imp null mutation. Thus, *oskar* regulation requires the IMP binding elements, but not IMP itself. Although many factors have been shown to play a role in the translational repression of unlocalized *oskar* mRNA, much less is known about how translation is activated once the mRNA is localized at the posterior pole. Here we show that this translational de-repression requires multiple copies of the IBE, establishing a parallel requirement for this repeated motif in the regulation of localized maternal mRNAs in *Drosophila* and *Xenopus*. Since IMP itself is dispensable in the germline, translational activation of *oskar* mRNA must depend on another factor that recognizes IBEs. (S.K. and T.P.M. contributed equally, and D.S.J. and B.J.S. contributed equally.)

## Structure of Nuclear Envelope (2704-2721)

2704

### Nesprin-2: An Essential Giant Scaffolder of the Nuclear Envelope

H. Zaim,[1] Y. Lüke,[1] M. Munck,[1] M. Wehnert,[2] G. Walz,[3] A. Noegel,[1] I. Karakesisoglou[1]; [1]Institute for Biochemistry I, Medical Faculty, University of Cologne, Cologne, Germany, [2]Institute of Human Genetics, Ernst-Moritz-Arndt-University, Greifswald, Germany, [3]University Hospital Freiburg, Department of Medicine, Nephrology, Freiburg, Germany

The vertebrate proteins Nesprin-1 and Nesprin-2 together with ANC-1 of *C. elegans* and MSP-300 of *D. melanogaster* belong to a novel family of α-actinin type actin binding proteins residing at the nuclear membrane. Recently, we established linkages and interconnections between Nesprins, lamin A/C and emerin. While the Nesprin-2 subcellular distribution depends upon the lamin A/C network, emerin itself requires Nesprin-2 for proper localization at the nuclear envelope. Lamin A/C mutations may therefore disrupt the localization and function of Nesprin-2 at the nuclear envelope. In agreement with such a scenario we report that the S143F lamin A/C mutation, which causes an early-onset myopathy and progeria in humans, affects specifically the localization of Nesprin-2. Interestingly the expression levels and the subcellular localization of Nesprin-1 is unaltered in the progeroid cells, suggesting that while Nesprin-1 and -2 are similar in their domain architecture they may be functionally divergent. We observed a miss-localization of Nesprin-2 in 40% of the mutant cells, which was accompanied by dramatic nuclear defects. Similar data where obtained in Nesprin-2 knockout mouse dermal fibroblasts. Loss of Nesprin-2 resulted in nuclear deformations and in the miss-localization of emerin. Our data imply a scaffolding function of Nesprin-2 at the nuclear membrane and suggest a potential involvement of this multi-isomeric protein in human disease.

### Structural Analysis of the Domain Topology of the Nucleoporin Nup214/CAN Depending on the Conformational State of the Nuclear Pore Complex

S. M. Paulillo,[1] M. A. Powers,[2] K. S. Ullman,[3] B. Fahrenkrog[1]; [1]M.E. Müller Institute for Structural Biology, University of Basel, Basel, Switzerland, [2]Department of Cell Biology, Emory University School of Medicine, Atlanta, GA, [3]Department of Oncological Sciences, Hunstman Cancer Institute, University of Utah, Salt Lake City, UT

Nuclear pore complexes (NPCs) mediate communication between the nucleus and cytoplasm in eukaryotic cells and are the major gateways for the diffusion of small molecules, as well as signal-mediated transport of proteins, RNAs and RNPs. The NPC is composed of ~30 different proteins (nucleoporins) and most of them are localized symmetrically on both sides of the NPC, whereas only few nucleoporins localize to either its cytoplasmic or nuclear face. The presence of distinct phenylalanine-glycine (FG) repeats domain is a common feature of many nucleoporins. Most likely, the FG repeat motifs play a critical role for the interaction between the NPC and soluble transport receptors. We have recently mapped the domain topology of the vertebrate nucleoporin Nup214/CAN within the *Xenopus laevis* NPC by using domain-specific antibodies in combination with expression of epitope-tagged Nup214/CAN in *Xenopus laevis* oocytes. By doing so, we could show that this nucleoporin is anchored to the cytoplasmic side of the NPC by its non-FG-repeat domains (i.e. its N-terminal and central domain), whereas its C-terminal FG-repeat region appears mobile within the NPC. Moreover, the localization of the FG-repeat domain correlates with the transport state of the NPC. In this context, an arrest of nuclear transport restricts the FG-repeats of Nup214/CAN to their anchoring site within the NPC. Additionally, the localization of the FG-repeat domain is influenced by excessive import or export cargo, indicating that FG-repeat domains chaperone cargo through the NPC. Cellular calcium and ATP levels affect NPC conformation and nuclear transport. We show now that conformational changes of the NPC induced by $Ca^{2+}$ or ATP have only a minor effect on the mobile character of the FG-repeat domain of Nup214/CAN.

### Characterisation of Emerin-Nesprin Interaction

M. A. Wheeler,[1] Q. Zhang,[2] J. D. Davies,[2] C. M. Shanahan,[2] J. A. Ellis[1]; [1]Randall Division of Cell and Molecular Biophysics, King's College, London, United Kingdom, [2]Department of Medicine, Addenbrooke's Hospital, Cambridge, United Kingdom

X-linked Emery Dreifuss muscular dystrophy (EDMD) is a neuromuscular disease with associated cardiomyopathy and arises due to mutations in the inner nuclear membrane protein emerin. Recently we have identified nesprin-1 and 2 as emerin binding partners and shown that both emerin and the nesprins localise to the nuclear envelope and sarcoplasmic reticulum in cardiac tissue. This work was carried out to characterise the emerin-nesprin interaction and determine whether disruptions to this association contribute to defects observed in EDMD. To identify specific regions in both emerin and nesprin involved in the interaction between these proteins, fragments of nesprin-1α, 2α and 2β including each spectrin-like repeat (SR) were amplified and expressed as GST and $his_6$ tagged fusion proteins. Similarly, emerin constructs covering the entire protein were made. Using blot-overlay assays, GST pull-downs, in vitro transcription/translation co-immunoprecipitation and BIACORE analysis we have established that residues 368 to 919 (LEM-like domain to SR5) of nesprin-1α and 1-219 (SR1 to SR2) of nesprin-2β mediate binding to emerin. Having identified those residues that mediate the interaction between emerin and nesprin we have begun to determine whether emerin mutations found in patients with X-EDMD affect this association. To substantiate these findings we have characterised the subcellular localisation of nesprin and emerin in primary neonatal rat cardiomyocytes. This work will provide further insight into the emerin-nesprin interaction.

2707

### Predetermined Nuclear Pores Mediate Transport of Glucocorticoid-induced Cargos

Y. Ludwig, C. Schäfer, H. Oberleithner, V. Shahin; Institute of Physiology II, University of Münster, Münster (NRW), Germany

Steroid hormone induced gene expression is a vital intracellular process that requires translocation of hormone-receptor-dimers from the cytosol to the chromatin. Nuclear translocation of the several thousands dimers occurs through nuclear pore complexes (NPCs) whose total number exceeds many millions in the nuclear envelope. Hence, the question should be raised, whether each NPC could be non-randomly recruited to translocate hormone-receptor-dimers to their target genes that are in turn located in limited domains of the chromatin. To address this question, we expressed glucocorticoid receptors (GRs) in *X. laevis* oocytes and then stimulated them with a potent agonist, triamcinolone acetonide (TA). Over a time scale of 90 seconds to 24 hours after TA injection, nuclear envelope permeability and structure were investigated by fluorescence and atomic force

microscopy. Passive nuclear envelope permeability for fluorescent macromolecules transiently decreased during import of TA-induced GRs (5.53% after 90 seconds of TA stimulation) and export of newly-synthesized mRNA transcripts (10.35% after 20 minutes of TA stimulation) visualized on the nuclear envelope surface at single molecule level. During transport of GRs and mRNA, local areas of the nuclear envelope surface were found divided into two at least distinct populations of NPCs, transporting or resting ones that alternate with each other. We conclude that steroid hormone signalling to the nucleus occurs at selective sites of the nuclear envelope and involves predetermined NPCs.

**Biophysical Characterization of the Head-To-Tail Interaction of Human Lamin Dimers**

J. Schumacher,[1] L. Kapinos-Schneider,[2] N. Mucke,[3] A. Lustig,[2] S. V. Strelkov,[2] U. Aebi,[2] H. Herrmann[1]; [1]Molecular Genetics, German Cancer Research Center, Heidelberg, Germany, [2]M.E.Mueller Institute, University of Basel, Biozentrum, Basel, Switzerland, [3]Biophysics of Macromolecules, German Cancer Research Center, Heidelberg, Germany

We have recombinantly synthesized the amino- and carboxy-terminal end fragments of the alpha-helical rod domain (12 and 5 heptades, respectively) with varying parts of the flanking non-alpha-helical segments of human lamins A, B1 and B2. These fragments represent regions that were implicated in the head-to-tail association of lamin dimers (Heitlinger et al., J. Cell Biol. 113: 485-495). Hence, we analyzed their sedimentation properties by analytical ultracentrifugation after reconstitution from urea into buffers of different ionic strength. The amino-terminal fragments were soluble and sedimented with distinct profiles and peak values of around 1.9 *S* as expected for coiled-coil dimers. In contrast, the carboxy-terminal fragments were, except for that of lamin B2, largely insoluble and precipitated so that no meaningful *S* value could be determined. Precipitation was partly overcome by increasing the salt concentration that, in turn, yielded symmetrical peaks of around 1.5 *S* for these carboxy-terminal fragments in agreement with their smaller size compared to the amino-terminal fragments. Interestingly, mixing of equimolar amounts of the corresponding amino- and carboxy-terminal rod end fragments before centrifugation gave rise to entirely soluble complexes with *S* values peaking between 2.3 and 2.7 *S*. These *S* values are compatible with an ordered tetrameric association of the amino- and carboxy-terminal fragments, as was further corroborated by sedimentation equilibrium centrifugation analysis. Moreover, we show that this association, mimicking the head-to-tail interaction of lamin dimers, also occurs between the respective heterologous pairs of A- and B-type fragments, suggesting that A-type lamins may associate head-to-tail with B-type lamins in any combination. This finding is of considerable importance concerning the more general concept of how lamins may associate *in situ*, for example, within the nuclear lamina.

**Association of Nup153 with the Nuclear Lamina**

K. J. Roux, P. Enarson, M. Crisp, B. Burke; Anatomy and Cell Biology, University of Florida, Gainesville, FL

The nuclear envelope (NE) consists of two contiguous lipid bilayers that delineate the nucleus from the cytoplasm. Studded with large nuclear pore complexes (NPCs) the NE is composed of multiple protein subunits that span the inner (INM) and outer nuclear membrane (ONM). NPCs facilitate regulated transit of macromolecules between the nucleus and cytosol. With a purported role in protein and RNA trafficking, Nup153 is a highly mobile O-linked nucleoplasmic glycoprotein detected at the NPC basket. Nup153 has three distinct domains, an N-terminal region required for targeting and assembly to the NPC, a central zinc finger motif and a C-terminal domain with multiple FG repeats involved in selective nuclear transport. The N-terminal region of Nup153 (aa 3-144) targets the protein to the surface of the inner nuclear membrane (INM) while aa 39-339 are required for NPC assembly. We hypothesized that the INM targeting motif of Nup153 (N144) may interact with nuclear lamins, the filamentous proteins that constitute the mesh-like lamina adjacent to the INM. Our studies identified the requisite expression of lamins A and C (LaA/C) for the proper targeting of N144 to the NE. Furthermore, exogenous wild type, prelamin A and LaA Δ50 (progerin), but not LaC or the fully processed mature LaA colocalize with N144. These results suggest that, by means of the interaction between Nup153 and immature lamin A, NPCs may nucleate *de novo* lamina assembly.

**Nuclear Transport May be Regulated by Competition Among Karyopherins for the Translocation Channel of the Nuclear Pore Complex**

N. Shulga,[1] L. J. Terry,[2] A. Mason,[1] S. Wente,[2] D. S. Goldfarb[1]; [1]Biology, University of Rochester, Rochester, NY, [2]Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN

The nuclear pore complex (NPC) catalyzes the translocation of macromolecules across the nuclear envelope. Cargos are funneled to the NPC by a large family of targeting receptors called karyopherins (Kaps). Kap-cargo complexes bind to 11 phenylalanine-glycine (FG) repeat-containing nucleoporins within or about the central translocation channel. We have been investigating the requirements that different Kaps have for various FG-repeat domains. Based on these studies we already know that not all Kaps are affected identically by the targeted deletion of various FG-repeat domains (Strawn et al., Nat. Cell Biol. 6:197-206 (2004). We are currently testing the hypothesis that nuclear trafficking can be regulated in response to physiological cues by modulating the interaction of certain Kaps with the translocation channel. Kap60p/Kap95p (importin α/β1)-mediated translocation is significantly more resistant than either Kap121p or Kap104p-mediated transport to the deletion of certain FG-domains. Now, we have mapped in some detail which FG-repeat domains are most critical for Kap104p-mediated transport. In some FG-domain deletions, heat shock or over-expression of *SSA1* (Hsp70) both stimulates Kap95p-mediated transport and inhibits Kap104p-mediated transport. Together, these results indicate that Kap95p competes better than Kap104p and Kap121p for the translocation channel, and argue against the alternative hypothesis that Kaps follow physically distinct pathways through the translocation channel. It remains possible that the preferential binding of various Kaps to certain classes of FG-repeat motifs also controls passage through to the translocation channel. We conclude that the nuclear transport of protein and RNA cargos could be regulated in vivo by controlling competition among Kaps for access to FG-repeats within the translocation channel, for example, during heat shock.

**The Lamina of Hutchinson Gilford Progeria Syndrome Cell Nuclei Lacks the Ability to Rearrange**

K. N. Dahl,[1] P. Scaffidi,[2] D. E. Discher,[3] T. Misteli,[2] K. L. Wilson[1]; [1]Department of Cell Biology, Johns Hopkins School of Medicine, Baltimore, MD, [2]National Cancer Institute, NIH, Bethesda, MD, [3]Department of Chemical and Biomolecular Engineering, University of Pennsylvania,

Philadelphia, PA
The premature aging disease Hutchinson-Gilford Progeria Syndrome (HGPS) is caused by mutations in *LMNA*, the gene encoding A-type lamins. Lamins polymerize to form a network of structural filaments at the nuclear envelope and throughout the nucleus, with hypothesized roles in the mechanical stability of the nucleus. Both mechanical stability and mechano-sensitive gene expression are defective in *lmna*-null cells, but the underlying nature of the mechanical properties of the lamina are poorly understood. In this study, micropipette aspiration was used to quantify the viscoelastic properties of isolated, somatic nuclei. The effects and distribution of the applied forces were visualized using GFP-lamin B and Hoechst 33342 stained chromatin. To experimentally separate the mechanical contributions of major nuclear elements (chromatin or lamina), nuclei were also pre-swelled using different concentrations of salt. At high salt, chromatin condenses and is the primary force-bearing element. With low salt the lamina of the nucleus sustains much of the load. The mechanical properties of nuclei from a variety of cells, including those from HGPS patients, were measured. Nuclei from HGPS patients show significant reduction in the ability to rearrange the lamina under mechanical stress and deformation in both the salt swelling/shrinking and micropipette aspiration assays. In contrast to normal nuclei, which 'buckle' homogeneously in response to mechanical stress, HGPS nuclei collapsed along major axes, suggesting catastrophic failure to distribute applied forces across the entire lamina. When visualized using crossed polarizers wildtype nuclei appeared dark, consistent with a randomly-oriented lamina network. However HGPS nuclei were strikingly birefringent suggesting the HGPS lamin network has locally-ordered microdomains. These microdomains can explain most of the mechanical differences seen here between HGPS and normal cells, and may have functional consequences in disease.

2712

**Targeting Protein for Xklp2 (TPX2) is Required for Nuclear Expansion in Xenopus Egg Extracts**

L. O'Brien,[1] L. Wells,[2] C. Wiese[1]; [1]Dept. of Biochemistry, UW-Madison, Madison, WI, [2]Complex Carbohydrate Research Center, University of Georgia, Athens, GA
The Targeting Protein for Xklp2 (TPX2) is necessary for mitotic spindle assembly, but it localizes to the nucleus during interphase (Wittmann et. al., 2000. JCB 149:1405). Mass spectrometry analysis of TPX2 interacting proteins revealed that Lamin associated polypeptide 2 (LAP2), a lamin and chromatin binding protein important for nuclear assembly, is a potential binding partner of TPX2. Consistent with this, purified LAP2 and TPX2 interacted *in vitro* and these proteins could be co-immunoprecipitated from interphase extracts. To determine whether LAP2 binding reflects a role for TPX2 in the nucleus, we depleted TPX2 from interphase *Xenopus* egg extracts and induced the extracts to assemble nuclei. Although nuclei formed in TPX2-depleted extracts possessed nuclear membranes, a lamina and nuclear pore complexes, and they were able to import rhodamine-labeled nucleoplasmin and to exclude 155 kD dextran, these nuclei were significantly smaller than those assembled in mock depleted extracts. Immunofluorescence staining showed that LAP2 localized to the nuclear rim in mock-depleted nuclei but was diffusely distributed in TPX2-depleted nuclei, suggesting that TPX2 may be involved in targeting LAP2 to the nuclear rim. Our data further suggest that the interaction between TPX2 and LAP2 may be required to allow nuclei to grow.

2713

**Barrier-to-Autointegration Factor (BAF) Accumulates in the Nucleus During S Phase and Its Loss Delays Progression of S Phase in HeLa Cells**

T. Haraguchi,[1] T. Koujin,[1] T. Kojidani,[1] H. Osakada,[1] C. Mori,[1] K. L. Wilson,[2] Y. Hiraoka[1]; [1]CREST Research Project, Kansai Advanced Research Center, Kobe, Japan, [2]Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD
Barrier-to-autointegration factor (BAF), a DNA-bridging protein, is essential for embryonic development in *C. elegans* and *Drosophila*. BAF has roles in chromosome condensation/decondensation, nuclear assembly, and gene expression, including cyclin gene expression in *Drosophila*, but its functions are poorly understood in mammalian cells. We examined the subcellular localization of BAF by indirect immunofluorescence staining using a specific antibody for endogenous BAF and HA-tagged BAF in various human cell lines. The cells studied included both mortal (TIG1, and WI-38) and transformed/immortalized lines from various tissues (e.g., A431, SiHa, and HeLa). In interphase cells, BAF localization varied both within and between cell types. Interestingly, BAF localized mainly in the nucleus in some cells, but the cytoplasm of others, suggesting its interphase localization is dynamically regulated during the cell cycle, and perhaps further regulated by cell type. In TIG1 cells, which are mortal, the fraction of cells with predominantly nuclear-localized BAF ('nucleus-positive') decreased upon aging, suggesting BAF is involved in cell proliferation or aging events. Consistent with proliferative roles, studies with immortal cell lines including HeLa cells showed that ~ 30% of non-synchronized cells were nucleus-positive for BAF, whereas ~80% of S-phase-synchronized cells were nucleus-positive. Independently supporting this result, ~80% of actively-replicating (BrdU positive) cells in non-synchronized populations were nucleus-positive for BAF. These results suggested that BAF localizes predominantly in the nucleus during S phase. To test this idea, HeLa cells were subjected to RNAi to downregulate BAF expression. In BAF-RNAi cells the fraction of BrdU-positive cells was 50%, compared to 30% of nonspecific-RNAi controls, indicating that S-phase was prolonged by loss of BAF. These results suggest that BAF concentration in the nucleus is required for normal progression through S-phase in human cells.

2714

**Dynamics and Ultrastructure of the Reforming Nuclear Envelope at Telophase as Revealed by Time-lapse, FRAP, FRET and EM Analyses**

T. Shimi,[1] T. Koujin,[1] T. Kojidani,[1] A. Yamamoto,[2] Y. Hiraoka,[1] T. Haraguchi[1]; [1]CREST Research Project, Kansai Advanced Research Center, Kobe, Japan, [2]Nagahama-Bio University, Nagahama, Japan
Reformation of the nuclear envelope (NE) during mitotic telophase is essential for higher eukaryotic cells to re-establish functional nuclear structures. To understand early (telophase) events of NE assembly, we examined the localization, mobility, and molecular interactions of NE proteins in living cells using fusions with GFP variants. We particularly focused on BAF, a DNA-binding protein that recruits nuclear membrane proteins (e.g., emerin) and A-type lamins to reforming nuclei. In human cells, BAF, lamin A, emerin and other 'LEM-domain' proteins (MAN1, LAP2beta) all localize in a specialized structure close to the central region of a telophase chromosome mass, designated the "core region", when the NE is reforming at telophase. Previous FRAP analysis showed that BAF is highly mobile, whereas lamin A is immobile in the interphase NE.

In contrast, BAF and lamin A as well as emerin, MAN1 and LAP2beta all have similarly low mobility in the core region, suggesting they co-assemble stable structure(s) in the core region. iFRET and time-lapse FRET analyses of the core region showed BAF associates very tightly with other BAF molecules (very high level of FRET with BAF), and also associates, albeit more weakly with emerin (low but detectable FRET). These results show that BAF directly interacts with itself and emerin in the core region. To further examine the re-forming nuclear envelope in high resolution, we combined live observation with EM observation, and found that BAF formed an electron-dense structure at the surface of the core region. We conclude that BAF is organizes as a solid immobile structure in the core region, which recruits emerin and lamin A. We hypothesize that formation of this stable BAF complex is a key step in re-forming a functional nucleus.

**Flexible Nucleoporins as Entropic Barriers to Nucleocytoplasmic Transport**

R. Y. H. Lim,[1] J. Köser,[1] N. Huang,[1] K. Schwarz-Herion,[1] J. Deng,[2] A. K. H. Lau,[2] B. Fahrenkrog,[1] U. Aebi[1]; [1]M.E. Müller Institute for Structural Biology, Biozentrum, University of Basel, Basel, Switzerland, [2]Institute of Materials Research and Engineering (IMRE), Singapore, Singapore

Natively unfolded phenylalanine-glycine (FG)-repeat domains are alleged to form the physical constituents of the selective gate in nuclear pore complexes (NPCs) during nucleocytoplasmic transport. At present, several key aspects of the barrier remain elusive and experimentally unsubstantiated. Examples include the conformational make-up of the FG-repeat domains, the simultaneous trapping mechanism of the barrier, and how these characteristics contribute to the overall kinetics of nucleocytoplasmic transport. To provide insight into the gating mechanism, an experimental platform which mimics the general physical dimensions of NPCs has been constructed to investigate the behavior of surface-tethered, FG-repeat domains at the nanoscale. Atomic force microscope force measurements indicate that the collective behavior of such FG-repeat domains gives rise to a long-range, exponentially decaying repulsive force in physiological buffer. This force acts as a barrier which can effectively repel oncoming passive cargoes from the NPC near-field. The measured force is appropriately described by the Alexander-de Gennes scaling theory which indicates that the molecules are thermally mobile and exist in an extended polymer brush-like conformation. This assertion is confirmed by observing that the brush-like conformation undergoes a reversible collapse transition by increasing the hydrophobic content in the buffer. Importantly, this finding does not preclude the fact that the entropic barrier can also serve to “trap” cargoes containing nuclear localization signals (NLS) in the near-field of an NPC via specific binding interactions between transport receptors (e.g. Karyopherin/Importin) and FG-sites. These results reveal how FG-repeat domains may simultaneously function as an entropic barrier and a selective trap in the near-field of native NPCs i.e. selective gate.

**Nesprins and Sun Domain Proteins Link the Actin Cytoskeleton to the Nuclear Lamina**

M. Crisp,[1] Q. Liu,[1] K. J. Roux,[1] B. Burke,[1] P. D. Stahl,[2] D. Hodzic[2]; [1]Anatomy and Cell Biology, University of Florida, Gainesville, FL, [2]Cell Biology and Physiology, Washington University School of Medicine, St. Louis, MO

Nesprins and SUN domain proteins link the actin cytoskeleton to the nuclear lamina The nuclear envelope (NE) defines the barrier between the nucleus and cytoplasm. Its major features are the inner and outer nuclear membranes (INM and ONM) separated by a 50-100nm perinuclear space (PNS). The mammalian INM contains roughly 50 unique polypeptides. Among these, Sun1 and Sun2, a pair of type II integral membrane proteins, are characterized by an evolutionarily-conserved C-terminal stretch of 200 amino acids (SUN domain) that localize in the perinuclear space. Sun proteins are anchored in the INM via their nucleoplasmic N-terminal domains which interact with components of the nuclear lamina (NL). The NL is a major structural element of the NE that is closely associated with the nuclear face of the INM and is composed primarily of A- and B-type lamins. In the case of Sun2, its localization within the INM is partially dependent upon the presence of A-type lamins. While the ONM is biochemically related to the ER, it does contain certain unique proteins. One of these is nesprin2 giant, an 800kDa type II membrane protein that contains a small C-terminal lumenal domain and a giant cytoplasmic domain featuring multiple spectrin repeats and an N-terminal actin binding region. Localization of nesprin2 giant is dependent upon the Sun proteins since co-depletion of Sun1 and 2 by RNAi leads to loss of ONM-associated nesprin. Furthermore, overexpression of a soluble form of the Sun1 lumenal domain leads to a similar loss of nesprin2 giant from the ONM. Cells subjected to either treatment exhibit dilation of the ONM. Our data indicate that Sun1/2 and nesprins interact across the PNS. In this way these proteins form a molecular linkage between the actin cytoskeleton and the NL.

2717

**Sorting of Membrane Proteins to the INM: Protein-protein Interactions Occurring during this Process**

S. C. Braunagel; Entomology, Texas A&M University, College Station, TX

A short sequence of 33 amino acids derived from an envelope protein of the occlusion derived virus of baculovirus is sufficient to direct fusion-proteins to the viral envelope which assembles in the nucleus; and in the absence of infection, direct fusion-proteins to the inner nuclear membrane (INM). This sequence has been named a viral INM sorting motif. Using the viral sorting motif as probe, chemical crosslinking studies designed to covalently crosslink temporal intermediates in the trafficking pathway suggest that during infection, specific protein-protein interactions regulate trafficking from the ER to the INM: sorting begins at the translocon; and during transit from the ER to INM multiple protein-protein interactions are detected. A putative cellular cognate of a viral protein that crosslinks to the INM-sorting motif has been identified and has been named SMAP-10 (sorting motif associated protein of 10 kDa). Directed studies of SMAP-10 show that like its viral counterpart, it is membrane associated, present within the ER and likely functions as a cellular sorting factor to facilitate transport of integral membrane proteins to the INM. These data suggest that for some integral membrane proteins, the mechanism of protein trafficking to the INM involves multiple sorting events; and the study of the trafficking of baculovirus envelope proteins represents a viable model system to identify and expand our understanding of the molecular basis of protein sorting to the INM.

2718

**Study of the Nuclear Pore Complex Nup107-160 in Interphase and Mitosis**

M. Platani; Gene Expression Unit, European Molecular Biology Laboratory, Heidelberg, Germany

Fellow In eukaryotes, trafficking between the nucleus and the cytoplasm occurs via large multiprotein structures inserted in the nuclear envelope

(NE), the nuclear pore complexes (NPC). At the beginning of mitosis the nuclear envelope and the NPC break down. NPC disassembly is initiated by direct phosphorylation of a subset of nucleoporins via the mitotic cdc2/cylcin B kinase [1]. Reformation of the nuclear envelope at the end of mitosis involves early association of a subset of nucleoporins (the Nup107-160 complex) with chromatin followed by association of nuclear envelope precursor membranes. The Nup107-160 complex, composed of nine nucleoporins, has been demonstrated to play a critical role in postmitotic NPC formation since its absence results in nuclei with nuclear envelope devoid of NPCs [2,3]. To further characterize the mechanism of the temporal and spatial regulation of the Nup107-160 complex in NPC reassembly around chromatin, we are using the *in vitro Xenopus* system for biochemical studies and mammalian HeLa cells for high resolution live cell imaging. We generated antibodies against three of the nine components of the complex the Nup43, Nup37 and seh1. Preliminary data do suggest differences in the phosphorylation state of the complex between interphase and mitosis. Combining biochemical analysis and RNAi we are trying to understand how the modification of the complex is achieved and how this affects its interaction with chromatin and final assembly into a functional NPC. 1. Suntharalingam, M. et al. Peering through the Pore: Nuclear Pore Complex Structure Assembly , and Function. *Developmental Cell* **4,** 775-789 (2003).

2719

**Sequence Preference in RNA Recognition by the Nucleoporin Nup153**

A. E. Bilak, J. Ball, C. Dimaano, K. Ullman; Oncological Sciences, Huntsman Cancer Institute, Salt Lake City, UT

Nuclear pore complexes bridge the inner and outer nuclear membrane to form aqueous channels through which traffic between the cytoplasm and nucleus takes place. These macromolecular structures are composed of multiple copies of ~30 different proteins that work coordinately to guide cargo-receptor complexes in transit. Interactions between nuclear pore proteins and transport receptors facilitate movement through the pore, although in some cases nuclear pore proteins contact cargo directly. In exploring the range of interactions that are possible at the pore complex, we previously found that the pore protein Nup153 can bind RNA directly. The ability to bind RNA was consequently mapped to 150 amino acids. This novel RNA binding region was found to bind to several different mRNAs, but not to tRNA, snRNA, or 5S rRNA, when tested in an in vitro pull-down assay. Here, we have further characterized the RNA recognition properties of this nuclear pore protein. We first used RNaseH-directed cleavage to determine if there was a dominant binding sequence within a short, plasmid-derived RNA that is recognized by the Nup153 RNA binding domain. We found that these shorter RNA fragments reveal distinct binding preferences. While the molecular determinants of recognition have yet to be fully defined, our results to date indicate that nucleotide bias (toward cytidine and guanosine) contributes to recognition. However, nucleotide content did not strictly correlate with binding ability. Using synthetic RNA oligonucleotides, we tested and confirmed that sequence arrangement is important as well. Given the previous observation that the Nup153 RNA binding domain can associate with a spectrum of mRNAs, our working model is that an RNA motif with a fair degree of flexibility allows Nup153 to discriminate between different classes of RNA and may mediate direct contact during the process of mRNA export.

2720

**Impact of Karmellae on Nuclear Organization and Inheritance in S cerevisiae**

T. Hattier, A. M. Tartakoff; Pathology, Case Western Reserve University, Cleveland, OH

Overexpression of a number of individual transmembrane proteins of the ER results in the production of “karmellae,” which are compatible with ongoing cell growth. As first described by R. Wright and J. Rine in their studies of HMG CoA-Reductase I overexpression (JCB, 107, 101-114 (1998)), these multilayered structures often surround more than half of the perimeter of the nucleus. The characteristic myelin-like units are highly enriched in the overexpressed protein and lack nuclear pores (NPC). As a result, the nucleus becomes anatomically and functionally polarized, with import and export being restricted to only a fraction of the perimeter. By construction of strains in which individual proteins are tagged with GFP or RFP, we observe that the nucleolus associates closely with karmellae, while the spindle pole body does not. Lac operator-tagged centromeric and telomeric loci do not show an obvious preference for either portion of the nuclear perimeter. Selected electron micrographs of Wright and Rine show that karmellae are retained by the mother cell and do not enter the bud. We have confirmed these observations by examining cells in anaphase which express GFP-tagged HMG CoA-Reductase. Since the septin ring has been implicated in segregation of cortical proteins between mother and bud, we have also studied tagged karmellae in septin mutants. Restriction of these structures is not altered upon inactivation of individual septins. Similar behavior is characteristic of the ESCapades which are produced upon accumulation of the lamin-like protein, Esc1p (see accompanying poster/talk). We therefore suggest that their lack of inheritance - rather than resulting from the presence of a physical barrier - reflects the existence of a coherent “maternal domain” of the nuclear perimeter.

2721

**Functional Analysis of C38D43, an AT-hook Protein Implicated in Nuclear Pore Function and Chromosome Segregation in Caenorhabditis elegans**

A. G. Fernandez, F. Piano; Biology, New York University, New York, NY

The advent of functional genomics has enhanced the potential for specific functional prediction of genes. Using an RNAi-based approach, several studies of the early *C. elegans* embryo have revealed detailed phenotypes for hundreds of genes required for embryogenesis. Through the systematic analyses of discrete characters in the early embryo and the generation of a phenotypic signature based on a digital representation of these characters, we developed phenoclustering, a means of grouping genes based on phenotype. Using this technique, a novel AT-hook domain protein C38D4.3 was grouped in one case with genes known to be required for chromosome separation (Piano et. al, 2002) and in another study with the nucleoporins (Sönnichsen et al., 2005 ). *In vivo* localization of C38D4.3 showed that it shuttles between the kinetochore and the nuclear periphery during the cell cycle. To test the hypothesis that this gene is required for chromosome segregation, we have analyzed a histone:GFP fusion in embryos RNAi-depleted of C38D4.3 and observed chromatin bridges at anaphase. We are now studying this gene by analyzing how its localization changes when genes with similar phenotypic signatures are depleted using RNAi. Using this approach we have identified *npp-9*, the *C. elegans* homologue of RanBP2, as a gene required for the proper nuclear envelope localization of C38D4.3. RanBP2 is an effector of the small GTPase Ran that is required for nucleocytoplasmic transport and postmitotic nuclear envelope re-formation. Thus our observations are consistent with the idea that C38D4.3 functions in both chromosome segregation and the nuclear envelope, providing support for both hypotheses generated by phenoclustering.

## Invertebrate Development (2722-2734)

2722

### Echinoid Mosaic Epithelia as a Model for Developmental Boundaries in Drosophila

C. E. Laplante, L. A. Nilson; Biology, McGill University, Montreal, PQ, Canada

Smooth boundaries between cell populations can reflect sorting based on affinity differences, but the causes of these differences and the subcellular structure of the boundary remain obscure. The *Drosophila* ovarian follicular epithelium is a simple model system that allows the generation of ectopic boundaries through the production of genetic mosaics. In follicular epithelia mosaic for the *echinoid*$^{F72}$ (*ed*$^{F72}$) allele, an actomyosin ring assembles at the clone border, constricting the clones apically. Interestingly, levels of DE-Cadherin and β-catenin are reduced at the interface between *ed*$^{F72}$ mutant and non-mutant cells, indicating a destabilization of adherens junctions at the clone border. While this boundary is reminiscent of multicellular contractile rings that assemble during *Drosophila* embryonic dorsal closure, wound healing and apoptotic cell extrusion, we have found no evidence of Jun kinase activity at the *ed*$^{F72}$ clone border and the *ed*$^{F72}$ mutant cells are not apoptotic. During mid-oogenesis *ed*$^{F72}$ mutant clones are indistinguishable from wild type cells, suggesting that *ed* may be temporally regulated. Correspondingly, Ed levels are high during early and late oogenesis but are greatly reduced during mid-oogenesis suggesting that the actomyosin ring between mutant and wild type cells disassembles in the absence of an Ed expression boundary. After mid-oogenesis, Ed first reappears in a dorsal-anterior subset of follicle cells, generating an endogenous Ed expression boundary with the neighboring cells. Interestingly, this localization corresponds to a smooth morphological boundary between two cell populations that will ultimately cooperate to form an epithelial tube. This work implicates Ed in a cell sorting process in the *Drosophila* follicular epithelium, and suggests that the local formation of a contractile actomyosin structure and regulation of adherens junctions may represent a general cell sorting mechanism applicable to developmental boundaries.

### Individual Nuclei in the Drosophila Syncytial Blastoderm Embryo Possess an Organized and Restricted ER/Golgi Membrane System in the Absence of Plasma Membrane Boundaries

M. Mavrakis,[1] D. Frescas,[1] R. DeLotto,[2] J. Lippincott-Schwartz[1]; [1]NIH, Bethesda, MD, [2]University of Copenhagen, Copenhagen, Denmark

Protein secretion within all eukaryotic cells is controlled by the endoplasmic reticulum (ER) and Golgi apparatus, whose spatial organization and dynamics are closely associated with the nucleus and centrosomally-derived microtubules. The Drosophila syncytial blastoderm, a multi-nucleated single cell embryo, initially lacks this organization- with nuclei and centrosome-derived microtubules localized deep within the embryo interior, and maternally-derived ER and Golgi distributed at the embryo cortex. Here, we use GFP reporters, live cell imaging and biophysical techniques to investigate how ER and Golgi structures become associated with nuclei in the syncytial blastoderm, and how the ER and Golgi become equally apportioned into separate cells at cellularization. When nuclei were still localized in the embryo interior, we found that cortical ER existed as a single interconnected membrane system within which resident ER components rapidly diffused. The Golgi apparatus was closely associated with the cortical ER and consisted of thousands of small structures containing proteins undergoing constitutive cycling into and out of the ER. Upon nuclear arrival at the cortex, the lateral diffusion and inter-organellar movement of ER and Golgi components became restricted to ER and Golgi membranes surrounding individual nuclei, resulting in each nucleus being surrounded by a distinct ER and Golgi membrane system in the absence of a plasma membrane boundary. This unexpected endomembrane organization within the embryo could serve to ensure that equivalent amounts of ER and Golgi are packaged with nuclei at cellularization. It may further allow secretory products to be released in a spatially and temporally controlled fashion across the embryo both before and during cellularization.

2724

### Drosophila Myosin V

A. Hong, J. Toth, J. R. Sellers; NHLBI, NIH, Bethesda, MD

Class V myosins have been studied extensively in the metazoans and are known to be involved in a wide range of cellular functions. In addition, multiple cargoes of Myosin V have been identified. However, little is known about the functions of the Drosophila myosin V. Our lab is investigating the role of Drosophila myosin V and its potential binding partners by studying the localizations of myosin V in the embryo, larva and adult flies. In the embryo, myosin V is expressed in the neuroblasts in the central nervous system. In the larva, the protein is detected in the salivary gland, imaginal rings, proventriculus, gastric caeca, the digestive system and the Malphigian tubules. The staining of myosin V is punctuated and in some cells it is localized subcortically, suggesting a possibility of its association with other vesicles. Myosin V is strongly expressed in the third instar larva in the imaginal rings. These cells are precursors of the adult tissues and this suggests a correlation between the lethal phase of Myosin V mutants that occurs during the third instar larva. We are examining the role of Myosin V in the transition from a larva to a pupa and adult. From the yeast 2-hybrid analysis, we have a few potential binding partners of Myosin V and we are performing biochemical and genetic interaction studies.

### Biological Mechanisms of Sex Determination and Sex-specific Gene Regulation: Biochemical Studies of Doublesex

W. Zhang, B. li, Y. Yang, J. R. Bayrer, M. A. Weiss; Biochemistry, Case Western Reserve University, Cleveland, OH

*Doublesex (dsx)* is a transcription factor in *Drosophila* that regulates somatic sexual differentiation. Male- and female-specific splicing isoforms of DSX share a novel DNA-binding domain (the DM motif), broadly conserved among metazoan sex-determining pathways. Mutations or deletions of these genes are associated with intersexual abnormalities, including the human birth defects termed “9p syndrome”. Here, we characterize the DM motif by site-directed and random mutagenesis using a yeast one-hybrid system and extend this analysis by chemogenetic complementation in vitro. Mutations that impair DNA binding tend to occur at conserved positions whereas neutral substitutions occur at non-conserved sites. Evidence for a specific salt bridge between a conserved lysine and the DNA backbone is obtained through the synthesis of non-standard protein- and DNA analogs. Second, structure-function relationships in the female-specific C-terminal dimerization domain were investigated by characterizing the sex-specific interaction between DSX$^{F}$ and its putative transcriptional coactivator IX. Our data suggest that the dimerization domain instead of the sex-specific tail is responsible for IX binding. Finally, to elucidate the mechanism by which of DSX$^{F}$ controls female sex-specific behavior, we

have identified two temperature-sensitive mutations in the $DSX^F$ C-terminal dimerization domain. Allelic replacement of wild-type *dsx* by our designed temperature-sensitive alleles promises to provide definitive evidence for the functions of $DSX^F$ in somatic sexual differentiation and courtship behavior. Together, these results provide molecular links between the structure of $DSX^F$ and its function in the regulation of sexual dimorphism.

2726

**The *Drosophila* Dnase II Enzyme Is Required for Hemocyte Immune Function**

C. Seong, R. Ramirez, R. J. Aguilera; Biology, University of Texas at El Paso, El Paso, TX

DNase II enzymes are highly conserved proteins that are required for the degradation of DNA within phagocytes. Engulfment of apoptotic cells and/or bacteria by phagocytic cells requires the function of this nuclease to completely destroy ingested DNA within phagolysosomes. Mutation of the *dnase II* gene results in an increase of undegraded apoptotic DNA within phagocytic cells in mice, nematodes (*C. elegans)*, and fruit flies (*Drosophila melanogaster*). Reduction of DNase II enzymatic activity in *Drosophila dnase Il* hypomorphic mutants results in increased accumulation of DNA in the ovaries with no other obvious phenotypic abnormalities. Due to the importance of DNA clearance after bacterial infection, we hypothesized that a severe reduction of DNase II activity should result in an inability of mutant animals to mount an efficient immune response. To test this hypothesis, we have generated RNAi-*dnase II* transgenic flies. As expected, expression of the RNAi-*dnase II* construct in hemocytes and in whole animals resulted in a severe reduction of DNase II activity and a significant decrease in hemocytes. Furthermore, infection of RNAi-*dnase II* flies with gram negative and positive bacteria resulted in a severe reduction in fly viability. These results confirm that DNase II is essential for hemocyte function and implicate this enzyme as an important component of the immune system of *D. melanogaster*.

2727

**Inhibition of Apoptosis by p26: Implications for Small Heat Shock Protein Function during Development of *Artemia franciscana* Embryos**

T. S. Villeneuve,[1] X. Ma,[2] Y. Sun,[1] M. M. Oulton,[1] A. E. Oliver,[2] T. H. MacRae[1]; [1]Biology, Dalhousie University, Halifax, NS, Canada, [2]Center for Biostabilization, University of California, Davis, CA

p26, an abundantly expressed small heat shock protein, is thought to establish stress resistance in oviparously developing embryos of the crustacean, *Artemia franciscana*, by preventing irreversible protein denaturation, but this molecular chaperone may also promote survival by inhibiting apoptosis. To test this possibility stably transfected mammalian cells producing p26 were generated and their ability to resist apoptosis was determined. Examination of immunofluorescently stained transfected 293H cells by confocal microscopy demonstrated p26 is diffusely distributed in the cytoplasm with a minor amount in nuclei, and as shown by immunoprobing of western blots, p26 constituted approximately 0.6% of soluble cell protein. p26 localization and quantity were unchanged during prolonged culture and the protein had no apparent ill effects on transfected cells. Molecular sieve chromatography in Sepharose 6B revealed p26 oligomers composed of at least 20 monomers, with a second fraction occurring as larger aggregates. A similar pattern was observed in sucrose gradients but overall oligomer size was smaller. Mammalian cells containing p26 were more thermotolerant than cells transfected with expression vector only, and as measured by annexin V labeling, Hoescht 33342 nuclear staining and pro-caspase-3 activation, transfected cells resisted heat- and staurosporine-induced apoptosis more effectively than control cells. These properties of p26 are potentially important to *Artemia* embryos because they are frequently exposed to high temperature in their natural habitat. p26 also blocked apoptosis in transfected cells during drying and rehydration, conditions thought to activate diapause embryos. The findings demonstrate that in addition to functioning as a molecular chaperone, p26 inhibits apoptosis. This is an activity shared by other small heat shock proteins and it has the potential to play an important protective role during *Artemia* development.

2728

**Synthesis and Function of ArHsp21 and ArHsp22, Small Heat Shock Proteins from *Artemia franciscana***

Z. Qiu, T. H. MacRae; Biology, Dalhousie University, Halifax, NS, Canada

Oviparously developing embryos of *Artemia franciscana* are released from females as encysted gastrulae (cysts) which enter diapause, a profound state of metabolic dormancy characterized by extreme resistance to stress. Cysts withstand environmental insults such as high temperature, desiccation, and long term anoxia, with their protection thought to depend upon molecular chaperones. Screening of a cDNA library generated by subtractive hybridization identified two small heat shock proteins in oviparous embryos, these in addition to p26, a thoroughly described member of this chaperone group found in *Artemia*. Full length cDNA sequence was obtained for each small heat shock protein using 3-' and 5'- RACE, and probing of Southern blots with labeled cDNA indicated a single gene for each protein. The small heat shock proteins, named ArHsp21 and ArHsp22, are 29% and 39% identical to p26 in amino acid sequence and they form oligomers, as is characteristic of these proteins. ArHsp21 and ArHsp22 prevented citrate synthase denaturation at 43 °C and the aggregation of insulin under reducing conditions at room temperature, standard *in vitro* assays for chaperone activity. Real time PCR and immunoprobing of western blots demonstrated these small heat shock proteins are synthesized predominately in oviparously developing embryos, with neither detectable by the time larvae reach second instar. After a one hour heat shock at 39 °C small amounts of ArHsp22, but not ArHsp21, were synthesized in adult *Artemia*. ArHsp21 and ArHsp22 have the ability to confer stress resistance during oviparous development of *Artemia* embryos, and ArHsp22 also offers protection to mature animals encountering unfavorable environmental conditions.

2729

**Characterization of p8, a Developmentally Regulated Co-transcription Factor from *Artemia franciscana* Embryos**

Z. Qiu, T. H. MacRae; Biology, Dalhousie University, Halifax, NS, Canada

Embryos of the brine shrimp *Artemia franciscana* undergo either oviparous or ovoviviparous development, with pathway selection dependent on genetic and environmental factors. Ovoviviparous development results in release of swimming larvae from females. In the oviparous pathway, however, development arrests at gastrulation, encystment pertains and metabolism shuts down, a complex process undoubtedly subject to several regulatory mechanisms. Screening of a library produced by subtractive hybridization yielded a partial cDNA from oviparous *Artemia* embryos for the co-transcription factor p8, a protein known to influence cell growth in other organisms. Full length p8 cDNA sequence was obtained by 3'- and 5'-RACE, yielding a deduced amino acid sequence 55% and 66% identical to human and *Drosophila* p8, respectively. Probing of restriction

digested genomic DNA on Southern blots with labeled cDNA indicated a single p8 gene in *Artemia.* As demonstrated by 5'-RACE the p8 gene has two transcription start sites, both of which are active, but proteins of only one size are produced implying a single translation start site. Approximately one kb of putative upstream regulatory region was obtained by LA PCR *In Vitro* Cloning technology and sequence analysis identified several potential transcription factor binding sites. Real time RT-PCR showed that p8 mRNA was restricted almost entirely to the oviparous pathway, peaking in amount at one day post-fertilization and then declining gradually during encystment. The synthesis and localization of p8 in *Artemia* embryos will be further analyzed by application of immunological procedures using available antibodies. p8 has the potential to influence *Artemia* embryo development, perhaps by aiding in the selection of expressed genes as oviparous development initiates.

2730

**The Identification of Microtubule-Associated Proteins during Development of the Brine Shrimp, *Artemia franciscana***

P. A. O'Connell,[1] D. M. Pinto,[2] K. A. Chisholm,[2] T. H. MacRae[1]; [1]Biology, Dalhousie University, Halifax, NS, Canada, [2]National Research Council Institute for Marine Biosciences, Halifax, NS, Canada

Microtubules are dynamic polymers that influence cell shape, polarity, and movement of intracellular components. The organization and function of microtubules are determined by microtubule-associated proteins (MAPs) which associate with these cytoskeletal elements *in vivo* and co-purify with tubulin *in vitro.* This study represents the first large scale identification of MAPs in post-diapause cysts of the crustacean *Artemia franciscana*, where MAPs are defined as salt-extractable proteins which co-purify with microtubules upon taxol-induced tubulin assembly and centrifugation through sucrose cushions. MAPs obtained from encysted *Artemia* after 0, 6, and 12 hours of development were resolved by two-dimensional gel electrophoresis. One hundred and ninety three MAPs, 73 from undeveloped cysts, and 60 each from cysts developed 6 and 12 hours, were selected for identification by mass spectrometry. High confidence peptide identity data ($p<0.05$) were obtained for 85 of the *Artemia* MAPs, and fifteen occurred in at least 2 stages of development. The identified MAPs were grouped according to function. For example, molecular chaperones were identified and they likely arise as part of a stress response in which tubulin and other proteins are protected as embryos encyst and enter diapause. The observation of several ribosomal proteins and elongation factors suggests encysted embryos are primed to synthesize proteins once development resumes and the association of metabolic enzymes with microtubules may facilitate the flow of intermediates through metabolic pathways, thus promoting growth. The study has revealed many interesting MAPs within *Artemia* embryos, indicating how protein-protein interactions within the cytoskeleton contribute to development and growth.

2731

**Detection of Lectin from Banana Prawn (*Penaeus merguiensis*) by Hemagglutination and ELISA**

W. Rittidach,[1] P. Utarabhand,[2] J. L. Hedrick[1]; [1]Animal Science, University of California, Davis, CA, [2]Biochemistry, Prince of Songkla University, Hatyai, Thailand

Lectins in the hemolymph of invertebrates are active participants in cellular and humoral immune recognition mechanisms. The quantification of lectin in shrimp hemolymph is essential to evaluate shrimp's resistance to pathogenic bacteria. In our studies, serum lectin of *Penaeus merguiensis* contained high hemagglutinating activity against rabbit red blood cells. Hemagglutination was inhibited by *N*-acetyl neuraminic acid and fetuin. We purified lectin from *Penaeus merguiensis* hemolymph by affinity chromatography on a fetuin-agarose column and subsequently by gel filtration chromatography using a Superose 12 column. The molecular mass of the lectin was approximately 316.2 kDa. Purified lectin shows two bands (32.3 and 30.9 kDa) on SDS-PAGE with similar isoelectric points of 6.0. The amino acid composition of the purified lectin was determined on a Waters Picotag system. Purified lectin is mainly composed of hydrophobic and polar amino acids. An amount of the lectin antibody was raised by the purified lectin in the albino male rabbit. The serum IgG fraction was partially purified by ammonium sulfate precipitation and DEAE-Sephacel column. The partially purified antibody reacted with the purified lectin by a Western blot of the hemolymph. The antibody was used to develop ELISA (Enzyme-Linked Immunosorbent Assay). The ELISA standard curve was linear over a range of 0.17-2.33 ng/µl lectin. The level of hemolymph lectin was determined by means of ELISA and hemagglutination. Since the lectin level and hemagglutination activity in shrimp hemolymph changed in different stages of oogenesis, the hemolymph lectin may be involved in oogenesis of *Penaeus merguiensis.*

2732

**Differential Effect of Illumination on *in hospite* and Isolated Zooxanthellae: Identification of the 36 kDa Protein and its Role in Cnidarian-dinoflagellate Endosymbiosis**

C. Chen,[1] H. Huang,[1] T. Yeh,[1] H. Huang,[2] W. Uang,[1] L. Fang[3]; [1]Institute of Marine Biotechnology, National Dong Hwa University, Checheng, Pingtung, Taiwan Republic of China, [2]Research and Planning, National Museum of Marine Biology & Aquarium, Checheng, Pingtung, Taiwan Republic of China, [3]Institute of Marine Biodiversity and Evolution, National Dong Hwa University, Checheng, Pingtung, Taiwan Republic of China

Cnidarian-dinoflagellate endosymbiosis represents an important cellular regulation in various marine invertebrates, such as reef-building corals and anemones. The symbiont dinoflagellate (e.g. the *Symbiodinium* spp., or zooxanthellae in generic name) reside in endoderm cells of host animals, which initiates a dynamic inter-transportation of nutrition and a series of complex cell-cell interaction. Nevertheless, molecular mechanism of this regulation to maintain the endosymbiotic state remains unknown. By using isolated symbiotic endodermal cells, we focus to investigate how illumination used to provide photosynthesis and culture isolated zooxanthellae can affect zooxanthellae *in hospite* (*i.e.* zooxanthellae that are included in endodermal cells). A novel microscopic application where digital fluorescence microscopy is combined with *P*ulse *A*mplitude *M*odulated microscopy (Microscopy-PAM), was used to examine photosynthetic efficiency (Fv/Fm) of zooxanthellae. Upon illumination (0-100 $\mu E m^{-2} s^{-1}$), photosynthesis efficiency of cultured isolated zooxanthellae remains un-altered, while those of *in hospite* zooxanthellae significantly decrease in a dose-dependent manner. Illumination initiates the breakdown and permeabilization of membrane in symbiotic endodermal cells but not isolated zooxanthellae, indicating the presence of a membrane structure in symbiotic endodermal cells that is sensitive to illumination. Finally, changes of protein expression in symbiotic endodermal cells were specifically analyzed. Results show that a protein with molecular weight ~36 kDa decreased upon illumination in a dose-dependent manner. The disappearance of 36 kDa protein upon illumination is not due to the membrane breakdown. These results suggest that both specific membrane and protein may be critical in regulating the endosymbiosis in cnidarian species.

2733

**Translocation of Symbiotic Zooxanthellae from Ectoderm to Endoderm during the Development of Planula Larvae in Coral *Euphyllia glabrescens***

H. Huang,[1] L. Fang,[2] C. Chen[3]; [1]Research and Planning, National Museum of Marine Biology & Aquarium, Checheng, Pingtung, Taiwan Republic of China, [2]Institute of Marine Biodiversity and Evolution, National Dong Hwa University, Checheng, Pingtung, Taiwan Republic of China, [3]Institution of Marine Biotechnology, National Dong Hwa University, Checheng, Pingtung, Taiwan Republic of China

In endosymbiotic Cnidaria-dinoflagellate associations, sites of initial zooxanthellae (*i.e. Symbiodinium* spp.) acquisition, distribution and their effects on host animal development are unclear. Taking advantage of various autofluorescence expressed by larval tissues, we followed the distribution of symbiotic zooxanthellae during the process of larval release, settlement and metamorphorsis in a stony coral *Euphyllia glabrescens.* Results showed that planula larvae freshly released from parental animals already contain differentiated oral aperture in the region of blastopore, indicating the complement of gastrulation and formation of two distinct germ layers, the ectoderm and the endoderm. At this early stage, 70-80% of symbiotic zooxanthellae distribute in the ectoderm layer. During the following developmental process, symbiotic zooxanthellae translocate from the ectoderm into the endoderm by passing through the extracellular matrix mesoglea. Later on, all zooxanthellae (~100%) re-distribute into endodermal cells during the early stage of metamorphosis when tentacles start to emerge around the oral region. Quantitative analysis indicates that symbiotic zooxanthella is able to translocate in a directional manner between different germ layers either passively or actively during early development. Secondly, cellular sites of initial zooxanthellae acquisition and final establishment of stable endosymbiosis are different. Finally, the dynamic re-distribution of intracellular zooxanthellae between different germ layers may act as a pivotal signaling in determining the embryonic development of corals.

**Searching the Site of Interaction between Microorganisms and Antimicrobial Peptides from the Hemocytes of the Spider *Acanthoscurria gomesiana***

A. H. Fukuzawa,[1] B. C. Vellutini,[2] P. I. Silva Júnior,[3] R. A. Mortara,[4] J. M. C. da Silva,[2] S. Daffre[1]; [1]Parasitologia, Universidade de São Paulo, São Paulo, Brazil, [2]Histologia e Embriologia, Universidade de São Paulo, São Paulo, Brazil, [3]Laboratório de Artrópodes, Instituto Butantan, São Paulo, Brazil, [4]Microbiologia, Imunologia e Parasitologia, Universidade Federal de São Paulo, São Paulo, Brazil

Invertebrates protect themselves against microbial infection by production of different antimicrobial peptides (AMPs). We previously presented the purification and characterization of two AMPs, gomesin and acanthoscurrin, from the hemocytes of naïve spider *A. gomesiana* (*J. Biol. Chem.*, 275: 33464, 2000; *Develop. Comp. Immunol.*, 27: 781, 2003). We also showed that gomesin is stored in granules of the hemocytes (*Insect. Biochem. Molec.*, 33: 1011, 2003). The main aim of the current work was to investigate the site of interaction between those AMPs and invader microorganisms: (i) in the plasma, after releasing of AMPs by the hemocytes or (ii) in the phagossomes after the fusion of granules containing AMPs. Firstly, the localization of gomesin and acanthoscurrin was compared by immunofluorescence, showing that 57% of hemocytes store both AMPs, either in the same granule or in different granules. Those AMPs were detected in the plasma after an experimental infection of spiders. Interestingly, despite phagocytosis be a conserved immune response described for almost all groups of arthropods, we did not observe the occurrence of such process after microbial challenge with *Sacharomyces cereviseae* in the spiders heart. In addition, it was noticed that the heart of spider presents some cells without granules, which probably are prehemocytes. Moreover, a challenged heart exhibited more hemocytes with granules than the naïve one, indicating a possible migration of these cells to the site of injury. Therefore, our results strongly suggest that the hemocytes might first migrate to the site of injury and then release their AMPs. Phagocytosis should have a subsequent role, being responsible for the clearance of cellular debris and remodeling of damaged tissues. Supported by FAPESP/CNPq

**Inositol Polyphosphate Pathway Regulates Vertebrate Left-Right Morphogenesis**

B. Sarmah,[1] B. Appel,[2] S. R. Wente[1]; [1]Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN, [2]Biological Sciences, Vanderbilt University, Nashville, TN

Vertebrate body plans have a conserved left-right (LR) asymmetry manifested in the position and anatomy of the heart, visceral organs, and brain. Recently, we reported that the inositol 1,3,4,5,6-pentakisphosphate ($IP_5$) 2-kinase (Ipk1), an enzyme in the inositol polyphosphate (IP) pathway, is critical for the establishment of LR asymmetry in zebrafish (Sarmah et al., Dev. Cell 9, 133-145, 2005). Ipk1 catalyzes the conversion of $IP_5$ to inositol hexakisphosphate ($IP_6$). *ipk1* knockdown by antisense morpholino oligonucleotide injection randomizes LR-specific gene expression and organ placement, effects that are associated with reduced left-biased intracellular $Ca^{2+}$ flux in cells surrounding the ciliated Kupffer's vesicle (KV). A role for asymmetric $Ca^{2+}$ flux, potentially generated by cilia driven nodal flow, in establishing LR asymmetry in mice has also been reported by others. However, current understanding of the mechanisms that trigger and propagate this $Ca^{2+}$ flux in any vertebrate is poor. Strikingly, we observed that a reduction in Ipk1 activity is also associated with a decrease in KV-cilia beating raising the possibility that Ipk1 might mediate ciliary function. Zebrafish embryos express *ipk1* symmetrically in the axial mesendoderm and KV region. Ipk1 localizes uniformly throughout the cell. *ipk1* knockdown lowers production of $IP_6$ and more highly phosphorylated IPs (e.g., inositol pyrophosphate $IP_7$), and results in accumulation of precursor IPs (e.g., inositol tetrakisphosphate $IP_4$ and $IP_5$). Interestingly, knockdown of *ipk2*, encoding an inositol polyphosphate kinase for $IP_4$ and $IP_5$ synthesis, results in a phenotype comparable to *ipk1* knockdown. In contrast, embryos deficient in the $IP_6$-kinase exhibit an axis defect comparable to embryos overexpressing *ipk1*. Overall, our studies for the first time link the IP pathway, $Ca^{2+}$ signaling, and ciliary function together in mediating early events in LR morphogenesis and set a precedent for discovering future roles of IPs in vertebrate development.

2736

**PINCH Regulates Epithelial Morphogenesis in *Drosophila* Embryonic Dorsal Closure Where it Stabilizes Integrin Complexes**

M. A. Smith,[1] M. C. Elias,[2] J. L. Kadrmas,[2] S. M. Pronovost,[3] M. C. Beckerle,[1,2] R. A. Montague,[4] D. P. Kiehart[4]; [1]Department of Biology, University of Utah, Salt Lake City, UT, [2]Department of Oncological Sciences, University of Utah, Salt Lake City, UT, [3]University of Utah, Salt

Lake City, UT, [4]Developmental, Cell and Molecular Biology Group, Department of Biology, Duke University, Durham, NC

The coordination of integrin-mediated adhesion with signaling cascades is critical for developmental processes such as cell adhesion and motility. During *Drosophila melanogaster* embryonic dorsal closure, both integrin-mediated adhesion and signaling and Jun N-terminal kinase (JNK) signaling are required for proper migration and suturing of embryonic epithelia. We have previously shown that *Drosophila* PINCH, a five LIM domain scaffolding protein required for integrin related functions in the wing and for actin-membrane anchorage in muscle, is required for dorsal closure and for regulation of JNK signaling. In *Drosophila* embryos PINCH co-localizes with β-integrin, where it is concentrated at phosphotyrosine-rich adherens junctions in the leading edge cells of the migrating lateral epithelia. PINCH also colocalizes with β-integrin at cell-cell junctions in the amnioserosa. We have performed an analysis of embryos lacking maternally contributed PINCH. We show B-integrin stability and localization to the leading edge and amnioserosa is dependent on PINCH, and β-integrin levels are decreased in whole embryos lacking PINCH. However, removal of zygotic PINCH from β-integrin mutants does not exacerbate the *myospheroid* cuticle defect. PINCH is also essential for normal distribution of phosphotyrosine activation at the epithelial leading edge. Additionally, live analysis of PINCH mutants shows defects in stability of cell adhesion, and disruption of tissue migration, including proper assembly and function of the actin purse string at the epithelial leading edge. Our findings reveal multiple roles for PINCH in normal integrin function in *Drosophila* embryonic dorsal closure and suggest a general role for PINCH in signal integration during epithelial morphogenesis.

### Initial Studies of FAK in *Ascidia ceratodes* Sperm Activation

E. Soria, R. A. Koch; Biology, California State University, Fullerton, Fullerton, CA

In ascidians, sperm activation also known as mitochondrial translocation (MTL), is characterized by the sperm mitochondrion binding to the outer surface of the egg complex and translocating off the head and down the tail. MTL is initiated by sperm-egg contact and involves cell-signaling communication that triggers actin cytoskeletal reorganization and myosin activation. We proposed that FAK, a key mediator of integrin-initiated signaling, responds to integrin-dependent sperm-egg adhesion and anchoring of the sperm mitochondrion to follicle cells located on the outer surface of the egg complex by signaling to cytoskeletal remodeling as required for MTL and sperm penetration. Previous work, has shown that integrins are present in *Ascidia ceratodes* sperm and required in MTL and fertilization. Anti-FAK and specific phospho-tyrosine antibodies, were used in indirect immunofluorescence to confirm the presence of FAK proteins in cells. Based on analysis of the genome database for the ascidian *Ciona intestinalis* we found that Ciona FAK-like proteins have several pentapeptides with a central tyrosine (Y) residue that align to human FAK sequences at the following sites, ciFAK Y260 to hsFAK Y397, ciFAK Y268 to hsFAK Y407, ciFAK Y440 to hsFAK Y576 and ciFAK Y441 to hs FAK Y577 and ciFAK Y671 to hsFAK Y861. Our data indicated that hs FAK Y925 did not have a Ciona counter part. The similarity of peptide sequences that contain tyrosines known to be phosphorylated during adhesion-induced signaling is being exploited to identify tyrosine residues that are involved in ascidian sperm activation. Our data support the presence of FAK in ascidian sperm and predict a role for FAK in adhesion-initiated sperm activation and ultimately in fertilization. (Funded by NIHR25GM56820).

### The Hormonal Herbicide, 2,4-D, Induces a Signaling Response in Xenopus Oocytes that Interferes with Meiotic Maturation In Vitro

B. Stebbins-Boaz,[1] A. Compton,[1] A. LaChapelle,[2] M. Monnie,[1] J. Oost,[1] M. Ruygrok,[1] J. Swenson[1]; [1]Biology, Willamette University, Salem, OR, [2]Biology, LaChapelle, Salem, OR

Oocytes must undergo meiotic maturation for fertilization and embryo formation. In oocytes from the frog, Xenopus, this is triggered in vitro by progesterone, which activates the Mos-MAPK-p90rsk-cdc2/cyclin B1 signaling cascade leading to germinal vesicle breakdown (GVBD). Environmental contaminants that mimic hormones, endocrine disruptors, could potentially interfere with this pathway thus leading to poor egg formation and lowered fertility. Global amphibian declines may be explained in part by such effects. We have examined the oocyte response to the commonly used hormonal herbicide, 2,4-D, and found that it blocks maturation in vitro. Previous data showed that 2,4-D triggered MAPK phosphorylation while blocking Mos expression, cdc2/cyclin B1 activation and GVBD. To further characterize 2,4-D's mode of inhibition, we hypothesized that 2,4-D-activated MAPK does not fully activate the known maturation target, p90rsk. Western analysis showed partial phosphorylation of p90rsk in 2,4-D-treated oocytes relative to progesterone controls. To determine whether the failure of Mos expression in the presence of 2,4-D is due to decreased Mos stability, mature oocytes were incubated in 2,4-D for various times and subjected to western analysis. Results showed that Mos was stable once synthesized. Thus, 2,4-D does not by itself induce Mos degradation. We are investigating whether 2,4-D blocks Mos expression at the translational level by inhibiting Mos mRNA polyadenylation. Finally, to investigate whether 2,4-D acts upstream of Mos, we have examined whether 2,4-D recruits the endogenous maturation inhibitor, protein kinase A (PKA). Oocytes were microinjected with the PKA-inhibitor, PKI, and treated with 2,4-D. Controls showed that PKI, alone, induced maturation as expected. Preliminary results showed that 2,4-D inhibited this response suggesting that PKA is not an essential factor in 2,4-D-induced inhibition and that 2,4-D targets one or more downstream factors.

2739

### Involvement of Tyrosine Kinases, Specifically Src Family Kinases, Focal Adhesion Kinase (Fak), and Agonist-Induced PLC in the Activation and Development of Bovine Oocytes

B. J. Pate,[1] K. L. White,[1] D. B. DeWald,[2] L. F. Rickords,[1] G. Li,[1] K. I. Aston,[1] B. R. Sessions,[1] T. D. Bunch[1]; [1]Animal, Dairy, and Veterinary Sciences, Utah State University, Logan, UT, [2]Department of Biology, Utah State University, Logan, UT

In addition to contributing a genetic element to the oocyte at fertilization, the sperm cell induces the oocyte to leave its arrested state and resume metabolism in a process referred to as activation. A key to mammalian oocyte activation is release of intracellular calcium stores resulting in repetitive transients. The mediators of bovine activation are unknown at present, but are believed to be either a sperm-oocyte receptor interaction or a soluble cytosolic factor released by the sperm into the oocyte following fertilization. In either case, intracellular signaling pathways are initiated and perpetuated in such a way that the oocyte is induced to develop. The pathways leading to bovine oocyte activation have not been elucidated. Here we use known inhibitors of various intracellular signaling molecules to increase understanding of pathways involved in bovine oocyte activation. The tyrosine kinase inhibitor Genistein inhibited activation, while tyrosine kinase activator sodium orthovanadate induced activation.

The specific Src family kinase inhibitor PP1 also inhibited activation. In addition, an antibody directed against focal adhesion kinase, a mediator of integrin associated pathways, blocked oocyte activation. Wortmannin, a potent inhibitor of PI3-kinase had no effect on oocyte activation. These data indicate the involvement of tyrosine kinases, specifically one or more Src family kinases and focal adhesion kinase. We also used the phospholipase C inhibitor U73122 to block development and intracellular calcium transients. Inhibitor U73122 functions by blocking ligand-induced activation of PLC isoforms. An inactive analogue of U73122 referred to as U73343 had no significant effect on release of intracellular calcium. Together these data provides support for the receptor-mediated hypothesis of bovine oocyte activation by demonstrating the requirement of kinases and PLC isoforms associated with outside-in signaling.

### *Drosophila* Mnk (Chk2) is Required for Inhibition of the Mid-blastula Transition in Response to DNA Damage

S. Takada, W. E. Theurkauf; Program in Molecular Medicine, University of Massachusetts Medical School, Worcester, MA

The mid-blastula transition (MBT) is the switch from maternal to zygotic control of early embryogenesis and is characterized by activation of zygotic gene transcription. It is preceded by a progressive increase in cell-cycle length and followed by dramatic morphological changes of the embryo. In *Drosophila melanogaster*, embryonic development initiates with rapid 13 syncytial divisions. Interphase (S phase) length in early cycles is only 5min and dramatically increases after division cycle10, up to 60-70 min for interphase14. Sudden increase of zygotic gene transcription is observed during interphase14, and cellularization and gastrulation take place. Embryos from DNA replication checkpoint mutant such as *grp* (DmChk1) and *mei-41* (DmATR) are defective in the pre-MBT cell-cycle lengthening. They also do not activate zygotic transcription and die without going through proper morphological changes (Sibon et al.1997 Nature 388:93; 1999 Curr. Biol. 9:302). Here, we show that a null mutation in Mnk (DmChk2) gene rescues the defective MBT in *grp* embryos without rescuing the pre-MBT cell cycle defects. *mnk grp* double-mutant embryos go though fast cell cycles like *grp* embryos, however, they activate zygotic transcription, cellularize and gastrulate. Injection of the DNA damaging reagents into wild-type embryos immediately before the MBT inhibits cellularization, however, mutant embryos lacking Mnk (DmChk2) cellularize. Chk2 is a conserved kinase that transduces signals leading apoptosis, DNA repair or cell-cycle checkpoint activation in response to DNA damage. We previously showed that Mnk is required for inhibiting chromosome segregation and also eliminating damaged nuclei from the embryo proper in response to DNA damage during the pre-MBT. Our results indicates that Mnk (DmChk2) transmits the DNA damage signal and inhibits the MBT and prevents further development of the embryo in the presence of DNA lesions.

### Structural Basis for Notch Receptor Glycosylation by Fringe

M. Jinek,[1] S. M. Cohen,[2] E. Conti[1]; [1]Structural and Computational Biology Unit, European Molecular Biology Laboratory, Heidelberg, Germany, [2]Developmental Biology Unit, European Molecular Biology Laboratory, Heidelberg, Germany

The Notch pathway is an evolutionarily conserved pathway that controls many aspects of metazoan development. Modification of the Notch receptor by Fringe modulates the interactions between the receptor and its ligands, and constitutes a mechanism for establishment of tissue boundaries in *Drosophila* and vertebrates. Fringe is a Golgi-resident glycosyltransferase that transfers an N-acetylglucosamine (GlcNAc) monosaccharide from UDP-GlcNAc to specific fucosylated epidermal growth factor (EGF)-like repeats found in the extacellular domain of Notch and its ligands. We have determined the X-ray crystal structure of murine Manic Fringe at 1.8 Å resolution. Despite the lack of sequence similarity, the catalytic domain resembles those found in other glycosyltransferases, such as the *Bacillus subtilis* glycosyltransferase SpsA and rabbit N-acetylglucosaminyltransferase I. Based on these comparisons, we have identified residues responsible for substrate binding and catalysis and suggest a mechanism for the Fringe-mediated glycosylation of Notch.

### Characterization of DetaD Endocytosis and Recycling

G. Palardy, M. Goswami, A. Chitnis; Laboratory of Molecular Genetics, NICHD NIH, Bethesda, MD

To understand the mechanism by which Delta internalization and ubiquitylation promotes activation of its receptor, Notch, we have investigated trafficking of fluorescent-tagged forms of deltaD in cell culture using Hela and Cos7 cell lines. The zdD2 monoclonal antibody, which recognizes the deltaD extracellular domain was used to monitor Notch-independent deltaD trafficking, while a soluble form of the Notch2 receptor (NECD-Fc), including the Notch2 extracellular domain (NECD) fused to an Fc fragment, was used to monitor Delta trafficking following interaction with its receptor. We find that pre-clustering of NECD-Fc is required for effective interaction with DeltaD and the interaction promotes Delta ubiquitylation in COS7 cells. Internalized deltaD co-localizes with proteins associated with both clathrin and non-clathin mediated endocytosis, suggesting it can be internalized by different mechanisms. In addition, DeltaD is resistant to TX-100 extraction following interaction with pre-clustered NECD-Fc, while it is efficiently stripped from the plasma membrane in the absence of NECD-Fc. This suggests that association with Notch segregates Delta to a distinct compartment of the plasma membrane that could bias its internalization mechanism and subsequent trafficking. DeltaD co-localizes with rab-11-GFP and with rab22-GFP, consistent with it eventually entering a recycling pathway associated with non-clathrin mediated endocytosis. The GTP-locked Arf6 mutant, Arf6(Q67L), which prevents passage of proteins internalized through a non-clathrin dependent endocytosis to the sorting endosome, reduces the amount of deltaD on the surface available to bind NECD-Fc. Rab22(Q64L), a mutant that interferes with recycling of non-clathrin dependent cargo also reduces the amount of deltaD on the plasma membrane. In contrast to effects of interfering with recycling, inhibition of protein synthesis for 2 hours does not significantly reduce surface DeltaD. Together these observations suggest DeltaD internalization and recycling may determine availability of Delta to the Notch receptor at the cell surface.

### Enhancers and Suppressors of the Smoothened Tumor Suppressor

D. J. Casso, T. B. Kornberg; Biochemistry and Biophysics, UCSF, San Francisco, CA

The Hedgehog (Hh) protein acts as a critical regulator of development in a range of organisms from insects to vertebrates, and many of the downstream effectors of Hh signaling are corrupted in human cancers. Response to the Hh signal is regulated by two transmembrane proteins: Patched (Ptc) which binds Hh and negatively regulates signaling, and Smoothened (Smo) which is required downstream of Ptc to positively

regulate the pathway. While Smo is predicted to have a 7-transmembrane topology, it is not known how it controls Hh signaling. To identify novel components of the Hh pathway, we used a genetic screen to identify enhancers and suppressors of Smo in the fruit fly Drosophila melanogaster. We created a fly line in which Smo activity is reduced by expressing a Smo RNAi in the wing, causing a weak "fused" phenotype which is characteristic of a reduced response to Hh. We show that this phenotype can be suppressed by ectopic expression of Smo, or by heterozygous loss of function mutations in Ptc or Costal-2, both negative regulaors of Hh signalling. In addition, we show that heterozygous loss of function mutations in Hh, Smo, and Engrailed (all of which activate the pathway) enhance the phenotype. By screening a collection of chromosomal deletions on the second and third chromosomes, we identified 12 enhancer and 6 suppressor loci, including the loci of the above mentioned genes. The identification of the Smo enhancer and suppressor genes at these loci is underway.

2744

### *Drosophila* Hedgehog Signaling Effect on HRP-Smoothened Subcellular Localization Visualized using SBF-SEM

J. Buchanan,[1] A. J. Zhu,[2] R. Y. Arakaki,[1] S. J. Smith,[1] W. Denk,[3] M. P. Scott[2]; [1]Molecular and Cellular Physiology, Stanford University School of Medicine, Stanford, CA, [2]Developmental Biology, Stanford University School of Medicine, Stanford, CA, [3]Department of Biomedical Optics, Max-Planck Institute for Medical Research, Heidelberg, Germany

Hedgehog (Hh) is a secreted protein that influences patterning and morphogenesis in *Drosophila*. The regulation of Hh signaling by its receptor Patched (Ptc) and activator Smoothened (Smo) may involve intracellular trafficking through the late endosomal-lysosomal pathway. Following Hedgehog activation, the trans-membrane protein Smo accumulates at the cell surface in *Drosophila* salivary gland cells. In this study, we have used a functional HRP-Smo fusion protein to investigate Smo localization in response to Hh signaling by TEM (Transmission Electron Microscopy). In addition, we used SBF-SEM (Serial Block Face Scanning EM , Denk and Horstmann, *PLoS Biology* Vol. 2, No. 11, e329 DOI: 10.1371 ) to collect image stacks. This method allows collection of 3D data using automated serial sectioning by a special ultramicrotome mounted inside the SEM vacuum chamber. The block face is imaged after each section using backscattered electrons creating a TEM-like image. By examining image stacks of salivary glands from transgenic flies expressing *HRP-smo*, we were able to follow the distribution of the electron dense HRP-smo in 1000 thin sections (50μm) of tissue. The HRP-Smo was localized to numerous small clathrin coated vesicles, a small number of lysosomes and multivesicular bodies (MVBs). Following the addition of Hh protein, the HRP-Smo accumulated in dense patches between the digitated membranes of neighboring epithelial cells. Small HRP-Smo containing vesicles accumulated along the lateral cell membranes. Larger tubular structures containing HRP were also evident in this region. There was a large increase in HRP- positive lysosomes following Hh stimulation. The combination of HRP fusion protein and SBF-SEM greatly improves the precise localization and 3D distribution of Smoothened in Hh+ and Hh- treated salivary glands.

### CKIε Regulates Wnt-Mediated Small G Protein Activation by Stimulating the Degradation of a GTPase Activation Protein

I. Tsai, Z. Gao, D. M. Virshup; Department of Oncological Science, University of Utah, Salt Lake City, UT

Wnt signaling is an important signaling pathway for cell proliferation and embryonic development. Recent studies indicate Wnt signaling can activate small G protein pathways including as RhoA and Rac, promoting cell planar polarity and cell motility. Casein kinase I epsilon (CKIε) is a positive regulator of the canonical Wnt signaling pathway, and previous studies have shown the activity of CKIε is stimulated by Wnt signaling. To understand if CKIε is also involved in Wnt-mediated small G protein activation, we screened for additional binding partners of CKIε by using the two hybrid method. Here we report identification of an upstream regulator (a GTPase activation protein (GAP) protein) of a Ras- family small G protein. CKIε interacts with this GAP protein and reduces its stability in mammalian cells. Similarly, overexpression of CKIε rescues the inhibition of the small GTPase by the GAP protein. Upon stimulation by Wnt-conditioned medium, the GTP-bound form of the Ras-family small G protein is increased. However, activation of this small G protein by Wnt signaling was blocked by the specific inhibitor of CKIε, IC261, implying CKIε is required for this Wnt-mediated small G protein activation. Treatment of IC261 also leads to the reduction of Wnt-mediated cell motility. Our findings support a model that Wnt signaling activates CKIε, promoting the degradation of a GAP protein of Ras-family small G protein, leading to the activation of this small G protein pathway and cell motility.

### Characterization and Manipulation of G protein-mediated Signal Transduction in *Dictyostelium*

B. Raisley, W. Watson, S. Burch, J. Griffin, J. Melton, J. Hadwiger; Microbiology and Molecular Genetics, Oklahoma State University, Stillwater, OK

The soil amoeba *Dictyostelium discoideum* detects and forages on bacteria, but when depleted of nutrients it undergoes multicellular development with spore production. The sensing of folic acid released from bacteria by *Dictyostelium* stimulates cyclic nucleotide accumulation, $Ca^{2+}$ influx, chemotaxis, and gene regulation through a Gα4-specific G protein-mediated pathway. The use of this pathway as the foundation for the development of a biosensor, studying the specificity of G protein function, and the identification of a folic acid receptor gene are areas of investigation. As a natural detector of folic acid, *Dictyostelium* is an excellent candidate for utilization as a biological sensor of bacteria. To use *Dictyostelium* in this manner, a GFP-apoaequorin gene fusion was created and expressed from different promoters. The bioluminescent output of the encoded proteins is expected to allow rapid detection of $Ca^{2+}$ influx in *Dictyostelium* stimulated by folic acid. The specificity of Gα subunit function in this pathway was tested by expressing chimeric Gα2 and Gα5 subunits with a Gα4-specific receptor interaction domain. These proteins, Gα2/4 and Gα5/4, were used in attempts to restore responses to folic acid in cells lacking the Gα4 subunit. The Gα2/4 subunit partially restored some responses, but the Gα5/4 did not and even inhibited responses in cells with a functional Gα4 subunit. These results suggest that Gα subunit specificity is not limited to receptor interaction domains. Because a folic acid receptor has yet to be characterized in *Dictyostelium*, a search is being conducted by disrupting genes that encode putative heptahelical proteins. These putative receptors share sequence identity with human $GABA_B$ receptors and might function as heterodimers. This receptor search and analysis is in collaboration with Dr. Dale Hereld at the University of Texas-Houston Medical School.

2747

**PldB, a Putative Phospholipase D Homologue Negatively Regulates Quorum Sensing in *Dictyostelium discoideum* Development**

Y. Chen, V. Rodrick, Y. Yan, D. Brazill; Biological Sciences, Hunter College, City University of New York, New York, NY

Quorum sensing, the ability to measure the local cell density, is required for animal cells to achieve proper cell growth, differentiation and development. However, because of the genetic intractability of mammalian cells, we study quorum sensing in the genetically pliable unicellular eukaryote *Dictyostelium discoideum*. *Dictyostelium discoideum* cells live as individual cells under vegetative condition. When starved, they are able to calculate the concentration of surrounding starving cells by simultaneously secreting and sensing a glycoprotein named conditioned medium factor (CMF). A high density of starving cells ($>10^5$cells/cm$^2$) results in a high level of CMF, which allows cell aggregation and development. Here, we describe the role of a putative phospholipase D (PLD) homologue, PldB, in quorum sensing pathways. PldB is present during early development when quorum sensing is occurring as well as in later development. *pldB*$^-$ cells can aggregate at low cell density, while cells overexpressing *pldB*are unable to aggregate or form fruiting bodies even at high cell density, implying that PldB is a negative regulator of quorum sensing. This phenotype is cell autonomous since mixing a small number of *pldB*$^-$ cells with wild-type cells does not make the wild-type cells behave like *pldB*$^-$ cells, nor does a small number of wild-type cells make *pldB*$^-$ cells behave like wild-type cells. *pldB*$^-$ cells develop faster than wild-type cells, indicating that *pldB* is involved in the timing of development. Analysis of early developmental gene expression shows that cAMP receptor cAR1, used in aggregation, is expressed at higher levels earlier in *pldB*$^-$ cells than in wild-type cells, which may explain the rapid aggregation phenotype of *pldB*$^-$ cells. Moreover, western blot analysis and GFP-tagged PldB reveal that PldB protein is localized to cytoplasmic membrane as well as vesicles.

**Identification and Characterization of $GABA_B$ Receptor like-proteins in *Dictyostelium discoideum***

Y. V. Prabhu, A. A. Noegel; University of Cologne, Center for Biochemistry, Medical Faculty, Cologne, Germany

GPCRs are a superfamily of diverse integral membrane proteins that allow detection and transduction of a large variety of extracellular signals. In *Dictyostelium* only seven members of one family, the crl (cAMP receptor like) family, had been identified and studied in detail. The analysis of the genome sequence uncovered 48 additional putative GPCRs grouped into the secretin (family 2), metabotropic glutamate/GABA B (family 3) and the frizzled / smoothened (family 5) families of receptors. The presence of family 2, 3 and 5 receptors in *Dictyostelium* was indeed surprising because they had been thought to be animal-specific. GABA (gamma amino butyric acid), the principal inhibitory neurotransmitter in mammalian brain, signals through ionotropic ($GABA_{(A)}$/$GABA_{(C)}$ ) and metabotropic $GABA_{(B)}$ receptor systems. The functional $GABA_B$ receptor is a heterodimer of receptor 1 and receptor 2 subtypes. The *Dictyostelium* genome harbours 17 different genes encoding $GABA_B$ receptor like proteins of which 15 resemble the subtype 2 and two appear to be closer to the subtype1. Yeast two hybrid studies led us speculate that the C termini of these receptors alone may not be sufficient for their interaction(s) to form heterodimers. The detailed analysis of one of each type of receptors named as GrlA and GrlJ was undertaken. Both these receptors are expressed throughout the development of *Dictyostelium*. To gain more insight into the *in vivo* function of these proteins, we generated knockout mutants by homologous recombination. Mutant analysis revealed GrlA to be a player in the later developmental stages acting in a stalk specific manner by displaying delayed expression of a prestalk specific gene, ecmB.

**Expression and Role of CaMK-II during Zebrafish Development**

R. M. Tombes,[1] C. R. Barrett,[1] J. A. Lister[2]; [1]Biology, Virginia Commonwealth University, Richmond, VA, [2]Human Genetics, Virginia Commonwealth University, Richmond, VA

CaMK-II is a $Ca^{2+}$/calmodulin-dependent protein kinase that is encoded by four genes (α, β, γ, and δ) and has widespread and pleiotropic roles throughout the lifespan of metazoan organisms. The role of CaMK-II in early vertebrate development was examined in the zebrafish, *Danio rerio*. All four CaMK-II genes have recently been identified in zebrafish and δ CaMK-II expression has been detected in early embryos. We have found that total CaMK-II activity is expressed rapidly upon fertilization, increasing by 20-fold between one and three days of development. Zebrafish embryos were injected soon after fertilization with a CaMK-II anti-sense morpholino oligonucleotide designed against the first exon of zebrafish δ CaMK-II. Injected embryos exhibited developmental aberrations including diminished, curved tails, jaw deformities, and heart irregularities. KN-93, a CaMK-II antagonist, suppresses the activity of all CaMK-II isozymes. Phenotypes of embryos incubated with KN-93 were similar to those seen with the morpholino oligonucleotide in that circulatory system defects as well as jaw and body axis length abnormalities were observed in a concentration-dependent manner. The proposed involvement of CaMK-II in the Wnt pathway is supported by the similarity of slb and ppt mutant phenotypes (associated with Wnt11 and Wnt5a respectively) to the CaMK-II morpholino phenotype. Our findings indicate that CaMK-II is a naturally expressed developmental kinase that is necessary for the proper development of the heart/circulatory system and may be required for the formation of a linear spine.

**Expression Analyses of Profilins and their Effects on Zebrafish Development**

T. Chan, C. Wu, S. Lai, H. Chang, S. Lee; Institue of Zoology, National Taiwan University, Taipei, Taiwan Republic of China

Profilin, an actin-binding protein, has been demonstrated to be essential for cell division and survival in several animal species. The regulatory role of profilin in development is presumably via its mediation on actin microfilament assembly and profilin-associated signaling molecules. Massive reorganizations of actin microfilament are central to the proper progression in embryogenesis. However, little information is available regarding the characterization and functions of profilin in zebrafish embryos. By blasting zebrafish genome, we have identified a cDNA clone corresponding to a profilin II like protein, which we designate it as zpfnII here. Using RT-PCR analysis, a 423 bp zpfnII transcript is highly expressed in early embryonic stages and all adult tissues examined in zebrafish. However, by whole-mount in situ hybridization, zpfnII was found to be ubiquitously expressed in all blastomeres of early embryos, but was localized mainly in brain and neuronal tissues in later stage embryos. Overexpression of zpfnII-GFP caused defects in somite and neuron formation. Furthermore, morpholino knock-down of zpfnII induced a shorten body axis and more serious abnormality in body shape. These results suggest that zpfnII is required for proper neuron, somite and possibly body axis formation in zebrafish development. In addition, we also identified a splice variant of zpfnII with 782 bp (zpfnII782), which was strongly expressed in brain and

neuron in both adults and 1-2 days embryos in both RT-PCR and whole mount *in situ* hybridization analyses. It implies that zpfnII782 may play a more specific role in brain development and neurogenesis

2751

**Citron Kinase is Essential for Embryonic Development in Zebrafish**

M. Chien, S. Lee; Institue of Zoology, National Taiwan University, Taipei, Taiwan Republic of China

Citron kinase, a serine-threonine kinases, is a target molecule for activated Rho, which is involved in cytokinesis and embryonic development. While its role in cytokinesis is well documented, the effects of inhibition of citron kinase vary on species. The discribancy in citron kinases inhibition on the embryonic development may be due to the efficacy of gene inhibition, gene compensation or species differences. Zebrafish, a recent evolved vertebrate, whose gene functions can be effiiently knowcking down by morpolino antisense oligonucleotides (MO). To study the role of citron kinase in zbrafish development, we have isolated a 1.8 kb clone containing the N-terminal kinase doamin of zebrafish citron kinase by *in silica* cloning. We showed that citron kinase mRNAs were ubiquitously existed in different developmental stage embryos and adult zebrafish tissues by RT-PCR. By whole-mount in situ hybridization, we observed that citron kinase expressed in the entire embryo until 18 hour post fertilization and the expression of citron kinase mRNA was limited to the proliferative neuroblasts and tissues. Lastly, we demonstrated that knockdowning citron kinase by MO dose-dependently resulted in cytokinesis defects, irregular shapes of embryos, delayed growth and failure in epiboly, which sbsequently casued embryonic death within 24 h post fertilization. Altogether, these results suggest that citron kinase is essential for the early development in zebrafish.

2752

**Mesenchymal p66$^{Shc}$ Expression Induces Fetal Mouse Lung Branching Morphogenesis While Epithelial Expression Attenuates Branching**

M. K. Lee, S. M. Smith; Center for Craniofacial Molecular Biology, University of Southern California, Los Angeles, CA

Shc adaptor proteins mediate mitogenic signaling by a number of different cytosolic and membrane-bound kinases. In mammals, the Shc proteins are expressed as three isoforms with different and opposing functions. While the 52 and 46 kDa isoforms mediate activation of the Erk1/Erk2 MAP kinases, the 66 kDa Shc isoform (p66$^{Shc}$) sequesters Grb2 and antagonizes Erk activation. Unlike the ubiquitous 52 kDa isoform, p66$^{Shc}$ is developmentally regulated. p66$^{Shc}$ is highly expressed in both epithelial and mesenchymal tissues within the early fetal mouse lung, but expression decreases and becomes progressively restricted to epithelial cells as the lung matures. We hypothesized that lung branching morphogenesis is dependent on regulated p66$^{Shc}$ expression within these two tissues. To address this postulate, either an siRNA specific for p66$^{Shc}$ or an adenoviral vector encoding p66$^{Shc}$ was applied to the luminal or mesenchymal surfaces of fetal mouse lung explants at 12 days post-conceptual age. The explants were then cultured in serum-free defined medium for four days. To confirm cellular uptake, siRNA preparations were labeled with a non-silencing siRNA conjugated to Cy5, and the adenoviral vectors concomitantly expressed green fluorescent protein. Vector uptake was confirmed by epifluorescence microscopy, Shc isoform expression was evaluated by Western analysis, and lung branching was assessed morphologically. Induction of mesenchymal p66$^{Shc}$ was associated with increased airway branching while attenuated mesenchymal p66$^{Shc}$ expression correlated with reduced branching. In contrast, induced epithelial p66$^{Shc}$ expression coincided with reduced airway branching morphogenesis while attenuated epithelial p66$^{Shc}$ was associated with increased branching. These results suggest that p66$^{Shc}$ modulates lung branching morphogenesis, and that p66$^{Shc}$ signaling in mesenchymal cells has opposite effects on branching morphogenesis to epithelial p66$^{Shc}$ signaling.

2753

**Activation of FAK is Necessary for Osteogenic Differentiation of Human Mesenchymal Stem Cells on Laminin-5**

R. F. Klees,[1] R. M. Salasznyk,[1] A. Boskey,[2] G. E. Plopper[1]; [1]Biology, Rensselaer Polytechnic Polytechnic, Troy, NY, [2]Biology, Hospital for Special Surgery, New York City, NY

Mesenchymal stem cell differentiation into osteoblasts and the signaling events that shape this differentiation are poorly understood. We recently established that contact with specific extracellular matrix proteins, in particular laminin-5, is sufficient to induce an osteogenic phenotype in human mesenchymal stem cells (hMSC) through an extracellular signal-related kinase (ERK)-dependent pathway. Activation of ERK 1/2 by laminin-5 induces phosphorylation of the runx2/cbfa-1 transcription factor that controls osteogenic gene expression. We hypothesized that focal adhesion kinase (FAK) mediated signaling pathways supply a link between cell surface integrin-ECM binding and activation of ERK 1/2, and that laminin-5, a well known activator of FAK, promotes its osteogenic effects through this pathway. To test this hypothesis, we plated hMSC on a laminin-5 matrix in the presence or absence of FAK-specific small inhibitory RNAs (siRNA), and assayed for phosphorylation of runx2/cbfa-1 as well as expression of established osteogenic differentiation markers (bone sialoprotein 2, osteocalcin, alkaline phosphatase, calcium deposition, and mineral:matrix ratio). We found that siRNA treatment reduced total endogenous FAK protein by ~40%, and reduced FAK phosphorylation on Y397 in cells plated on laminin-5 for 30 minutes. hMSC transfected with FAK siRNA and plated on laminin-5 also exhibited a decrease in ERK 1/2 phosphorylation after 1 hr, and reduced serine phosphorylation of Runx2/Cbfa-1 after 8 days. Finally, FAK inhibition blocked osteogenic differentiation of hMSC, as assessed by lowered expression of osteogenic genes (RT-PCR), decreased alkaline phosphatase activity, greatly reduced calcium deposition, and a lower mineral:matrix ratio after 28 days in culture. These results establish FAK as an important mediator of laminin-5 induced osteogenic differentiation of hMSC.

2754

**Roles for the Tumor Suppressor Genes *Adenomatous Polyposis Coli 1* and *2* in Cell Adhesion and Axon Outgrowth in the Developing *Drosophila* Larval Brain**

M. A. Hayden,[1] K. Akong, [1] M. Peifer[2]; [1]Curriculum in Genetics and Molecular Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC, [2]Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Adenomatous Polyposis Coli (APC) is a multi-domain protein that was first characterized as a tumor suppressor, which acts as a negative regulator of the Wnt/Wingless (Wg) signaling pathway. Mutations in human *APC* lead to the development of colon carcinoma. APC acts in a complex with several other proteins to negatively regulate the levels of free β-catenin /Armadillo by helping to facilitate its phosphorylation, allowing subsequent ubiquitin-mediated destruction. In addition, APC has Wg-independent roles in the regulation of the cytoskeleton during normal development. Two

APC genes have been identified in both mammals and in *Drosophila* (*APC1* and *APC2*). We have found that both APC1 and APC2 play redundant roles in larval brain development. Using mosaic analyses, we generated GFP-marked *APC* double mutant clones in the larval brain to examine what roles APCs play in Wg-dependent and Wg-independent events. A null allele of APC1 combined with one of several alleles of APC2 result in varying degrees of structural aberrations in the larval brain. These defects arise in both epithelial tissues and axon projections. Double mutant cells segregate from their neighbors to form epithelial "loops," while double mutant neurons form tangled axonal "knots". We are currently examining how the defects seen relate to changes in cell adhesion, Wg signaling, and/or altered regulation of the cytoskeleton.

2755

**Structure-Function Analysis of the Neurogenic Gene Product Big Brain**

M. K. Renihan,[1,2] G. Boulianne[1,2]; [1]Developmental Biology, Hospital for Sick Children, Toronto, ON, Canada, [2]University of Toronto, Toronto, ON, Canada

The neurogenic gene product Big brain, Bib, is essential for the development of the embryonic nervous system. *bib* mutant embryos display neural hyperplasia at the expense of ectodermal tissue. Although some evidence suggests that *bib* acts in the Notch pathway in a cell autonomous manner, little is known about *bib* function *in vivo*. *bib* is predicted to encode a protein containing a short N-terminal cytoplasmic region, 6 transmembrane domains and a long C-terminal cytoplasmic tail containing several potential regulatory regions and protein-protein interaction domains. Recently, studies using *Xenopus* oocytes as a model system have shown that Bib can function as a non-selective monovalent cation channel, and have revealed regions of this protein that affect its channel function and that undergo post-translational modification. However, whether channel function and post-translational modification are critical for Bib's role in *Drosophila* development or Notch signalling remains unclear. To determine which regions of Bib are necessary and/or sufficient for its function during *Drosophila* development and in Notch signalling we are employing the GAL4-UAS system and cell culture to express: (1) a deletion construct lacking the C-terminal tail of Bib; (2) various mutations in the first transmembrane domain that have been shown in *Xenopus* oocytes to affect Bib function; (3) various mutations in the C-terminal cytoplasmic tail and most C-terminal transmembrane domain; and (4) the entire Bib protein. Using a structure-function approach will provide insight into the role of Bib in Notch signalling and *Drosophila* development.

2756

**aPKCζ Signaling Regulates the Stratification of Neural Progenitor Cells**

S. Ghosh,[1] T. Marquardt,[2] J. P. Thaler,[2] S. L. Pfaff,[2] T. Hunter[1]; [1]MCBL, Salk Institute for Biological Studies, La Jolla, CA, [2]GEL, Salk Institute for Biological Studies, La Jolla, CA

The role of neuroepithelial cell polarity in controlling segregation of cell-fate determinants during stem cell divisions and in the developmental patterning of the central nervous system is of crucial importance, yet is poorly understood. Here we show that atypical Protein Kinase C ζ/λ (aPKCζ/λ) localizes at the apical 'end-feet' of radial progenitor cells in the developing chick spinal cord. Consistent with a role in regulating neuroepithelial polarity, mislocalized aPKCζ activity disrupts the polarized distribution of cell adhesion proteins and induces the premature delamination of undifferentiated neural progenitor cells, but the loss of cell polarity is dispensable for cell-fate specification during neurogenesis. aPKCζ integrates signals from the PI 3-Kinase and the Rac/Cdc42 pathways and the localized activation of aPKCz regulates the timing of neuronal precursor cell delamination and migration.

2757

**Role of Trio GEF in the Migration and Proper Organisation of Inferior Olivary Neurons**

S. Backer,[1] S. Marcos,[1] M. Hidalgo-Sanchez,[1] E. Portales,[2] P. Fort,[2] A. Debant,[2] C. Gauthier-Rouvière,[2] E. Bloch-Gallego[1]; [1]Institut Cochin - Département Génétique et Développement, INSERM U. 567, Paris, France, [2]CRBM-CNRS FRE 2593, Montpellier, France

During embryonic development, inferior olivary neurons (ION) first follow a circumferential migration from their birthplace in the alar part of the brainstem to the vicinity of the floor-plate, where they get packed in a club-shaped domain. Then ION organize into a laminated structure. As we had previously shown that the Rho GTPases Rac1/Cdc42 are involved in axon outgrowth of ION during tangential migration, whereas the Rho/ROCK pathway is involved in nucleokinesis, we aimed at further characterizing the regulators of Rho-GTPases activity that could direct the migration and organization of ION. We have analyzed the involvement of the guanine nucleotide exchange factor TRIO that contains two GEF domains for RhoG/Rac1 and RhoA. We have characterized the expression and activation of Rac, Cdc42 and Rho during ION development. We have studied the successive steps of ION development in TRIO deficient mice. In the absence of Trio, initial axon outgrowth and nucleokinesis occur properly but the second step of ION development to get a proper laminated structure is affected. Thus, other GEFs, involved in the control of the activities of Rac/Cdc42 and RhoA during the initial circumferential migration remain to be characterized and we further investigate potential upstream regulators of Trio involved in the maturation and organization of ION, with a special care on receptors of chemotropic factors and adhesion molecules.

2758

**A Role for Duplin in SRF-mediated Signaling**

J. M. Rodenberg, B. P. Herring; Cellular & Integrative Physiology, Indiana University School of Medicine, Indianapolis, IN

Differentiated smooth muscle cells have the remarkable ability to switch between a quiescent contractile phenotype and a proliferative, synthetic phenotype under many pathological conditions. Serum response factor (SRF) is a transcription factor that is crucial for regulating genes characteristic of contractile smooth muscle cells as well as activating genes required for cell proliferation. The ability of SRF to regulate these two disparate phenotypes is dependent on its ability to interact with proteins that alter its activity towards differentiation genes as opposed to proliferation genes. Identifying and unraveling the function of these SRF-associated proteins is thus crucial for understanding the mechanisms regulating the phenotype of smooth muscle cells. A yeast two-hybrid screen using SRF as bait identified the protein Duplin. Duplin is a nuclear protein that was previously shown to bind to β-catenin and inhibit its signaling. Interestingly, knocking out Duplin is embryonic lethal, due to defects in gastrulation, although expression of β-catenin target genes was unaffected (Nishiyama, et al. 2004). SRF-GST fusion proteins demonstrate a direct interaction of SRF with the amino-terminal portion of Duplin. Preliminary results from mammalian two-hybrid experiments in

cos cells also indicate a direct interaction between SRF and Duplin. The phenotype of SRF knockout mice is similar to the Duplin knockout mice with a failure of mesoderm formation during gastrulation. Together these data suggest that Duplin may play an important role in modulating SRF-dependent gene expression. shRNA is currently being used to knock-down Duplin expression in smooth muscle and nonmuscle cells to determine the effects on SRF-dependent genes involved in differentiation and growth. Although much of the physiological significance of Duplin remains unknown, from our preliminary data we can conclude that Duplin binds SRF independently of possible interactions with β-catenin. Funding: NIH R01 DK61130 (BPH).

**Smad7 Enhances Myogenesis by Inhibition of Myostatin but not Transforming Growth Factor-β Signaling**

H. D. Kollias, R. L. S. Perry, J. C. McDermott; Biology, York University, Toronto, ON, Canada

TGF-β and myostatin signaling mediated by the Smad downstream effectors, potently repress skeletal muscle cell differentiation. Based on the possibility that inhibition of these pathways might enhance myogenesis, the role of the inhibitory Smad (Smad7) during skeletal muscle cell differentiation was assessed. In these studies we document that increased expression of Smad7 differentially abrogates myostatin but not TGF-$\beta_1$ mediated repression of myogenesis. Further, constitutive expression of exogenous Smad7 enhanced skeletal muscle differentiation and cellular hypertrophy. Interestingly, targeting of endogenous Smad7 by siRNA inhibited C2C12 muscle cell differentiation indicating requirement for Smad7 during myogenesis. Congruent with a role for Smad7 in myogenesis we also observed that the Smad7 promoter is up-regulated by muscle regulatory factors, MyoD and myf5. Finally, we document that Smad7 can augment the myogenic conversion of 10T/2 fibroblasts by myf5. Taken together these data implicate Smad7 as a fundamental regulator of myostatin signaling and differentiation in skeletal muscle cells.

**Possible Role for A Kinase Anchoring in Muscle Cell Differentiation**

A. Andrews, J. Camaren, J. George, A. Medford, S. K. Byrd; Biology, Fort Lewis College, Durango, CO

The objective of our study was to examine the involvement of A kinase anchoring proteins (AKAPs) in muscle cell differentiation. L6 myoblasts were initially grown in high serum, and then switched to low serum to promote differentiation. Cells were grown for a period of nine days in differentiation medium containing either 10 µM Ht31, a peptide that inhibits binding of the regulatory subunit of PKA (RII); 10 µM Ht31P, which does not block RII binding; or normal medium. Cells were harvested at 0, 3, 6, and 9 days of growth in differentiation medium. Fresh media and peptides were added daily. Western blots of whole cell lysates were examined for the production of skeletal specific myosin and for changes in AKAPs. We specifically examined changes in mAKAP, a 222Kd protein known to be present in the perinuclear area as well at near the ryanodine receptor in mature muscle. We found that the myoblasts incubated with Ht31 produced greater amounts of myosin sooner in the differentiation process. There was a 28% increase in myosin by day 6 and 90% by day 9, over the controls. This pattern of more rapid differentiation in the presence of Ht31 was mirrored by production of mAKAP, with progressively greater mAKAP at day 6 and at day 9. We suggest that up regulation of certain AKAPs and the associated changes in signaling scaffolds may play a role in muscle cell differentiation.

**Microvascular Tubes Derived from Mouse Embryonic Stem Cells Sustain Blood Flow**

X. Zhou, I. Gallicano; Cell Biology, Georgetown University Medical Center, Washington, DC

The recent production of somatic cell nuclear transfer (SCNT)-derived embryonic stem cells has brought therapeutic cloning closer to reality. Among the potential applications of therapeutic cloning is therapeutic angiogenesis. While recent progress has been made with clinical therapeutic angiogenesis, it has been met with limited success. One reason for this limit has been the cell types used to generate the collateral vessels used for shunting around coronary blockages. Consequently, we developed a procedure using the embryonic stem (ES) cell model system to generate microvascular tubes similar to small vessels found in vivo. We then evaluated their ability to graft and sustain blood flow by transplanting them onto EGFP expressing E9 day embryo hearts. Microvascular tubes generated from embryonic stem cells have not been thoroughly tested for their ability to graft and function within the heart primarily because of issues including immune rejection of the foreign cells comprising collateral vessels, and limited methodologies to prevent teratoma risk. However, since recent therapeutic cloning techniques have provided evidence of diminished risk of immune rejection, we improved the methodology for generating and isolating tubes from ES cells to evaluate their applicability for therapeutic angiogenesis. Here, we demonstrate that microvascular tubes generated from ES cells are capable of grafting onto E9 day embryo hearts and sustaining the flow of blood cells as verified by EGFP expressing blood cells within non-EGFP ES cell-derived microvascular tubes.

**Impact of Oxygen Tension on Proliferation and Differentiation of Hematopoietic Stem/Progenitor Cells (HSPC)**

T. McKinnon, N. Baal, K. Reisinger, M. T. Zygmunt; Obstetrics and Gynecology, University of Giessen, Giessen, Germany

Early human development commences under the influence of low oxygen concentration until vasculogenesis takes place. However, chronically low oxygen tensions are associated with early pregnancy losses due to vascular malformation. We describe *in vitro* culture system to mimic low oxygen environments during pregnancy [i.e. hypoxia (1% $O_2$), normoxia (8% $O_2$) and as a control, hyperoxia (21% $O_2$)] in order to investigate placental vasculogenesis using HSPC. Concurrent real-time oxygen concentrations were measured with Sensor Dish Reader 2 (PreSens, Regensburg, Germany). HSPC, which can contribute to the first vessel system, contain both endothelial and hematopoietic progenitor cells. CD133+ cells isolated from umbilical cord blood collected from term pregnancies have been extensively characterized as HSPC and used in models for vasculogenesis. We expand HSPC in media containing Flt3-ligand, stem cell factor and thrombopoietin; they express several pluripotency markers, including Oct4, Sox-1, Sox-2, FGF4 and Rex-1 at RNA and protein levels. HSPC cultured in hyperoxia proliferate rapidly for approximately 20 days and continue in culture for >40 days. Conversely, HSPC number in low oxygen tensions is maintained for >40 days without significant increases in cell number. Decreased proliferation of HSPC in low oxygen environments was not due to significant changes in the proportion of cells in G1/G0, S or G2/M. HSPC expansion for 7-10 days resulted in decreased CD133 and CD34 expression while further HSPC culture in low

oxygen resulted in significant increases in differentiation markers (CD14, CD11b) and still retain their potential to differentiate into endothelial cells. We have established a novel, low oxygen *in vitro* culture system. Using this system we demonstrated that HSPC grown in physiologic placental oxygen tensions switch from a proliferating to a more differentiated phenotype and display possible prerequisites for vessel assembly.

**Hematopoietic Stem Cell Localization on a 3-D Matrix**

S. L. Snabes,[1] L. Noll,[1] D. Smith,[1] N. Kotov,[2] E. Elliott,[2] J. Bahng,[2] J. Lee,[2] L. Lasky[3]; [1]Research, Aastrom Biosciences, Ann Arbor, MI, [2]Chemical Engineering, Biomedical Engineering, Materials Science, University of Michigan, Ann Arbor, MI, [3]Pathology and Internal Medicine, University of Ohio, Columbus, OH

Modeling intricate microenvironments such as bone marrow has until recently proven difficult. Previous methods involved growing cells on 2-D surfaces, where cultures are frequently passaged or diluted and where differentiation pressures vary greatly from their natural state. These cultures result in an unnatural cellular organization that can only be maintained for limited periods of time. We therefore constructed a culture system that incorporates a 3-D substrate into a circumfusion flowloop where the local microenvironment differs based upon proximity to nutrients, gasses, and by-product concentration. We then compared this 3-D matrix/perfusion system to 3-D matrices in rotary bioreactors, spinner flasks, and static wells to ascertain the effects of gravity and perfusion on stem cell localization. Functional tissue and cellular development were ascertained by frequent flow cytometry, cytospins, colony assays, gene microarrays, lactate analysis, cell and viability counts, SEM and confocal microscopy. Our findings suggest that stem cell organization throughout a 3-D matrix differs greatly depending on how the matrix is integrated with its fluid and gaseous environment. Imaged cultures from the perfusion systems demonstrate tissue density with 80+% viabilities for up to 360+ days. Unlike static cultures where cells localize in layers on the matrix surface, the perfusion matrix revealed large aggregates of cells of varying morphology, function, and size in close association that form tissue density layers throughout the matrix depth. These cultures appear indicative of normal bone marrow (1.5%+ CD34+), allowing us to investigate the role of hypoxia and nutrient proximity on cellular localization. Furthermore, by utilizing an environment that allows for cells to release from marrow (matrix) to circulation (flow loop); we can analyze both cultured marrow tissue and circulating HSC's. Support: DAMD17-02-1-07-04

**Deficiency in Gata-4 or Gata-6 Diminishes Definitive Hematopoiesis in Murine Embryonic Stem Cell Derived Embryoid Bodies**

M. S. Pierre, M. Yoder; Herman B Wells Center for Pediatric Research, Department of Pediatrics, Indiana University School of Medicine, Indianapolis, IN

Previous investigators have reported that differentiation of embryonic stem (ES) cells deficient in either GATA-4 or GATA-6 results in embryoid body (EB) with disrupted differentiation of visceral endoderm (VE) and defective blood island formation. **OBJECTIVES**: In the current study, the ability of GATA-4 and GATA-6 null ES cell derived EB to commit to early hematopoietic lineages was compared to that of wild-type and heterozygous EB cells using secondary hematopoietic progenitor plating assays. **METHODS**: Cells dissociated from day 2 or day 3 EB plated into blast colony forming cell (BL-CFC) assays revealed no difference in wild-type, heterozygous or homozygous deficient EB ability to differentiate into hemangioblast. **RESULTS:** Analysis of primitive erythroid progenitors using cells dissociated from day 4, 5, 6 or 7 EB showed similar numbers of primitive erythroid progenitor colonies obtained from wild-type, heterozygous and homozygous deficient EB. Definitive hematopoiesis of EB was assessed by secondary plating of day 8, 9 and 10 EB into definitive erythroid and granulocyte/macrophage progenitor assays. The number of definitive erythroid progenitor colonies obtained from day 8 and 9 heterozygous and homozygous deficient EB was significantly reduced compared to wild-type EB ($p < 0.05$), but by day 10 the number of colonies obtained was greatly reduced but similar from all EB. The number of granulocyte/ macrophage colonies obtained from day 8 homozygous deficient EB was significantly reduced ($p < 0.05$) compared to wild-type, while comparison of day 9 and 10 EB revealed no significant difference. **CONCLUSION**: These results suggest that GATA-4 and GATA-6 transcription factors are not important for hemangioblast formation or primitive hematopoiesis but are necessary for normal definitive hematopoiesis in EB.

**Facilitation of Allogeneic Stem Cell Engraftment Requires a TCRβ-FcRγ Signaling Pathway**

K. N. Taylor, Y. L. Colson; Division of Thoracic Surgery, Department of Surgery, Brigham and Women's Hospital, Boston, MA

The transplantation of purified allogeneic hematopoietic stem cells (SC) fails to establish reliable engraftment capable of rescuing MHC-disparate allogeneic recipients from radiation-induced aplasia. The facilitating cell (FC), a bone marrow-derived cell population, promotes allogeneic SC engraftment without graft vs. host disease (GVHD), thus contributing to the successful reconstitution of the immune system. Biochemical analysis has shown that T cell receptor beta (TCRβ) is present on the FC, but not within the conventional αβTCR complex. Instead, TCRβ is disulfide linked to FCp33, a unique 33kDa protein that is distinct from previously described TCR proteins. Furthermore, FC isolated from TCRβ-deficient mice fail to facilitate engraftment of purified allogeneic SC. Given that *in vivo* FC-mediated SC engraftment is dependent on FcRγ but not CD3ζ, we hypothesized that FC signaling utilizes an FcRγ pathway. Therefore, we investigate the signaling pathway necessary for FC-mediated SC alloengraftment. The current study demonstrates that FcRγ gene and protein expression is significantly greater than CD3ζ expression within the FC as evident by real-time PCR and western blot analysis of immunoprecipitated proteins. Furthermore, the dominant FcRγ protein expression within the FC suggests that FcRγ is associated with the TCRβ complex in these cells. To confirm this, TCRβ immunoprecipitation was performed and revealed the presence of FcRγ and Fcp33 in the co-precipitate, thus demonstrating the association of FcRγ with the unique TCRβ-Fcp33 signaling complex. Furthermore, in vivo studies showed that CD16, an FcRγ-dependent receptor, was not required for FC function. In conclusion, unlike mature $TCR\beta^+$ T cells that utilize CD3ζ signaling and elicit alloreactive responses, FC facilitation of SC alloengraftment without GVHD is mediated through the TCRβ-FCp33 receptor complex via an FcRγ-dependent signaling pathway. These findings provide the first evidence that TCRβ-FcRγ signaling pathways are important in allogeneic SC reconstitution.

**Isolation and Characterization of Myogenic Stem Cells from Adult Murine Skeletal Muscle and Bone Marrow**

Z. Qu-Petersen; The Copenhagen Muscle Research Centre and Department of Neurology, Copenhagen National University Hospital, Copenhagen, Denmark

Skeletal muscle contains a stem cell pool of committed and pluripotent myogenic cells responsible for the growth and repair of postnatal muscle tissue. Investigations suggest that the pluripotent myogenic stem cells (pMySCs) can be of muscle and haematopoietic origins. To identify the pMySCs in different sources, we recently isolated distinct populations of MySCs from skeletal muscle and bone marrow of C57 BL/6 normal mice (5-7 weeks old) by preplate and clonal culture technique. Both populations are clonogenic, capable of extensive proliferation, and multi-lineage differentiation, demonstrating their property of stem cells. By flow cytometry, the muscle-derived MySCs (m-MySCs) were phenotypically characterized as Sca-1(+)CD34(-)CD24(-) while the bone marrow-derived MySCs (bm-MySCs) were characterized as Sca-1(+)CD34(low)CD24(+). Following initial differentiation in culture, both populations displayed a high degree of myogenicity, with 86% of m-MySCs and 64% of bm-MySCs capable of committing into myogenic lineage, but different myogenic pathways were identified. The m-MySCs generated three major progenies concerning specific neurons, glial cells and myoblasts, all of which contributed in vitro to multiple-myotube formation. The roles of the different myotubes (neuron/glia-reated or myoblast-related) in muscle development and regeneration should be investigated further. In contrast, only myoblast-related myotube formation was observed with bm-MySCs in culture. However, the capacity of bm-MySC's clonal-proliferation and robust myofiber formation both in vitro and over transplantation suggest their potential use in muscular disease. In conclusion, the bm-MySCs represent a population of more committed myogenic stem cells in hematopoietic system, while the m-MySC represent a novel class of pluripotent neuromuscular progenitors/stem cells within skeletal muscle.

**Identification of a Novel Monoclonal Antibody to a Cell Surface Antigen that Isolates Neuronal Stem Cells From Murine and Pig Adult Skeletal Muscle and Murine Embryo**

S. O. Winitsky, T. V. Gopal, S. Hassanzadeh, Y. A. Kassahun, N. D. Epstein; NHLBI, NIH, Bethesda, MD

We have previously reported a novel population (named SPOC cells) of non-satellite, non-hematopoietic, cells in adult murine skeletal muscle that differentiate into cardiac myocytes in vitro and in vivo (PLOS, April, 2005). We now report a novel monoclonal antibody (MP804), raised from the total SPOC cell isolate, which when used in conjunction with Sca1, separates the fresh undifferentiated SPOC cells into 3 distinct classes that mature in vitro into either cardiomyocytes, adipocytes or cells with neuronal markers and morphology. The $Sca1^{-}/MP804^{+}$ cells, grown in isolation retain the 804 antigen from their initial undifferentiated state through their differentiation into newly mature β-3 tubulin positive neuroepithelial cells. When not cultured in isolation from the complement of SPOC cells, the neuronal phenotype is suppressed. The 804 antigen is restricted to a subset of cells in murine olfactory lobe, hippocampus and the subependymal layer of the lateral ventricle, the 3 known sites of neuronal stem cells. The 804 antigen is conserved in pig and human. It appears first, in the day 12.5 mouse embryo. Culturing these $804^{+}$ embryonic cells produces the same β-3 tubulin positive cells as obtained from adult murine skeletal muscle. Typical neurospheres with $804^{+}$ centers and β-3 tubulin positive cells at the periphery can be cultured as well, from adult pig skeletal muscle SPOC cells. MP804 has been used to immunoprecipitate the antigen. Mass Spectroscopy shows that 804 antigen co-precipitates with the NMDA receptor in hippocampus, but not peripheral brain. Further identification of the 804 antigen is underway. This represents to our knowledge, the first neuronal stem cell antigen suitable for stem cell detection and isolation.

**Satellite Cells from Neonatal Rat Muscle Co-express Multiple Myosin Heavy Chain Isoforms In Vitro**

J. M. Churko, P. A. Merrifield; Anatomy & Cell Biology, University of Western Ontario, London, ON, Canada

Satellite cells (SCs) are myogenic stem cells, located beneath the basal lamina, which play an important role in postnatal skeletal muscle growth and regeneration. SCs can be identified and isolated based upon the expression of markers such as Pax7 and M-cadherin and are heterogeneous with respect to proliferation kinetics and cell fate. Some activated SCs progress to form differentiated muscle fibers while others maintain a stem cell phenotype, and there is controversy as to whether the fiber type potential of SCs is predetermined. For example, mouse SCs express a fast or slow myosin heavy chain (MyHC) phenotype in vitro based upon the fiber type from which they were derived (Rosenblatt et al, Differentiation 60, 39. 1996), while cultured human SCs are reported to co-express both slow and fast MyHCs within the same myotube following differentiation, regardless of their source (Bonavaud et al, Neuromuscul Disord. 11, 747. 2001). To examine the pattern of MyHC in rat SCs, we used Dynal immunobeads to isolate M-cadherin positive (Mcad +) SCs from neonatal rat hindlimb muscle and examined MyHC expression in vitro using western blot and immunocytochemical methods. In both mass and clonal density cell culture, Mcad + cells differentiated to form myotubes which co-expressed both fast (mab 212F, MY32) and slow (mab NOQ, 10D10) MyHCs within the same myotube. These results demonstrate that rat SCs - like SCs from human tissue - are uncommitted with respect to fiber type potential and co-express multiple MyHC isoforms in the absence of external cues such as innervation. **Quantitative Characterization of Label-Retaining Cells in the Mouse Mammary Gland**

R. Fernandez-Gonzalez,[1,2] C. Ortiz de Solorzano,[3] M. Barcellos-Hoff[1]; [1]Cancer Biology Department, Lawrence Berkeley National Laboratory, Berkeley, CA, [2]Joint Graduate Group in Bioengineering, UC Berkeley / UC San Francisco, Berkeley, CA, [3]Morphology and Imaging Group, Center for Applied Medical Research (CIMA), Pamplona, Spain

In many tissues, adult stem cells (ASC) have a precise spatial arrangement that determines both the architecture and function of the tissue, supported by a niche of specialized cells. Since fragments from any region of the mouse mammary gland can regenerate fully functional tissue when transplanted into parenchyma-free mammary stroma, we hypothesized that ASC are homogeneously and randomly distributed along the mammary ductal tree. To test this, we developed an image analysis tool for quantitative characterization of the spatial distribution of cell populations relative to the morphological features of the gland. The input for this tool is the location of epithelial nuclei and their immunostaining profile. Since there are no unique markers for mammary ASC, we studied long-term, label-retaining cells (LRC), which are slow-cycling cells supposed to contain a subpopulation of ASC. Young mice were labeled for 2 weeks with continuous bromodeoxyuridine infusion, followed by a 9-

week chase. LRC were identified in serial sections using antibodies against bromodeoxyuridine-substituted DNA, and their locations were recorded relative to the morphological structures. LRC frequency was higher in large vs. small ducts, and in areas proximal to the nipple vs. distal ones. Spatial analysis indicated that LRC are randomly distributed in smaller ducts, while in large ducts an LRC tends to be next to another one, i.e., they show up in small clusters. To test whether hormone receptor positive cells form a niche for LRC, we co-localized LRC and estrogen receptor α (ER+). Although distribution analysis indicated the independence of the single-labeled populations, a third of the LRC were ER+. This seems to indicate that ER+ cells are not a key component of a potential *niche* around LRC, but they may mark an LRC subpopulation. Supported by DOD BCRP 17-03-1-0594 predoctoral fellowship to RFG.

**The Characteristics of an Established Clonal Murine Intestinal Epitheliocyte (MIE)**

T. Kanaya,[1] H. Aso,[1] K. Miyazawa,[1] T. Minashima,[1] T. Kido,[1] K. Tahara,[2] T. Yamasaki,[2] K. Watanabe,[1] S. Ohwada,[1] T. Yamaguchi[1]; [1]Cellular Biology Laboratory, Graduate School of Agricultural Science, Tohoku University, Sendai, Japan, [2]R & D Center, BML Inc., Saitama, Japan

In murine small intestine, cells differentiate into one of five functional cell types, such as enterocytes, goblet cells, enteroendocrine cells, Paneth cells and M cells. All of these cells arose from intestinal epithelial stem cells located at the bottom of crypt. However, the differentiation processes of these cells have not been elucidated. To clarify the differentiation mechanisms of these intestinal epithelial cells, we attempted to establish clonal murine intestinal epithelial cell lines. The small intestine was removed from a C57BL/6 mouse and cut finely, and then seeded into a collagen-coated flask. After limiting dilution, we have established three clonal cell lines. These established clones of murine intestinal epitheliocyte (MIE) are able to grow constantly and assume a monolayer, cobblestone and epithelial-like morphology, with close contact between cells. All of three clones were strongly positive for cytokeratin, a marker for epithelial cells. One clone was selected upon the growing rate. The growth curve of MIE cells showed that cells grew to confluence by 5 days after seeding. Scanning electron microscopy showed that MIE cells formed microvilli tightly after 15 days of culture. Cell-cell adherens junction protein (beta-catenin) and tight junction proteins (ZO-1 and claudin 1) were observed in the cell-cell contact region of adjacent cells. Musashi-1 antigen and hes 1 transcriptional factor are known to be candidate markers for stem cells and early progenitor cells of intestinal epitheliocyte, which are restricted to the bottom of crypt. As MIE cells expressed Musashi-1 and hes 1, this cell line may have characteristics of immature intestinal epithelial cells. MIE cells can contribute to the elucidation of intestinal epithelial cell differentiation mechanisms.

**Papilla: A Niche for Human Renal Stem Cells**

T. Roitbak, E. Romero, A. Wandinger-Ness; Pathology, University of New Mexico, Albuquerque, NM

Many genetic, immunologic and environmentally caused renal disorders lead to kidney damage or loss. As a result, approximately 58,000 patients in the US are currently on the waiting list for a kidney transplant. Despite the advances in kidney transplantation, a significant shortage of donor organs requires many to remain on dialysis for extended periods of time. The role of stem cells in the treatment of pathophysiological disorders is therefore of significant interest. Until recently, the population of adult SC in kidney had not been identified. Based on published studies in rodents (Oliver et al., J Clin Invest. 2004, 114:795-804) we isolated and characterized a population of human primary kidney cells with the characteristics of adult renal stem cells. The cells were derived from the renal papilla of two independent patients. Ultrastructural analyses show these cells reside in situ exclusively in the loops of Henle of tubules found deep within the medulla and papilla. The cells are harbored between the tubular epithelia and readily associate with cortical tubular epithelia in vitro, both on filter cultures and in 3D collagen gel cultures. These putative adult human renal stem cells express numerous markers characteristic of stem cells, are able to adopt tubular epithelial-like and neuronal-like phenotypes, and in some cases form structures resembling neurospheres. Work is in progress to test their ability to incorporate into renal tubules of animal models. The experiments suggest that human papilla may serve as a niche for human renal stem cells and the results are important for the development of tissue engineering and alternate renal tissue repair strategies. Supported by UNM SOM RAC grant.

**Calcium Oscillations in Liver Stem Cells are Associated with Their Acquistion of a Cardiac Phenotype**

B. J. Muller-Borer,[1] W. E. Cascio,[1] G. L. Esch,[2] G. Butz,[2] H. Kim,[2] W. B. Coleman,[2] J. W. Grisham,[2] P. A. W. Anderson,[3] N. N. Malouf[2]; [1]Division of Cardiology, ECU Brody School of Medicine, Greenville, NC, [2]Pathology and Laboratory Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC, [3]Duke University Medical Center, Durham, NC

We examined in a cardiac microenvironment the plasticity of a liver stem cell line (WB F344) generated from a cloned, single, non-parenchymal epithelial cell from a normal adult male rat. Our previous studies suggested that WB F344 cells acquire a cardiac phenotype in the absence of fusion. Here, we begin investigating the mechanisms that induce these stem cells to acquire a cardiac phenotype. Neonatal cardiac myocytes were co-cultured with WB F344 cells. Intercellular communications were documented with Fluorescent Recovery After Photobleaching. Line scan confocal images recorded intracellular calcium signals. Real-time RT-PCR and immunocytochemistry monitored transcription of cardiac specifying transcription factors and expression of cardiac specific proteins. De novo oscillating $[Ca2+]_i$ spikes in the cytoplasm of WB F344 cells identified 24-36 hours after co-culture were synchronous with oscillating $[Ca2+]_i$ transients in adjacent cardiomyocytes. These were associated with transcription of NKx2.5, MEFc2, myocardin, Tbx5 and Tbx20 in the WB F344 cells. Differentiated WB F344-derived myocytes, expressing cardiac TnI and TnT in sarcomeres appeared 4-5 days later. A physical contact between the myocytes and the WB F344 cells was a requirement for the acquisition of $[Ca2+]_i$ spikes and eventually a cardiac phenotype. Intercellular communications between the two cell types, both expressing connexin 43, was achieved through shared gap junctional channels. Uncoupling the cells with carbenoxolone extinguished the $[Ca^{2+}]_i$ oscillations in the WB F344 cells but not those in the myocytes. Following removal of carbenoxolone, the WB F344 cells reacquired $[Ca2+]_i$ oscillations. We hypothesize that a signal, presumably transmitted via gap junctions into the WB F344 cells, resulted in oscillating calcium signals that were transduced into transcription of a cardiac specifying gene program and the acquisition of a cardiac phenotype in the WB F344 cells.

**Expansion of Hepatocytes in Mitomycin C Treated DPPIV Deficient Fischer Rats**

D. C. Hixson,[1,2] M. Carreiro,[1] R. Simper Ronan,[1] K. Brilliant[1]; [1]Department of Medicine, Rhode Island Hospital, Providence, RI, [2]Medicine and Pathology (Research), Brown University School of Medicine, Providence, RI

Compromising regeneration of donor hepatocytes by pretreatment of host rats with retrorsine has been widely used to promote selective expansion of transplanted hepatic progenitor cells. Retrorsine crosslinks DNA of host hepatocytes and prevents their proliferation in response to partial hepatectomy (PH), allowing selective expansion/differentiation of transplanted progenitors. Two shortcomings of this method are the length of the protocol (7 weeks) and the carcinogenicity of retrorsine, an activity that precludes human usage. In this report, we describe a clinically applicable protocol for expansion of transplanted progenitor cells that uses a one week pretreatment with Mitomycin C, a well characterized chemotherapy agent. To determine the efficacy of Mitomycin C, mutant Fischer 344 rats expressing inactive dipeptidyl peptidase IV (DPPIV) were injected i.p. with Mitomycin C (2 mg/kg). Seven days after treatment, host rats were given a 2/3 PH, injected intrasplenically with adult or fetal hepatocytes from DPPIV+ Fischer 344 rats followed by i.p. injection of antibiotics (5mg/kg) starting one day post-surgery. Histochemical staining of frozen sections from host rat livers for DPPIV enzymatic activity revealed well-defined colonies of donor derived hepatocytes by 2 weeks post transplantation. Comparative studies showed similar levels of engraftment in host rats treated with Mitomycin C and retrorsine. The size distribution of DPPIV+ donor hepatocyte colonies determined with ImageProPlus software was comparable in retrorsine and Mitomycin C treated host rats. Primary advantages of this protocol are the rapid production of donor colonies and the possibility of developing a clinically applicable protocol for repopulating a diseased liver with adult or fetal hepatic progenitor cells.

**Differentiation of Pluripotent Dental Pulp Stem Cells into Osteoblastic Lineage**

T. Nozaki, M. Shinohara, K. Ohura; Department of Pharmacology, Osaka Dental University, Osaka, Japan

**Objective**: To evaluate the potency of dental pulp stem cells as a source of osteoprogenitor cells by investigating the potential of rat dental pulp stem cells to differentiate into an osteoblastic lineage *in vitro*. **Methods**: Rat dental pulp stem cells were induced to differentiate using conditions reported to induce osteogenic differentiation of human bone marrow-derived mesenchymal stem cells. Nodule mineralization and alkaline phosphatase (ALP) activity were measured after the induction. Quantitative analysis of gene expression was performed using real-time RT-PCR to elucidate gene regulation in the potential osteoblastic lineage obtained. **Results**: Low levels of mineralization were detected at 3 weeks after induction, and this increased to 29 mineralized nodules at 6 weeks, as determined by von Kossa staining. The ratios of ALP-positive cells among the total cells were 44.4±1.0, 46.9±0.9, 40.5±0.5 and 21.0±1.8% at 1, 2, 3 and 6 weeks after induction, respectively, and the level of ALP activity was significantly decreased at 6 weeks ($p<0.05$). At 6 weeks after induction, Col1a2 (collagen type I) and Bglap (osteocalcin) were up-regulated by approximately 1.7-fold and 1.3-fold, respectively, compared with their corresponding levels at 1 week. These observations suggest that the rat dental pulp stem cells differentiated into osteoblastic cells and that the ALP activity decreased in parallel with the differentiation. Moreover, the expressions of Col1a2 and Bglap were inversely correlated with Alpl (alkaline phosphatase) expression after the induction, whereas Bmp2 (bone morphogenetic protein 2) expression showed a positive correlation with Alp1 expression. **Conclusions**: The present results suggest that rat dental pulp stem cells are able to differentiate into an osteoblastic lineage, and provide support for the hypothesis that mesenchymal stem cells in rat dental pulp may represent a source of osteoprogenitor cells that could function in clinically relevant osteogenic regeneration.

2775

**Oct-4-GFP Imaging of Cloned and Fertilized Mouse Embryos at the Morula Stage Predicts Success of Stem Cell Derivation**

P. J. Sammak,[1] F. Cavaleri,[2] H. Schöler,[2] G. Schatten,[1] M. Boiani[2]; [1]Pittsburgh Development Center, University of Pittsburgh, Pittsburgh, PA, [2]Max Planck Institute for Molecular Biomedicine, Muenster, Germany

Neither reproductive nor stem cell potentials of individual embryos can be accurately predicted, notwithstanding the importance of potentiality for biomedical research as well as reproductive medicine. Here, real-time Oct4-GFP detection is shown as a quantitative method for predicting developmental competence of mouse embryos generated by fertilization and by nuclear transfer (NT) for both ESC derivations as well as for pregnancies. Real-Time Spinning Disc Confocal Microscopy, with precise temperature and gas regulation, detects *Oct4* gene reprogramming in NT and fertilized mouse embryos. Embryos were observed in time lapse during development. Day 2 embryos began expressing Oct4-GFP at the 4-cell stage and became progressively, but not uniformly brighter within the next 10 hrs. In day 3-4 embryos, cells that were destined to become the inner cell mass could be identified within morulae by two characteristics, brightness and number of bright cells in apposition, before embryo compaction and cavitation. Blastomere quality was predicted during the morula stage and morulae were sorted into three groups, based on Oct4-GFP intensity and localization to the nascent inner cell mass (ICM), to evaluate the predictive value of this non-invasive imaging before blastocyst formation. Blastocyst development (type 1, 68%; type 2, 58%; type 3, 38%), ESC derivation rates cells (36%, 27%, 9%), and germ-line transmission of ESC (28%, 38%, 16% $GFP^+$ gonads) all demonstrate this method's power. 50% of NT-embryos developed to blastocysts and 25% established ESC lines, although only 1% develop to offspring. Higher order patterns of pluripotency markers within embryos are correlated to ES derivation success, providing a biologically-based distinction between NT-constructs with negligible reproductive potentials from those invaluable for therapeutic cloning.

**Comparative Analysis Between Diploid & Tetraploid Stem Cell - Derived Teratomas Using MRI and Histopathology**

C. A. Castro,[1] P. H. Mills,[2] J. H. Park,[3] J. A. Ozolek,[1] E. T. Ahrens,[2] G. P. Schatten[1]; [1]Pittsburgh Development Center, University of Pittsburgh, Pittsburgh, PA, [2]Biological Sciences, Carnegie Mellon, Pittsburgh, PA, [3]Medical Research Center, MizMedi Hospital, Seoul, Republic of Korea

Diploid and tetraploid monkey stem cell teratomas were grown for analysis and comparison. Stem cells were bilaterally injected in the testes of mice and allowed to grow for approximately 10 weeks. After growth, the teratomas were removed for 3-D MRI imaging and histopathological sectioning. Samples of the teratomas were taken fresh for karyotype confirmation and tissue was also frozen and stored for possible future DNA and RNA analysis. To non-invasively acquire volumetric tissue information and identify structures, each teratoma was positioned in an 11.7T microMRI system for imaging. Each image set was imported into 3-D scientific software for the browsing of serial images along the axial, sagittal

and coronal axes and the calculation of volumetric tissue statistics. Afterwards, the teratomas were serially sectioned in the long axis and stained using H&E and a battery of immunostains. The slides produced were analyzed to compare the microanatomy between the diploid and tetraploid teratomas. Also, serial sections were compared with the MRI "virtual histology". The tetraploid teratomas appear to have grown faster than the diploid. Both types presented three germ layers but in different percentages. The tetraploid teratomas appear to be less mature and less differentiated, and also more necrotic, apoptotic, mitotic, and disorganized. In addition, tetraploids appear to be more malignant with atypical mitosis, nuclei and cytoplasmic atypia and less organogenesis capabilities than the diploids. Histopathology and MRI shows that the anatomy of the tetraploid teratoma in general has the tendency to be abnormal while the anatomy of the diploid teratoma is more likely to be normal.

**Germline Stem Cells in *C elegans***

S. L. Crittenden,[1] K. A. Leonhard,[2] D. T. Byrd,[2] J. Kimble[1,2]; [1]Howard Hughes Medical Institute, Madison, WI, [2]Department of Biochemistry, University of Wisconsin-Madison, Madison, WI

The adult *C. elegans* germ line includes mitotically-dividing cells in the distal "mitotic region" and meiotic cells more proximally. A single somatic cell, the distal tip cell (DTC), provides a "niche" that promotes germline mitoses by GLP-1/Notch signaling. Downstream of GLP-1/Notch signaling, PUF RNA regulators promote mitosis by repressing meiosis-promoting GLD RNA regulators. We have investigated the self-renewal and division patterns of cells in the mitotic region. To investigate self-renewal, we labeled cells in the mitotic region with BrdU. Within 10 hours all mitotic germ cells are labeled. In a series of pulse/chase experiments, BrdU is lost from the mitotic region and BrdU labeled nuclei move into the proximal meiotic region. Therefore, cells in the mitotic region are capable of both self-renewal and generation of differentiating cells, both hallmarks of stem cells. The position of nuclei within the mitotic region does not affect the rate at which they lose BrdU labeling and all nuclei cycle at approximately the same rate. To investigate division patterns, we examined metaphase plates and mitotic spindles throughout the mitotic region, and see no asymmetric or oriented cell divisions. Our current model is that *C. elegans* germline stem cells are controlled by position with respect to the niche rather than by oriented asymmetric cell divisions.

2778

**Interstitial Cells in Reproductive Strategy of Colonial Hydroid *Obelia longissima***

A. V. Akhmadieva, A. I. Shukalyuk, V. V. Isaeva; Laboratory of Embryology, Institute of Marine Biology FEB RAS, Vladivostok, Russian Federation

In colonial invertebrates the line of totipotent or pluripotent stem cells is maintained throughout the life of the animal, and these self-renewing stem cells may give rise to all cell lines including germ cells. We performed histological, ultrastructural, histochemical and immunochemical studies of stem and gonial cells in the colonial hydroid *Obelia longissima.* Interstitial and gonial cells in *O. longissima* have morphological features typical for stem and germ cells in all studied *Metazoa*: large nucleus with diffuse chromatin and large nucleolus, basophilic cytoplasm including specific germinal bodies, surrounded with mitochondria; in oogenic cells annulate lamellae were also found. Interstitial and germ cells in *O. longissima* selectively express alkaline phosphatase activity, a histochemical marker for mammalian embryonic stem and primary germ cells. The specific deep brick-red color of interstitial and primary germ cells, migrating inside stolons and participating in medusoid formation, is comparable with that revealed in murine ESC *in vitro,* used as a standard. We also used proliferating cell nuclear antigen (PCNA; DAKO, USA) to detect self-renewing cells that have not left mitotic cycle. Stem and primary germ cells in *O. longissima* were PCNA-positive while differentiated somatic cells were PCNA-negative. Our findings show that properties of interstitial and germ cells in the colonial hydroid *O. longissima* is ensured by evolutionary conservative mechanisms, common for all studied invertebrate and vertebrate animals from cnidarians to mammals. A self-renewing pool of interstitial cells in the colonial hydroid provides the cell source for asexual and sexual reproduction and the cellular basis for realization of the life strategy including both alternating reproductive modes.

2779

**Stem and Germ Cells in Asexually Reproducing Animals: A Comparative Study**

A. I. Shukalyuk, V. V. Isaeva; Laboratory of Embryology, Institute of Marine Biology FEB RAS, Vladivostok, Russian Federation

A self-renewing pool of totipotent or pluripotent SC provides the cell source for asexual and sexual reproduction in colonial invertebrates or those capable of asexual reproduction. Our study provides a step forward in the elucidation of evolutionary conservative sub-cellular and molecular bases of "stemness," focusing on the comparative study of stem and germ cells in colonial rhizocephalan crustaceans, cnidarians, planarians, using different methodological approaches. Stem and germ cells of all studied animals have typical germinal bodies surrounded with mitochondria. Our data provide evidence of mitochondria involvement in biogenesis of germ determinants; the release of mitochondrial matrix in cytoplasm of gonial cells in cnidarians, turbellarians, echinoderms and vertebrates supposedly mediates the transport and incorporation of mitochondrial derivatives into germ determinants. These findings agree with data of other authors on the presence of mitochondrial ribosomal RNA in germ determinants. SC of colonial rhizocephalans and of a hydroid selectively express activity of alkaline phosphatase, a histochemical marker for mammalian embryonic SC and GC. We carried out immunocytochemical tests using proliferating cell nuclear antigen to detect self-renewing cells that have not left the mitotic cycle in stolons of the rhizocephalan *P. gracilis* and cnidarian *O. longissima*. Only stem and germ cells were PCNA-positive while differentiated cells were PCNA-negative. We found the evolutionary conservative gene *vasa* in the DNA of studied rhizocephalan crustaceans. We cloned *vasa*-related genes and other genes of DEAD-box family from the colonial rhizocephalan *Polyascus polygenea,* and phylogenetic analysis suggest that these genes are closely related to *vasa*-like genes of other Arthropoda. We found selective expression of *vasa*-like gene products in SC and GC in *P. polygenea*. Further studies of SC in a wide variety of metazoans may provide a clearer understanding of common, evolutionary conservative bases for totipotency and immortality.

### Autophagy Pathway Is Involved in the Degradation of Hirano Bodies

D. Kim, M. Fechheimer; Cellular Biology, University of Georgia, Athens, GA

Hirano bodies are actin-rich aggregates that have been found in a number of neurodegenerative diseases including Alzheimer's disease, Parkinson's disease, Amyotrophic Lateral Sclerosis, and other pathological conditions. The fate and mechanism of degradation of Hirano bodies are poorly understood. Here, we show that autophagy, a process mediating bulk degradation of cytoplasmic proteins or organelles, is involved in the degradation of Hirano bodies. The formation of Hirano bodies was controlled by regulated inducible expression of the 34 kD ΔEF1 protein in wild type or autophagy mutant strains of *Dictyostelium*. The growth rate of a *Dictyostelium* mutant strain (ATG $5^-$) with Hirano bodies was severely reduced up to 72hrs when compared to that of wild type *Dictyostelium* bearing Hirano bodies or autophagy mutant without Hirano bodies. We also observed the co-localization of atg8-GFP, an autophagosome marker protein, with Hirano bodies by fluorescence microscopy. Measurements of the rate of degradation of 34kDa ΔEF1-GFP protein in both wild type and autophagy mutant *Dictyostelium* were performed using flow cytometry and western blot analyses. The turnover of Hirano bodies is faster in wild type than in autophagy mutant (ATG $5^-$) *Dictyostelium* and the background expression level of 34kDa ΔEF1-GFP protein is significantly higher in autophagy mutant (ATG $5^-$) than in wild type *Dictyostelium*. These results suggest that autophagy is involved in the degradation of Hirano bodies. Yet, significant turnover of Hirano bodies still occurs in ATG$5^-$ cells, suggesting that other mechanisms such as ubiquitin-mediated degradation also contribute to turnover of Hirano bodies. Since failure of clearance of Hirano bodies by autophagy blocks cell growth in *Dictyostelium*, it is likely that degradation of Hirano bodies by autophagy may promote cellular function and survival during the progression of neurodegenerative disease.

2781

### Phosphatidylserine in Addition to Phosphatidylethanolamine is *in vitro* Target of the Mammalian Atg8 Modifiers, LC3, GABARAP And GATE-16

I. Tanida, Y. Sou, M. Komatsu, T. Ueno, E. Kominami; Department of Biochemistry, Juntendo University, School of Medicine, Tokyo, Japan

In yeast, phosphatidylethanolamine is a target of the Atg8 modifier in ubiquitylation-like reactions essential for autophagy. Three human Atg8 homologs, LC3, GABARAP and GATE-16, have been characterized as modifiers in reactions mediated by hAtg7, an E1-like enzyme, and hAtg3, an E2-like enzyme, as in yeast Atg8-lipidation, but their final target(s) has not been identified. Recently, results from the incubation of [$^{14}$C]ethanolamine in COS7 cells for 48 h has suggested that phosphatidylethanolamine is a target of LC3. These results are not conclusive, however, because of the long incubation time. To identify the phospholipid target(s) of the Atg8 homologs, we reconstituted the conjugation systems for the mammalian Atg8 homologs *in vitro* using purified recombinant Atg proteins and liposomes. Each purified mutant Atg8 homolog with an exposed C-terminal Gly formed an E1-substrate intermediate with hAtg7 *via* a thioester bond in an ATP-dependent manner, and formed an E2-substrate intermediate with hAtg3 *via* thioester bond dependent on ATP and hAtg7. When each Atg8 homolog was incubated with liposomes composed of the total lipids of HeLa cells, its conjugated form was observed in the presence of hAtg7, hAtg3 and ATP. *In vitro* conjugation using synthetic phospholipid liposomes showed that phosphatidylserine in addition to phosphatidylethanolamine is a target of LC3, GABARAP, and GATE-16. To our knowledge, this is the first report showing that phosphatidylserine is a target of ubiquitin-like modifiers.

2782

### Gold-Containing Endosome-Derived Vesicles that Cannot Fuse with Autophagosomes

C. Balane, J. Wolfe; Biology, Wesleyan University, Middletown, CT

Autophagy of the parental macronucleus occurs during the sexual life cycle of the unicellular ciliate *Tetrahymena thermophila*. The macronucleus undergoes massive compaction, acidification, and rapid degeneration. Nuclear acidification suggests lysosomal mediation, and therefore autophagy. In addition, acid phosphatase, a lysosomal enzyme, and the fluorescent lysosomal marker Texas Red Dextran (TRD) co-localize with degrading macronuclei. Such co-localization is impeded by autophagic inhibitors 3-Methyl Adenine and Bafilomycin A. In addition, both inhibitors prevent macronuclear loss, suggesting that TRD co-localization with the macronucleus corresponds to hydrolytic enzyme transfer. To monitor macronuclear autophagy by electron microscopy, cells were incubated with 6 nm colloidal gold together with TRD. Intracellular gold was visualized by silver enhancement. We expected that gold would co-localize with the degrading macronucleus. To our surprise, TRD became co-localized with degrading macronuclei, but the gold particles never did. We infer that although TRD and gold enter cells together, during the course of endosomal processing, two types of vesicles are formed, one of which excludes gold. This was confirmed cytologically; some vesicles contained both gold and TRD, while others contained TRD alone. We next tested sorting in cells whose lysosomes were loaded with TRD and an alternative marker for electron microscopy, cationized ferritin. Preliminary experiments indicate that fluoresceinated ferritin co-localizes with TRD in vesicles derived from the primary endosome. It was also observed that ferritin co-localizes with degrading macronuclei, together with TRD. Evidently, only gold-free vesicles can fuse with autophagosomes, while gold-positive vesicles cannot. One possibility relates to the non-organic nature of gold, another to its large size, a third to its density. It will be possible to distinguish among these alternatives using colloidal gold coated with protein, as well as particles of differing sizes and composition.

### Phagosome/Lysosome Fusion is Preceded by an Actin and Calmodulin-Dependent Docking Step

W. Stockinger, L. Jarzylo, E. Shieh, A. B. Castoreno, A. Nohturfft; MCB, Harvard University, Cambridge, MA

Particles greater than 0.5 µm in diameter such as microbes, apoptotic bodies and retinal outer segment fragments are often eliminated through an endocytic process called phagocytosis. Inside cells particles are stored in specialized vacuoles termed phagosomes. Phagosomes fuse with vesicles of the endosomal/lysosomal system, which allows for delivery of hydrolytic enzymes and eventually for the digestion of the engulfed material. In an effort to study the process of lysosome/phagosome fusion in biochemical detail we have developed a novel cell-free assay. In this assay tritium-labeled lysosomes are mixed with phagosomes containing scintillant latex beads. As the effective range of tritium-derived beta particles is less than 600 nm, scintillation requires close interaction between donors and acceptors. We found that the assay produces a signal in a cytosol, ATP and

temperature-dependent manner. When samples are subsequently treated with carbonate the signal is abolished, indicating that the vesicles have docked but not fused. When vesicles are allowed to dock and then exposed to $Ca^{2+}$, a complex is formed that remains resistant to carbonate. Through the use of inhibitors and through chromatographic fractionation of cytosol we show that docking requires actin polymerization and calmodulin. The results were confirmed by immunofluorescence microscopy and with a live-cell scintillation proximity assay. These findings offer new insights into the mechanisms of phagosome maturation and provide a useful new system for further biochemical dissection.

**Induction of Macroautophagy by Proteasome Inhibition in Living Cells**

D. W. Hailey, E. L. Whiteman, H. Lorenz, J. Lippincott-Schwartz; NIH / NICHD / CBMB, Bethesda, MD

Macroautophagy is an inducible process by which cytosolic components are sequestered in double-membrane bound vesicles and delivered to lysosomes for destruction. Increased numbers of autophagosomes are observed in some neurodegenerative disorders including Alzheimer's and Huntington's disease. Autophagosomes may play a protective role in these diseases by isolating and degrading misfolded or aggregated proteins. Suppression of proteosome activity is observed in many of these same neurologic diseases. We asked whether loss of proteosome activity can induce macroautophagy, and if so, what mechanisms regulate it under these conditions. We created stable cell lines expressing the mature autophagosome marker CFP-Atg8. Under growth conditions, we observe fewer than 10 autophagic vesicles per cell. These structures contain authentic substrates of macroautophagy (RFP-GAPDH and YFP-LDH). To mimic conditions of reduced proteosome capacity, we treated cells with low concentrations of proteosome inhibitors. This treatment dramatically increases the number of autophagic vesicles in a dose and time dependent manner, and CFP-Atg8 protein levels concomitantly increase. Concurrently, freely diffusing CFP-Atg8 is sharply reduced via its recruitment to membranes. This effect is abolished by addition of 3-methyladenine. Saturation of the 26S proteosome, effected by overexpression of CD3δ-YFP, similarly induces the appearance of autophagosomes. Aggregations of CD3δ-YFP in the ER membrane also colocalize with CFP-Atg8. Last, we studied the effect of proteosome inhibition on a marker for nascent autophagosomes, GFP-Atg5. We found that the mobility of GFP-Atg5 is dramatically reduced under these conditions, suggesting that loss of proteosome activity affects biogenesis of autophagosomes at an early step. Our data suggests a feedback mechanism in which impaired proteosomal degradation upregulates levels of critical component proteins of the autophagosome. We propose that autophagic induction may be stimulated by increasing the levels of these proteins and by recruiting autophagic machinery to proteosomal substrates.

2785

**Mycobacteria Escape from Phagosomes**

P. J. Peters,[1] N. van der Wel,[1] D. Houben,[1] D. Hava,[2] D. Fluitsma,[3] M. Brenner[2]; [1]Netherlands Cancer Institute, Amsterdam, The Netherlands, [2]Harvard Medical School, Boston, MA, [3]Free University, Amsterdam, The Netherlands

In macrophages, mycobacteria are assumed to reside in early endosomes. In the endocytic pathway MHC class II and CD1 antigen loading is facilitated while MHC class I loading of cytosolic antigens occurs in the ER. Since T-cells are known to be involved in the immune response to mycobacteria infections, the localisation of mycobateria was determined in both macrophages and dendritic cells in relation to the localization of the antigen presenting molecules. M. tuberculosis and M. leprae infection was monitored at different infection periods. Antigen presenting molecules MHC class II and CD1b but also LAMP1 were after infection, transiently detected on the phagosomes. No ER fusion with the phagosome was seen using a immunogold label quantification with ER resident proteins*. However detailed analysis using cryo-immunogold electron microscopy revealing all membranous compartments, demonstrated that after 48 hours of infection, the bacteria without LAMP labeling also missed the electron lucent space normally detected in the phagosome and importantly, were not enclosed by a host cell membrane. These cytosolic bacteria were detected in increasing numbers after 92 hours of infection. In conclusion, the trafficking of mycobacteria appears to involve more compartments then previously reported. The mycobacteria traffic through all compartments, which allow access to MHC class I, class II and CD1 presentation. The presence of mycobateria in the cytosol of skin and cultured cells, explains the MHC class I restricted CD8 T-cells involved in resistance to mycobacteria that was long a phenomenon not fully understood. * Touret et al., Cell 2005 in press

**A Novel Method to Purify Phagosomes Demonstrates a Modulation of Phagosomal Maturation by *Streptococcus Pyogenes* Bacteria**

P. Nordenfelt, P. Lönnbro, H. Tapper; Department of Clinical Sciences, Clinical and Experimental Infectious Medicine, Lund, Sweden

*Streptococcus pyogenes* can cause severe and potentially lethal infections by evading the host cellular immune system. In order to study the interaction between *S. pyogenes* and human phagocytes, we have developed a novel method for phagosome isolation using ATRA-differentiated neutrophil-like HL-60 cells and magnetic bead-coupled AP1 (wild-type) and BMJ71 (mutant, lacking M and H surface proteins) strains of *S. pyogenes* bacteria. After nitrogen cavitation of phagocytosing cells, pure phagosome preparations were obtained by magnetic separation. Isolated phagosomes at different stages of maturation were analysed by Western blot for the presence of the bactericidal protein myeloperoxidase (MPO), and we could demonstrate a difference in the maturation pattern between phagosomes containing wild-type and mutant streptococci. For the wild-type AP1 strain, phagosomal content of MPO diminished over time, whereas it increased for phagosomes containing the mutant BMJ71, lacking proteins M and H. Our novel method of phagosome isolation could be applied to the study of manipulation of phagosomal maturation also by other intracellular pathogens.

2787

**Analysis of Anti-Protease Activity in Dendritic Cell Lysosomes**

G. Baravalle, E. S. Trombetta, N. McCurley, I. Mellman; Department of Cell Biology and Section of Immunobiology, Yale University School of Medicine, New Haven, CT

Dendritic cells (DCs) are the immune system’s most potent antigen-presenting cells. Upon appropriate stimulation immature DCs, which are specialized for antigen capture, transform into mature cells that specialize in the presentation of antigenic peptide-MHC complexes (pMHC). This, in turn, leads to T cell stimulation. Despite these hallmark signs of DC maturation, the mechanisms that regulate their capacity for antigen processing and transportation of pMHC to the cell surface is not completely understood. It has been shown that DCs regulate their proteolytic

activity by a generalized activation of lysosomal function, which results in enhanced lysosomal acidification in mature DCs as compared to immature DCs. This decrease in the lysosomal pH of mature DCs augments antigen proteolysis, and thus results in the efficient formation of pMHCs. Our work on specific lysosomal protease-inhibitors hints at the control of antigen processing at the level of immature DCs. Performing *in vitro* degradation assays using a mixture of cell lysates of CD11c-purified immature or mature mouse bone marrow derived DCs and macrophages, we show that digestion of some proteins was decelerated by a factor contained primarily in immature DC lysates. Since treatment of the DC lysates with proteinase K led to a decrease of this effect, this factor may be a protein. Thus, the ability of DCs to developmentally regulate their capacity for proteolysis is likely not only due to control of lysosomal acidification but also to modulation of anti-protease activity. Supported by the Austrian Science Fund (FWF).

2788

**The Role of Atg9, a Multi-spanning TGN and Endosomal Membrane Protein, in Mammalian Autophagy**

A. R. J. Young,[1] R. Koechl,[1] X. W. Hu,[1] S. G. Crawshaw,[2] S. High,[2] J. Lippincott-Schwartz,[3] D. W. Hailey,[3] S. A. Tooze[1]; [1]Secretory Pathways Laboratory, Cancer Research UK London Research Institute, London, United Kingdom, [2]University of Manchester, Manchester, United Kingdom, [3]NIH / NICHD / CBMB, Bethesda, MD

During amino acid depravation cells undergo autophagy order to maintain homeostasis. Autophagosomes (AVs), autophagic vesicles, appear in the cytoplasm and engulf cytoplasm and organelles. These immature autophagosomes (AVis) fuse with vesicles of the endosomal/lysosomal system, and become degradative AVs, AVds. Their contents are degraded in a low pH, protease-containing environment without adversely affecting the viability of the cell. The origin of autophagic vesicles in mammalian cells is still unclear. There are now known to be between 20 and 30 genes in yeast (Atg, Autophagy genes) many of which are conserved in mammalian cells. We show that the mammalian ortholog of Atg9 localises to the Golgi complex, being enriched in the trans-Golgi network (TGN), and late endosomes, in particular Rab7 and Rab9 containing late endosomes. Mammalian Atg9 (mAtg9) is glycosylated, with the N-terminal domain present in the cytosol. In primary rat hepatocytes or in cell lines, under starvation conditions, a population of mAtg9 was found to localise transiently to AVs containing GFP-LC3. Using subcellular fractionation to isolate AVs from hepatocytes we find mAtg9 is enriched, as is LC3-II, a marker for AVs. Immunogold labelling of cryosections reveals that while a very minor amount of mAtg9 is found on the AV membranes, most is found on internal membranes, presumably engulfed by the AVi during formation. siRNA depletion of mAtg9 reduced the number of AVis in primary hepatocytes after starvation. The localization of mAtg9 changes upon starvation, becoming more dispersed, and less peri-nuclear. Knock down of mAtg1 (ULK-1) by siRNA causes Atg9 to accumulate in a peri-nuclear location. Our data suggest that AVs, nucleated by interaction between mAtg1 and mAtg9 arise from a TGN-derived compartment, which may overlap with Rab9-containing membranes.

2789

**Mechanisms Controlling Polarised Delivery of Secretory Lysosomes to the CTL Immunological Synapse**

J. C. Stinchcombe, G. M. Griffiths; Sir William Dunn School of Pathology, University of Oxford, Oxford, United Kingdom

Cytotoxic T-lymphocytes (CTL) kill infected cells by releasing cytotoxic proteins which induce apoptosis in their targets. CTL have evolved mechanisms to kill targets effectively whilst protecting neighbouring cells. 1) Cytotoxic proteins are stored intracellularly, and only released on contact with a target. Unusually, lysosomes act as secretory organelles in CTL. 2) Exocytosis occurs at a specific site on the cell surface, opposite a gap which forms in the otherwise tight CTL:target membrane contact and creates a sealed cleft into which material is secreted. Thus, released proteins are directed towards the target, but segregated from neighbouring cells. The secretory site is defined by 1) reorganisation of surface proteins into a secretory immunological synapse (ISS) in which adhesion molecules form a ring of cell:cell contact, surrounding the secretory site and a separate signalling domain, and 2) reorientation of the microtubule cytoskeleton (and its associated organelles) towards the target. We are investigating mechanisms of targeted lysosome delivery to the secretory site during killing, using light and electron microscopy. We find the MTOC moves from its steady state perinuclear location, to the cell surface at the centre of the ISS, reorganising microtubules to pass the surface within the secretory domain. Thus lysosomes are delivered to exocytic sites during polarised transport towards the MTOC. Following killing, the MTOC retracts from the surface, preventing further delivery and exocytosis of lysosomes. Therefore, MTOC positioning targets lysosomes to secretory sites, and controls secretion by controlling access of lysosomes to these sites. To determine molecules controlling lysosome secretion we identified genetic diseases showing defects in lysosome secretion, and used microscopy techniques to determine the secretory block. This approach has identified roles for AP3, rab27a, and munc13-4 in polarised movement, microtubule detachment and exocytosis of lysosomes, respectively.

2790

**Special Lipid Domains Found in Reservosomes from *Trypanosoma cruzi***

M. G. Pereira,[1] C. Vargas,[2] C. Sant'Anna,[1] W. De Souza,[1] G. C. Atella,[2] N. L. Cunha-e-Silva[1]; [1]Instituto de Biofisica Carlos Chagas Filho, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil, [2]Instituto de Bioquimica Médica, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Reservosomes are acidic compartments that store nutrients, found in epimastigote forms of *Trypanosoma cruzi.* They were first described as multivesicular bodies; however, further ultrastructural studies characterized reservosomes as single-membrane bound organelles that lack true internal vesicles and contain lipid inclusions dispersed in an electrondense protein matrix. The frontier between lipids and the dense protein matrix may assume the trilaminar aspect of a planar lipid bilayer. Reservosomes freeze-fractured inside intact cells present flattened lipid inclusions, similar to those usually found in reservosome ultrathin sections, as well as round inclusions, resembling internal vesicles. We have isolated reservosomes and shown that whole purified organelles present twice more lipids than proteins, cholesterol and ergosterol being their most important neutral lipids (Cunha-e-Silva *et al*, FEMS Microbiol Lett, 2002, 214: 7). Now we aim to describe the lipid composition of their purified membranes, analyze the existence of lipid subdomains correlating them with lipid inclusions of different appearance. The purified fraction was sonicated, treated with 1% Triton X-100 for 20 minutes on ice, mixed with the same volume of 80% sucrose, applied at the bottom of 5 and 30 % step sucrose gradient and spun for 22 hours at 100,000xg. The detergent resistant fraction was collected, an aliquot fixed for electron microscopy before extraction in a methanol/chloroform/water system. The chloroform phase was analyzed resulting in 70.3% cholesteryl ester, 6.9% cholesterol and 22.4% phospholipids. Morphologically, the fraction corresponds to planar bilayers found inside intact reservosomes. Moreover, the

presence of GM1 ganglioside detected with cholera toxin B subunit in the reservosome detergent resistant membrane fraction was an unexpected result. Different lipid domains in reservosomes may reflect specialized storing modes or *en bloc* lipid targeting for degradation.

2791

**Plasma Membrane ABCG1 Mediates Cellular Cholesterol Efflux to Lipoproteins**

E. B. Neufeld, K. O'Brien, S. J. Demosky, J. A. Stonik, S. L. Sabol, D. Malide, C. A. Combs, A. T. Remaley, S. Santamaina-Fojo, H. B. Brewer; NHLBI, NIH, Bethesda, MD

The ABCG1 transporter has been shown to play a role in the removal of cellular cholesterol by HDL and other lipoprotein acceptors. However, to date, little is known of the intracellular localization or site(s) of function of ABCG1. In the present study, we show that the carboxy-terminal GFP-tagged human ABCG1 transporter stably expressed in HeLa cells resides on the cell surface and traffics from the cell surface to cholesterol-enriched late endocytic vesicles and back to the cell surface. ABCG1-GFP on the cell surface (i) increases both plasma membrane and intracellular cholesterol, and, (ii) generates plasma membrane detergent-resistant cholesterol domains within which it does not itself reside. ABCG1-GFP expressing cells abnormally retain exogenously supplied fluorescent sphingomyelin on the cell surface and in endosomes. ABCG1-GFP expression enhanced efflux of cellular cholesterol to lipoproteins. ABCG1, unlike the ABCA1 transporter, supported neither the uptake nor lipidation of apoA-I, or, efflux of cellular phospholipids to lipoproteins. Taken together, these studies suggest that ABCG1 on the cell surface and endosomes generates pools of cholesterol that transfer specifically to extracellular lipid-laden lipoproteins. These studies establish that the ABCG1 and ABCA1 transporters generate different types of membrane cholesterol pools that are available for removal from the cell by distinctive mechanisms, involving lipoproteins (diffusion), and, lipid-poor apoA-I (micosolubilization), respectively.

2792

**Endocytic Processing in Living HuH7 and Trf1 Cells by Microscopy Assay: Defect in Vesicle Maturation in Trf1 Cells**

S. Nath,[1] J. W. Murray,[1] R. J. Stockert,[2] A. W. Wolkoff[3]; [1]Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, [2]Liver Research Center, Albert Einstein College of Medicine, Bronx, NY, [3]Anatomy and Structural Biology and Liver Research Center, Albert Einstein College of Medicine, Bronx, NY

The Trf1 cell line was selected from mutagenized human hepatoma (HuH7) cells following dual selection schemes using two toxic ligands that are endocytosed by distinct receptors. Trf1 cells are defective in cell surface receptor trafficking, characterized by intracellular trapping of receptors related to absence of a novel casein kinase 2 isoform, CK2α". As little is known regarding ligand trafficking in these cells, the present study was designed to investigate the trafficking of an endocytosed ligand asialoorosomucoid (ASOR), in HuH7 and Trf1 cells. **Methods:** Cells were cultured on MatTek dishes. In a typical single wave experiment the cells were incubated with Texas-Red labeled ASOR (10µg) for 30min at 4°C, washed and warmed up at 37°C. Digital images were captured at 1frame per second and analyzed using ImageJ software. **Results:** At early times (2min to 12min) following 37°C incubation, fluorescent ASOR was seen in intracellular vesicles that moved and distributed throughout the cell. After 12min of incubation, vesicles in HuH7 cells were seem to fuse, resulting in substantially increased fluorescence content (~5 times) and apparent size of individual vesicles. This fusion did not occur in endocytic vesicles within Trf1 cells, even after 60min following 37°C incubation. **Conclusion:** Although both cell types ultimately deliver endocytosed ligand to lysosomes, these data indicate marked differences in trafficking and maturation of endocytic vesicles between HuH7 and Trf1 cells. The mechanism resulting in reduced vesicle fusion in these endocytic trafficking mutants remains to be elucidated.

**Subcellular Nanomanipulation**

M. Nolan,[1] G. Hughes,[1] R. Gupta,[1] C. Mikoryak,[2] R. K. Draper[2]; [1]Zyvex Corporation, Richardson, TX, [2]Molecular and Cell Biology, University of Texas at Dallas, Richardson, TX

The dimensional scales of nanotechnology and cell biology meet at the subcellular level. One consequence of this convergence is that new tools developed for nanoscale applications are available for the study of cells. Described here is work with a nanomanipulator that has four actuators, each capable of controlling the movement of attached probes in three dimensions with a precision of 5 nm. The instrument is mounted on an inverted stage microscope with differential interference contrast (DIC), wide field, and confocal fluorescence capability. Tungsten probes whose tips were coated with platinum for interaction with thiols were functionalized with quantum dots so that the fluorescent tips of the probes could be followed with high-resolution fluorescence microscopy. The objective of this work was to determine whether the probes could be inserted into living cells and influence specific subcellular structures. The first model system explored was to generate sucrosomes in normal rat kidney (NRK) cells by incubating the cells with 30 mM sucrose, followed by staining the sucrosomes with an acidotropic fluorescent dye for visualization by fluorescence microscopy. Individual sucrosomes were then targeted for nanoprobing. We show that individual sucrosomes can be touched, nudged, pierced and affected by nanomanipulation within living cells. Future work will include nanomanipulation of other subcellular organelles.

2794

**Cellular Requirements for Human Rhinovirus 2 Uncoating**

U. Berka,[1] M. Brabec,[1] D. Blaas,[2] R. Fuchs[1]; [1]Department of Pathophysiology, Medical University of Vienna, Vienna, Austria, [2]Department of Medical Biochemistry, Medical University of Vienna, Vienna, Austria

Human rhinoviruses (HRV) are non-enveloped (+) RNA viruses. HRV2 - a minor receptor group virus - is internalized by lipoprotein receptors, dissociates from its receptors in early endosomes (pH $\leq$ 6.5) and undergoes uncoating at pH $\leq$ 5.6 in late endosomes. The RNA is translocated across the endosomal membrane into the cytoplasm where viral replication occurs. Uncoating can also take place at the plasma membrane when bound HRV2 is artificially exposed to pH $\leq$ 5.6 buffer. To analyze whether the pH gradient between endosomal or extracellular milieu and the pH-neutral cytoplasm is the driving force for RNA translocation we used membrane permeable (acetate pH 5.0) and impermeable [4-(2-Hydroxyethyl)-1-piperazinepropanesulfonic acid (EPPS) pH 5.0] buffers to induce virus uncoating at the plasma membrane of HeLa cells. The membrane permeability versus impermeability of these buffers was verified by determining the intracellular pH with a pH-sensitive dye. Two hours incubation in EPPS buffer did not affect the cytoplasmic pH whereas the cytoplasm rapidly equilibrated with the extracellular pH upon incubation

in acetate buffer. HRV2 was bound to HeLa cells (4°C, pH 7.4) followed by low pH treatment with EPPS or acetate (1 h, 4°C) to induce uncoating. Cells were then transferred into growth medium and the number of cells synthesizing viral protein was determined by immunofluorescence microscopy after 17 hrs. Incubation with membrane-permeable buffer (pH equilibrium conditions) slightly stimulated HRV2 infection and thus RNA membrane translocation as compared to membrane-impermeable buffer (conditions that maintain the pH gradient). This demonstrates that a pH gradient as present during the normal (endosomal) infection route is not required for RNA transport into the cytoplasm. Supported by Austrian Science Fund P17590.

**Tracking NGF Signaling Endosomes with Quantum Dots: One at a Time**

C. Wu,[1] B. Cui,[2] A. Ramirez,[1] K. Zhan,[1] L. Chen,[2] W. C. Mobley,[1] S. Chu[2,3]; [1]Neurology and Neurological Sciences, Stanford University Med Ctr, Stanford, CA, [2]Physics and Applied Physics, Stanford University, Stanford, CA, [3]Lawrence Berkeley National Laboratory, Berkeley, CA

Nerve growth factor (NGF) is a target-derived neurotrophic factor that plays a critical role in regulating neuronal survival and differentiation. It is well established that NGF binds to and activates its receptor, TrkA, at axonal terminals to elicit trophic signaling cascades in the corresponding cell bodies. A long-standing question is how the NGF signal is transported over substantial distances without losing the ability to induce robust and highly specific responses. The signaling endosome hypothesis addresses this issue. It stipulates that NGF binds to and activates TrkA at the axonal surface to recruit an array of signaling molecules from cytosol. Endocytosis of the NGF/TrkA/signaling proteins gives rise to signaling endosomes. The signaling endosome engages the microtubule network and dynein to effect retrograde transport to the cell body where it influences gene expression and activates other responses. In recent years strong evidence has been produced to support the hypothesis. However, direct visualization of the NGF signaling endosome during its genesis, activation and axonal trafficking has been lacking due to technical constraints. In the present study, we used biotinylated NGF in conjunction with a streptavidin-quantum dot 605 conjugate (BtNGF-Str-QD605) to track the real time movement of NGF in compartmentalized DRG cultures. NGF-containing endosomes traveled within the axon in a-stop-and-go fashion with an average speed of 1.6 μm/s. Furthermore, more than 99% moved only retrogradely. Importantly, BtNGF-Str-QD605 displayed significant colocalization with Trk, pErk1/2, and Rab5, all of which are integral components of the NGF signaling endosome. In a separate study, we demonstrated that inhibition of retrograde transport of NGF signaling endosomes caused atrophy in mature and death of immature DRG neurons. Taken together, these findings support the existence of NGF signaling endosome and point to a critical role in neuronal survival and maintenance.

## Leukocytes (2796-2807)

2796

**Modeling and Quantifying Leukemia Cell Deformability with Force Microscopy**

M. J. Rosenbluth,[1] W. A. Lam,[1,2] D. A. Fletcher[1]; [1]Department of Bioengineering, UC Berkeley, Berkeley, CA, [2]Department of Pediatrics, Division of Hematology/Oncology, UC San Francisco, San Francisco, CA

Atomic force microscopy (AFM) has become an important tool for quantifying mechanical properties of biological materials ranging from single molecules to cells and tissues. Current AFM techniques for measuring elastic and viscoelastic properties of cells are based on indentation of cells firmly adhered to a substrate, but these techniques are not appropriate for probing non-adherent cells, such as passive human leukocytes, due to a lateral instability of the cells under load. Here we present a method for characterizing non-adherent cells with AFM by mechanically immobilizing them in microfabricated wells. We apply this technique to compare the deformability of human myeloid and lymphoid leukemia cells at low deformation rates, and we find that both cell lines are well described by an elastic model based on Hertzian mechanics rather than a liquid droplet model frequently used to describe normal leukocytes. Myeloid leukemia (HL60) cells were measured to be a factor of 18 stiffer than lymphoid leukemia (Jurkat) cells on average ($E$ = 855 ± 670 Pa for HL60 cells, $E$ = 48 ± 35 Pa for Jurkat cells, mean ± SD). This work demonstrates a simple method for extending AFM mechanical property measurements to non-adherent cells and can be used as an assay to determine the effects of cytokines, chemotherapeutics, and cytoskeleton-perturbing agents on leukocyte deformability.

**Sirpβ1 Is Expressed as a Disulfide Linked Homodimer in Leukocytes and Positively Regulates Neutrophil Transepithelial Migration**

Y. Liu,[1] I. Soto,[1] Q. Tong,[1] K. Zen,[2] A. Chin[2]; [1]Biology, Georgia Sate University, Atlanta, GA, [2]Pathology, Emory University, Atlanta, GA

Signal regulatory proteins (SIRPs) comprise a family of cell surface signaling receptors differentially expressed in leukocytes and the central nervous system. Although the extracellular domains of SIRPs are highly similar, classical motifs in the cytoplasmic or transmembrane domains distinguish them as either activating (β) or inhibitory (α) isoforms. In human neutrophils (PMN), previously studies from our group have demonstrated multiple SIRP isoforms and that SIRPα binding to its ligand CD47 regulates PMN transmigration. However, given the highly homologous extracellular domain structures of SIRP family members, it was difficult to rigorously define identity and functional role of other SIRP proteins in PMN. In the present study, we utilized SIRPα and β isoform-specific antibodies and RT-PCR to define the major SIRP isoforms in human PMN. We identified that Bit/PTPNS-1 and SIRPβ1 are the major SIRPα and SIRPβ isoforms expressed in PMN, respectively. Furthermore, we found that, while SIRPα (Bit/PTPNS-1) is expressed as a monomer, SIRPβ1 is expressed on the cell surface as a disulfide-linked homodimer with bond formation mediated by Cys320 in the membrane proximal Ig loop. Subcellular localization by sucrose gradient fractionation studies revealed a major pool of SIRPβ1 within plasma membrane of PMN. In contrast, the majority of SIRPα (Bit/PTPNS-1) is present in fractions enriched in secondary granules and is translocated to the plasma membrane after chemoattractant (fMLP) stimulation. Functional studies revealed that antibody-mediated ligation of SIRPβ1 enhanced fMLP-driven PMN transepithelial migration. Co-immunoprecipitation experiments to identify associated adaptor proteins revealed a 10-12 kDa protein associated with SIRPβ1 that was tyrosine phosphorylated after PMN stimulation and is not DAP10/12 or FcRγ. These results provide new insights into the structure and function of SIRPs in leukocytes and their potential role(s) in fine-tuning responses to inflammatory stimuli.

2798

**Fas Activation Reduces Neutrophil Chemotaxis in Response to IL-8 but not fMLP**

B. Hendey, B. Desai, S. Lidder; Pharmacology, Rush University Medical Centre, Chicago, IL

Background: The loss of effector functions, including chemotaxis, has been observed in apoptotic Polymorphonuclear neutrophils (PMN) and may serve to limit inflammation. The expression of phosphatidylserine (PS) on the cell surface is important because they target PMN for removal by macrophages and are thought to play a role in limiting the inflammatory response. Objective: It has not been determined if the reduction in chemotaxis precedes PS externalization or if it is merely a consequence of cell death. Methods: We induced apoptosis in freshly isolated PMN by activating the Fas receptor using either soluble Fas ligand or a Fas activating antibody and examined both the timing of PS externalization and changes in chemotaxis. Results: An increase in PS externalization was not observed until after three hours of Fas activation, but there was no effect on subsequent fMLP-stimulated chemotaxis. Further, fMLP treatment reduces PS externalization in the Fas treated cells from 31.45 ±2.43% to 22.91 ± 3.96 %. In contrast to the results with fMLP, there was a reduction in IL-8-stimulated chemotaxis that preceded PS externalization. Flow cytometry indicates that treatment with either Fas activating antibody or sFasL for one hour reduced the mean fluorescence of the IL-8 receptors, CXCR1 and CXCR2 by about 20%. Fas activation also reduced IL-8-induced Akt phosphorylation. Conclusions: These results indicate that early effects of Fas activation on chemotaxis are agonist specific. Since IL-8 is classified as an intermediate chemoattractant and bacterial peptides such as fMLP are classified as a dominant or end target chemoattractant, the results are discussed within the context of FasL reducing the continued recruitment of neutrophils by an intermediate chemoattractant, IL-8, without affecting the migration of PMN close enough to the site of infection to encounter bacterial peptides.

**Structural Characterization of Sea Urchin Colorless Spherule Coelomocytes: Uniquely Motile Cells that Resemble Neutrophils**

M. B. Schott, T. J. Givens, A. Sturycz, L. Winslow; Biology, Northwestern College, St. Paul, MN

Colorless spherule coelomocytes are immune cells in the sea urchin, *Lytechinus variegatus*. These cells are ~30µ diameter, contain intracellular granules and possess a single flagellum. Digital video microscopy of live cells revealed a highly unique motility where the whip-like motion of the flagellum cause cells to spin in a circular or semi-circular motion with little or no directional translocation. Our approach was to use vital stain fluorescence imaging to determine the spatial intracellular distribution of organelles as a means of cellular characterization. DAPI staining revealed a large, single, nucleus that often appeared dumbbell shaped. The lobed nucleus was routinely found in the upper left quadrant of the cell opposite the point of attachment of the cell's single flagellum. DiOC6 staining revealed a bright lacework of endoplasmic reticulum that appeared to exclude the nuclear region. The fluorescent dye R123 showed even distribution of mitochondria throughout the cell. Colorless spherule cells stained with NBDC6, a fluorescent golgi marker, revealed accumulated clusters of fluorescence patches restricted to the same quadrant as the nucleus. Using DIC optics, numerous colorless granules are easily observed within the cytoplasm. These granules do not appear to be motile within the cell and are all of approximately the same size and dimension. Staining with the acidic dye, acridine orange revealed numerous fluorescent granules that seem to correlate with granules in companion DIC images. Colorless spherule cells were separated on Percoll gradients and intracellular granules were isolated by differential centrifugation. Isolated granules were analyzed by fluorescence staining with DiOC6 and acridine orange. Isolated granules stained brightly with both DiOC6 and acridine orange. Taken together, these data indicate that the colorless spherule coelomocytes many be akin to granulocytes in higher vertebrates such as neutrophils.

**Filopodia Formation in the KG1a Human Hematopoietic Cell Line and Earthworm Coelomocytes under Hypertonic Osmotic Stress**

M. D. Dutt, M. R. Kasschau, S. K. Murphy; Biological Sciences, University of the Sciences in Philadelphia, Philadelphia, PA

The human acute myelogenous leukemic cell line, KG1a extrudes long thin pseudopodia or "osmopodia" in medium with increasing salt concentrations (Oh et al, 2000). Similar podia, known as filopodia have been observed to form in earthworm (*Lumbricus terrestris*) coelomocytes (leukocytes) under high osmotic conditions (Ngo and Kasschau, 2004). Time course experiments performed indicate that when isotonic IMDM (Iscove's Modified Dulbeccos Medium) 255 mOsm is increased to 745 mOsm almost 30% of KG1a cell population shows "osmopodia" within 15 mins and more than 90% show "osmopodia" at the end of 1 hour of exposure to the hyperosmotic medium. KG1a cells exposed to 575 mOsm and 635 mOsm media show numerous, short podia whereas cells in higher osmolality media (695 mOsm and 745 mOsm) show few, long podia. Similar to the earthworm coelomocytes, exposure of KG1a cells to the actin depolymerizing agent, cytochalasin D, enhances the formation of "osmopodia" even when the cells are maintained at 255 mOsm (4% to 48% increase in "osmopodia" forming KG1a cells) and also does not inhibit the formation of "osmopodia" at 745 mOsm. Cytoskeletal studies on the earthworm filopodia suggest that they are based on microfilaments and microtubules (Ngo and Kasschau, 2004). Similar morphological responses to hyperosmotic conditions are exhibited by leukocytes from two diverse species. We hope to determine whether there is a common model of leukocyte adaptation to osmotic stress. In both cases podia probably help these mobile cells in the search for more suitable environmental conditions.

**The Role of Focal Adhesion Kinase (FAK) during the Innate Immune Response: Implications for Macrophage Migration, Cytokine Production and Phagocytosis**

K. A. Owen, B. Rey, A. H. Bouton; Microbiology, University of Virginia, Charlottesville, VA

The Role of Focal Adhesion Kinase (FAK) during the Innate Immune Response: Implications for Macrophage Migration, Cytokine Production and Phagocytosis As an important component of the innate immune system, macrophages have the ability to infiltrate sites of infection, initiate inflammatory responses and eliminate invading pathogens. In the present study, the use of mice in which the non-receptor tyrosine kinase FAK has been conditionally knocked-out in cells of macrophage lineage has allowed us to investigate the role of this molecule in common macrophage functions. Preliminary data indicate that FAK-deficient macrophages isolated from these mice exhibit altered spreading morphology by failing to produce abundant lamellipodia and filopodia 24 hours after plating on fibronectin. These cells also appear to respond with slower migratory kinetics compared to their wildtype littermates during wound healing assays. Furthermore, production of the pro-inflammatory cytokine IL-8 was strongly reduced in FAK-null macrophages upon infection with the gram-negative enteropathogen *Yersinia pseudotuberculosis*, a response that

may be due to an inability to efficiently activate ERK1/2. Finally, in some instances, phagocytosis of *Y. pseudotuberculosis* by these FAK-null macrophages was impaired. Taken together, these data suggest that FAK may constitute a vital link between multiple cell-surface receptors such as integrins, which are involved in migration and adhesion, and toll-like receptors (TLRs), which are involved in the recognition of pathogen-associated molecular patterns. Future experiments will help elucidate how this multifunctional molecule contributes to unique signaling outcomes in response to infection.

**Iron Modulation of Protein Tyrosine Phosphatase Activity in Macrophages**

M. A. Gomez,[1,2] M. Olivier[1,2]; [1]Microbiology and Immunology, McGill University, Montreal, PQ, Canada, [2]Centre for the Study of Host Resistance, Montreal, PQ, Canada

Protein tyrosine phosphorylation is a fundamental determinant in the outcome of a wide array of cellular processes, ranging from cell proliferation to cell death. Regulatory mechanisms of protein tyrosine phosphatases (PTP) in the cellular context are not fully understood. However, events including tyrosine phosphorylation, protein dimerization and oxidation have been proposed as biological modulators of PTP activity. Here we present iron as a modulator of PTP activity in a macrophage model. Inhibition of PTP activity by ferric citrate in macrophage protein lysates is comparable to that of the specific PTP inhibitor $Na_3VO_4$. Iron-dependent PTP inhibition is a reversible event: rescue of activity in iron treated protein lysates upon addition of the iron chelator desferoxamine (DFO) is evident. This inhibition is not a consequence of the iron-dependent generation of reactive oxygen species as determined by superoxide dismutase (SOD) and catalase treatment. Moreover, *in-silico* analyses indicate putative iron binding sites in the catalytic pocket or in its near vicinity in more than 20 human PTPs. In relation to macrophage functions, our results indicate that iron-loaded macrophages have a reduced level of PTP activation upon *Leishmania* infection, together with a differential chemokine gene expression profile. All together, our data shows a novel mechanism of PTP activity modulation by one of the most important and biologically relevant transition metals, iron. These findings open new and interesting avenues in the research of cellular iron metabolism and protein tyrosine phosphorylation homeostasis. Our ongoing research aims to answer questions regarding the molecular mechanisms underlying iron-dependent PTP activity modulation, and its putative implications in multiple cellular functions.

2803

**Activation of Primary Macrophages after Efficient Gene Transfer**

C. Thiel, K. Hein, A. Krumnow, M. Weigel, T. Males, N. Faust; Research and Development, amaxa GmbH, Koeln, Germany

The response of macrophages and monocytes to environmental stimuli, like for example hypoxia-induced chemokine expression, LPS-induced cytokine production, or activation through bacterial DNA, plays an important role in immunity and inflammation. The molecular dissection of the underlying signal transduction cascades has mostly had to rely on macrophage cell lines that are relatively easy to transfect. Corresponding studies in primary cells have been hampered by the fact that the only way to obtain genetically modified primary macrophages or monocytes was through viral infection or by isolating them from transgenic animals. It has thus also been very difficult to examine the effects of intracellular delivery of plasmid DNA containing CpG motifs on the activation status of primary macrophages; a question that is clearly important for gene therapy approaches involving myeloid cells. In the study presented here, we show efficient gene transfer into primary human and murine macrophages as well as human mononcytes by the non-viral nucleofection® method. Using a GFP-reporter construct we routinely obtain between 45 and 60 % transfection efficiency while the cells mainly retain viablity and function. We also show that primary macrophages, like macrophage cell lines, respond to the uptake of plasmid DNA by tumor necrosis factor alpha (TNFα)-production. TNFα-secretion ceases after several hours and the cells can subsequently be re-stimulated by bacterial lipopolysaccharide. These findings now for the first time make it possible to analyse in detail the function of signal transduction proteins in normal non-infected primary macrophages or monocytes.

2804

**Activated Macrophages Express and Secrete Collagen Type VI**

M. Schnoor, P. Cullen, B. Brennhausen, K. Stolle, J. Rauterberg, S. Lorkowski; Leibniz-Institute for Arteriosclerosis Research, Muenster, Germany

In response to inflammatory signals blood monocytes migrate into affected tissues and differentiate to mature macrophages in order to remove the cause of the inflammation. Macrophages synthesize proteases and are therefore thought to have destabilizing effects on the extracellular matrix, which in the case of the arterial wall is synthesized mostly by smooth muscle cells. In previous work, we showed that - contrary to expectations - macrophages produce collagen type VIII *in vitro* and in the atherosclerotic plaque, indicating that under certain conditions these cells may contribute to plaque stability and the structural integrity of tissues in general. Following from this result, we screened human monocyte-derived macrophages *in vitro* for the expression of other collagens using RT-PCR. Surprisingly, we found that both monocytes and macrophages express almost all collagen mRNAs. We selected collagen type VI for further study because it anchors cells to the extracellular matrix and may therefore contribute to tissue stability. On Western-Blot analysis, collagen type VI was found in the medium of freshly isolated monocytes, but appeared in increasing amounts during differentiation to mature macrophages. Inhibition of intracellular transport or glycosylation by monensin or tunicamycin reduced the amount of this collagen secreted by macrophages in cell culture, but secretion was not inhibited by nocodazol, indicating that tubular structures are not involved in this process. Secretion was increased by TGF-β and interleukins 4 and 10, which induce alternative activation of macrophages. We also found that the function of collagen type VI in macrophages *in vitro* appears to be participation in β1-integrin-mediated cell adhesion. Overall, our results show that macrophages have both synthetic and degrading properties due to their ability to express both proteases and collagens. This suggests a general role for these cells in tissue remodeling.

2805

**Activation of $A_{2A}$ Adenosine Receptors Regulates Chemokine-stimulated Integrin-mediated Adhesion and Cell Spreading of CD4+ T Lymphocytes under Shear Flow**

R. K. Polanowska-Grabowska,[1] J. A. DiVietro,[2] J. Linden,[3] M. B. Lawrence[2]; [1]Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA, [2]Biomedical Engineering, University of Virginia, Charlottesville, VA, [3]Division of Cardiovascular Medicine, University of

Virginia, Charlottesville, VA
Integrin-dependent adhesion, actin polymerization and cell spreading in T lymphocytes can be rapidly induced by chemokines such as SDF-1 (CXCL12). VLA-4 (α4β1) and LFA-1 (αLβ2) are the major integrins expressed on circulating lymphocytes which bind to ligands VCAM-1 and ICAM-1, respectively, on inflamed endothelium. Adenosine is an endogenous-purine nucleoside formed as the result of the breakdown of adenine nucleotides that are released from ischemic tissues, activated platelets, mast cells, and dying cells. In- vitro, $A_{2A}$ adenosine receptor agonists act, at least in part, through cyclic adenosine monophosphate (cAMP)-mediated pathways. Although $A_{2A}$ receptors possess anti-inflammatory properties their involvement in chemokine-stimulated lymphocyte adhesion under shear flow has not been studied. We have investigated if the specific adenosine receptor agonist ATL313 modulates integrin-dependent adhesion in SDF-1-stimulated human CD4+ lymphocytes. Adhesion assays to immobilized ICAM-1, VCAM-1 and P-selectin were performed using a parallel plate flow chamber at wall shear stresses of 0.5 to 1.0 dyne/cm$^2$. Treatment of CD4+ lymphocytes with ATL313 (1 μM) blocked SDF-1-stimulated adhesion to immobilized ICAM-1 and low density VCAM-1 (250 sites/μm$^2$) up to 80 and 50%, respectively. ATL313 also completely blocked cell spreading on ICAM-1. A combination of a suboptimal dose of ATL-313 (10 nM) with the type IV phosphodiesterase inhibitor rolipram (100 nM) synergistically decreased SDF-1-stimulated adhesion to ICAM-1 and to low density VCAM-1. The cAMP-dependent protein kinase A inhibitor (14-22 amide, cell-permeable, myristoylated) not only reversed the blocking effect of ATL313 but also stimulated adhesion and cell spreading on ICAM-1. Increasing cAMP with forskolin or loading with the cell-permeable cAMP analog blocked chemokine-stimulated adhesion and spreading. Therefore, activation of $A_{2A}$ adenosine receptors may counteract chemokine-stimulated integrin activation and adhesion to inflamed endothelium via a cAMP/PKA-mediated pathway.

### Intercellular Transfer of Cell Surface Proteins across Immunological Synapses

G. S. Williams, E. N. Nolte-'t Hoen, D. M. Davis; Division of Cell and Molecular Biology, Imperial College London, London, United Kingdom
It is now well established that cell surface proteins and membrane components transfer between immune cells. Several possible mechanisms for this may be envisaged: membrane fusion, proteolytic cleavage, uprooting of transmembrane proteins or transfer of exosomes, cell fragments or membrane. We have previously observed bi-directional transfer of full-length proteins across NK cell immunological synapses, therefore refuting proteolytic cleavage as a possible mechanism. Using transwell assays, we now show that intercellular protein transfer is contact-dependent and that the cytoplasmic dye calcein does not transfer. Thus, exosomes or other membrane compartments containing cytoplasm do not mediate transfer. Transfer of proteins is greatly increased when the opposing cell possesses a cognate binding partner, and for example, the extent of transfer of the NK cell receptor KIR2DL1 strongly correlates with the level of expression of its ligand, HLA-C, on target cells. However we observe transfer of multiple proteins including GPI-linked GFP, for which there cannot be a physiological receptor, and thus to some extent, proteins can transfer independently from specific recognition. Unexpectedly, we also found that expression of HLA-Cw6 in NK cells causes a reduction in acquisition of HLA-Cw6 from target cells. This could reflect endogenous MHC protein occupying KIR2DL1 on the NK cell surface due to a *cis* interaction, analogous to that recently demonstrated for murine Ly49 NK cell receptors. Thus in summary, we demonstrate that upon contact, NK and target cells exchange fragments of membrane enriched in proteins for which there are binding partners on the opposing cell. Transferred proteins constitute a lasting molecular imprint of NK-target cell interactions, which we speculate may modulate subsequent cell behaviour.

2807

### Effect of the PI3-kinase/PTEN Pathway on PKC Phosphorylation in Jurkat T lymphocytes

M. Freeley,[1] Y. Volkov,[2] J. Park,[3] R. Wange,[4] D. Kelleher,[2] A. Long[1]; [1]Biochemistry, Royal College of Surgeons in Ireland, Dublin, Ireland, [2]Clinical Medicine, Trinity College, Dublin, Ireland, [3]Pharmacology, Chungnam National University, Taejon, Republic of Korea, [4]Gerontology Research Centre, National Institute of Health, Baltimore, MD
The Jurkat leukemic T cell line is deficient in the expression of the lipid phosphatase PTEN, the loss of which results in unopposed PI3-kinase activity and therefore high basal levels of 3'-phosphoinositides such as PtdIns(3,4)$P_2$ and PtdIns(3,4,5)$P_3$. As a consequence of this deficiency, kinases that are dependent on 3'-phosphoinositides such as PKB/Akt are constitutively activated and phosphorylated (including the activation-loop residue Thr308). The PKC family of kinases also possess a conserved activation-loop residue analogous to Thr308 of PKB/Akt, and similar to PKB/Akt, this site is phosphorylated by the 3'-phosphoinositide-dependent protein kinase-1 (PDK-1). In this study we have addressed whether unopposed PI3-kinase activity in Jurkat T cells also affects PKC phosphorylation at the activation-loop site. We demonstrate that reducing the level of 3'-phosphoinositides in Jurkat cells with pharmacological inhibitors of PI3-kinase or expression of PTEN reduces PKB/Akt phosphorylation at Thr308 but has no effect on the corresponding activation-loop phosphorylation of PKC isoforms. We also demonstrate that the dephosphorylation of PKB/Akt at Thr308 is dependent on the activity of PP1/PP2a phosphatases and is not a consequence of reduced PDK-1 activity. We conclude therefore that the PI3-kinase/PTEN pathway does not affect PKC activation-loop phosphorylation in T cells.

## Cell Culture (2808-2825)

### Purification and Characterization of Laminin-5 from Conditioned Media of Cultured Human Foreskin Fibroblasts

S. O'Malley, K. Kingsley; Biomedical Sciences, University of Nevada, Las Vegas School of Dental Medicine, Las Vegas, NV
Laminins are extracellular proteins primarily present at the basement membrane, where they provide structural stability and exert many biological functions, including cell adhesion, migration, proliferation and differentiation, and may also be involved in angiogenesis and tumor invasion. We screened several human cell lines obtained from American Type Culture Collection for the expression of human laminin-5 subunits (alpha3, beta3, and gamma2) using monoclonal antibodies specific for the gamma2 subunit (Chemicon mAb. 19562, mAb. 1947, mAb. 1949). Monoclonal antibodies for the gamma2 subunit were utilized for affinity purification as the alpha3 subunit is not exclusive to laminin-5, but rather is found in other laminin isoforms, such as laminin-6 and laminin-7. One cell line, Human Foreskin Fibroblast (hFF) cell line CRL-1634 Hs27, obtained from American Type Culture Collection, expressed measurable amounts of laminin-5 into the cultured media one day post confluence, which was recovered after centrifugation and subsequent fractionation. These results are being verified by RT-PCR and Western analysis. These results suggest one possible, alternative source and method of laminin-5 purification from the conditioned media of this cell line.

2809

**Ceramide Induces Morphological Changes and Necrosis in Tumour Cells from Human Cervix-uterine Cancer: Possible Molecules Involved**

G. Gutiérrez Iglesias,[1,2] A. Parra Barrera,[1] E. Reyes Maldonado,[3] R. López-Marure[2]; [1]Urology, Hospital Infantil de Mexico, Mexico D.F., Mexico, [2]Physiology, National Institute of Cardiology, Mexico D.F., Mexico, [3]Morphology, Instituto Politecnico Nacional, Mexico D.F., Mexico

Ceramide is a potentially important mediator of several agents that affect cell growth, viability, and apoptotic and no apoptotic death. This lipid is derived from sphingomyelin hydrolysis, or produced by the de novo synthesis. We previously have demonstrated that ceramide inhibits the proliferation and induces death like necrosis of cervix-uterine cancer cells (CaCu) at a concentration of 3 μM, but it does not inhibit the proliferation of normal cells, although the mechanism for that is unknown. In this work, we evaluated the antiproliferative effect of ceramide C-6, the morphological changes and possible molecules that might be involved in the ceramide-induced death in three lines from CaCu. Morphological changes were evaluated with Papanicolaou staining, NFκB translocation was performed by electrophoretic mobility shift assay, reactive oxygen species (ROS) was determined by flow cytometry, and glutation production was quantified by HPLC. Ceramide C-6 induced morphological changes in cytoplasm and nuclei like necrosis. The translocation of NFκB and the production of ROS were increased by ceramide C-6. Finally, low levels of glutation were detected in the cells treated with ceramide C-6. These results indicate that ROS, NFkB and glutation are involved in ceramide C-6-induced necrotic death.

**Experiences of EBV Transformation for Human Blood Cell Biobank**

I. Chang,[1] J. Wu,[2] H. Lu,[1] H. Ko,[1] J. Kuo,[1] C. Wang,[1] S. Hwang[1]; [1]Bioresource Collection and Research Cneter, Food Industry Research and Development Institute, Hsinchu, Taiwan Republic of China, [2]Institute of Biomedical Sciences, Taipei, Taiwan Republic of China

The cell laboratory of Bioresource Collection and Research Center (BCRC) in Food Industrial Research and Development Institute joined to establish the Taiwan Han Chinese Cell and DNA bank that was initiated by the Institute of Biomedical Sciences, Academia Sinica, Taiwan in 2003. This cell-based genetic bank will be a medical platform for exploring in genetic disease research especially more frequent occurrence in Chinese. In this project, blood samples collected all over Taiwan were sent to BCRC for B cell immortalization. Briefly, mononuclear cells are isolated from blood samples by ficoll density gradient centrifugation and incubated with Epstein-Barr virus for 1 hour. After remove of Epstein-Barr virus, the infected lymphocytes are incubated at 37°C, 5% $CO_2$ atmosphere. The transformed cell lines will be successfully established during 8-10 weeks growth. After stringent quality control, including mycoplasma and microbial contamination detection, the cells will be stored in liquid nitrogen tank with computerized data management. The host genomic information will be preserved in these transformed cells forever. To date, more than 4000 human EBV-transformed cell lines have been established and preserved. The success rate for cell line establishment was 94%. In addition to this, we found that several factors including transport time of blood sample, density and viability of isolated mononuclear cells would have influence on transformation time required by B cell. A systematic data-retrieving intranet and barcode system were also established.

**Cyclic Mechanical Strain Inhibits the Proliferation of Human Dermal Fibroblasts**

W. Durante, D. Ensenat, K. J. Peyton; Medicine, Baylor College of Medicine, Houston, TX

Fibroblasts play a critical role in wound healing by depositing extracellular matrix needed to restore structure and function to the injured tissue. Recent studies suggest that mechanical stress may enhance wound healing by stimulating the production of extracellular matrix from fibroblasts. In the present study, we investigated whether cyclic mechanical strain also influences the growth of fibroblasts. Cultured human dermal fibroblasts were plated onto pronectin or collagen-coated Bioflex plates and subjected to a physiologically relevant level of cyclic strain (6% at 1 hertz) using the Flexercell 3000 Strain Unit. Treatment of fibroblasts with fetal bovine serum (10%) under static conditions for 7 days stimulated a time-dependent increase in cell number. However, the application of cyclic strain markedly reduced the growth rate of fibroblasts. A significant decrease in the number of fibroblasts was first noted after 2 days and this became more pronounced after 7 days of cyclic strain. The cyclic strain-mediated decrease in fibroblast growth was observed in both pronectin- and collagen-coated plates, and was not due to cell detachment. Cyclic strain inhibited serum-stimulated DNA synthesis. In addition, flow cytometric experiments revealed that cyclic strain decreased the fraction of cells in S phase and increased the percentage of cells in the $G_0/G_1$ phase of the cell cycle. In conclusion, the present study demonstrates that cyclic mechanical strain (6% at 1 hertz) inhibits fibroblast proliferation by arresting them in the $G_0/G_1$ phase of the cell cycle. The ability of cyclic strain to inhibit fibroblast proliferation while stimulating collagen synthesis may possibly affect wound healing by focusing cellular resources and activity on matrix deposition.

**Characterization of a Three-dimensional Culture of Cardiomyocytes: From the Cell to the Microtissue**

L. R. Garzoni,[1] M. D. Rossi,[2] V. P. Guarani,[2] A. D. N. Barros,[2] C. M. Takiya,[2] A. R. Nogueira,[1] D. Adesse,[1] M. N. L. Meirelles,[1] R. Borojevic[2]; [1]Department of Ultra-structure and Cell Biology-IOC, Fiocruz, Rio de Janeiro, Brazil, [2]Department of Histology and Embryology, ICB, UFRJ, Rio de Janeiro, Brazil

Strong differences on cells`s behaviour has been reported when comparing monolayer (2D) and threedimensional (3D) cell culture systems. In a 3D microenvironment the cells shows many aspects observed on tissue *in vivo* as for example the gene-function, extracellular matrix, growth factor production, responses to drug treatment and others. Here we presented a functional 3D cardiac microtissue from mono-dispersed expanded cell culture *in vitro*. Mouse embryos cardiomyocytes obtained from primary culture using trypsin and collagenase were maintained in DMEM with CFS and $CaCl_2$ at 37° C in 5% of $CO_2$ atmosphere. Utilizing a gravity-enforced system with a non adherent substrate, the isolated cells re-aggregated as spheroids and assembled in microtissues after 4 days. There was a direct correlation between the number of cells (3,000-25,000 cells) and the microtissue`s size (150-400μm). Most of microtissues produced with 3,000-6,000 cells were able to contract for more than 45 days and a time elapsed reduction on diameter and on the contractile activity was observed on microtissues with 25,000 cells. After ten days of culture, the immunofluorescence analyses showed extracellular matrix compounds as fibronectin, laminin and collagen IV. Most of cells consisted of cardiomyocytes, once they were positive for tropomyosin and conexin 43. The ultrastructural analyses showed cells presenting high number of

mitochondrias near of myofibrils, sarcoplasmic reticulum and intercalar discs. Other cellular types as fibroblasts were observed on the microtissues. Our results demonstrate that is possible to produce a functional cardiac microtissues *in vitro*, presenting cells highly differentiated, extracellular matrix and a long term contractile activity. We believe that it can be a powerful skill for studies on distinct fields of the basic and applied cardiovascular research including bioengineering, cellular migration analyses, parasites-host microtissues interactions, chemotherapy, angiogenesis, inflammation and cellular therapy.

**Glycosylation of Tyrosinase is Necessary for It to Enter the MHC Class I Processing and Presentation Pathway**

M. Ostankovitch,[1] M. Van Lith-Altrich,[1] V. Robilla,[1] D. N. Hebert,[2] V. H. Engelhard[1]; [1]University of Virginia, Charlottesville, VA, [2]Departement of Biochemistry and Molecular Biology, University of Massachusetts, Amherst, MA

Tyrosinase derived peptides bound to Major Histocompatibility Complex (MHC) class I molecules are recognized at the surface of melanomas by T lymphocytes. It has previously been proposed that processing and presentation of a $Tyr_{369}$ antigenic peptide containing a Asp in place of Asn at position 371 involves translation of tyrosinase in the endoplasmic reticulum (ER), export of full-length glycosylated tyrosinase to the cytosol, deglycosylation and deamidation in the cytosol by peptide N-glycanase (PNGase), degradation by the proteasome and retransport of deamidated peptides into the ER for association with MHC class I. The present work sought to provide greater insight into the identity of tyrosinase degradation intermediates and the role of glycosylation in protein degradation and antigen presentation. In melanoma cells treated with epoxomicin, proteasome substrates derived from tyrosinase were found as deglycosylated but also as unglycosylated forms in the membrane and in the cytosol. Glycosylated intermediates also were identified, but only when both proteasomes and PNGase activity were blocked. These results demonstrated that in addition to deglycosylated tyrosinase, unglycosylated and misfolded glycosylated tyrosinase molecules are also proteasome substrates. Little or no Asn-containing $Tyr_{369}$ epitope was presented on cells expressing either wild type or mutated unglycosylated tyrosinase, demonstrating the necessity of glycosylation for appropriate processing. Conversely, inhibition of PNGase blocked presentation of Asp-containing $Tyr_{369}$, demonstrating that deglycosylation was necessary for either deamidation or appropriate degradation. However, we found that inhibition of PNGase had no effect on epitope presentation in cells expressing an N371D tyrosinase mutant. These results demonstrate that glycosylation sites outside of the epitope are required for appropriate degradation of tyrosinase leading to epitope presentation.

**A Short-term *in vitro* Assay for Anti-tumor Promoters Using Human Lymphoblastoid Cells Latently Infected Epstein-barr Virus**

H. Tokuda,[1] T. Konoshima,[2] M. Takasaki,[2] J. Takayasu,[1] H. Nishino,[1] A. Iida[3]; [1]Department of Molecular Biochemistry, Kyoto Prefectural University of Medicine, Kyoto, Japan, [2]Chiba Institute of Technology, Chiba, Japan, [3]Department of Pharmaceutical Sciences, Kyoto University, Kyoto, Japan

The idea neoplastic development consists of at least two qualitatively different stages has gained general acceptance. The second, promotion stage has been suggested to be more critical in the development of human cancer that the first, initiation stage. Most tumor promoters do not bind DNA and are negative in Ames mutagenicity assay, whereas initiating carcinogenesis usually meet one or both these criteria. Recently, TPA only those other phorbol esters with tumor promoting activity and fatty acid, n-butyric acid have been found to induced the viral cyclin latently infected Epstein-Barr virus(EBV) genome carrying cells. We have suggested that a system consisting of EBV nonproducer Raji cells and each concentration of anti-tumor promoters, chemopreventive agents might be useful as a practical screening method of certain type of chemopreventive agents, anti-tumor promoters in our eatable and herbal plants. Interestingly, EBV-early antigen(EBV-EA) activation induced by TPA, can be diminished by the additional of chemopreventive agents, Brazilian herbal medicine, food colorants and vitamins to adequate culture medium. In this studies, we tried to arrange for the useful method of screening and detection of chemopreventive agents.

2815

**Assessment of Swine Sperm Quality after *in Vitro* Mycotoxin Zearalenone and Its Derivatives Exposure**

E. Benzoni,[1] F. Minervini,[2] F. Fornelli,[2] A. Giannoccaro,[2] M. Faustini,[1] R. Grande,[1] C. Mossali,[1] E. Munari,[1] M. Torre,[3] S. Villani,[3] V. Russo,[1] D. Vigo[1]; [1]Department of Veterinary Science and Technologies for Food Safety, University of Milan, Faculty of Veterinary Medicine, Milan, Italy, [2]Institute of Sciences of Food Production (ISPA), CNR, Bari, Italy, [3]Department of Chemical Pharmacology, University of Pavia, Pavia, Italy

Several chemicals out of different classes are capable of activating or blocking hormone receptor, in particular estrogen or androgen receptor. Particularly xenoestrogens (natural and synthetic products) can be present in foods and could induce modifications of reproductive functions in human and animals. Zearalenone (ZEA) and its derivatives (α and β-zearalenol) are fungal metabolites produced by *Fusarium* species frequent contaminants in cereals. For their known estrogenic activity in farm animals, we investigated the swine semen quality after *in vitro* exposure to ZEA and its derivatives (α and β-ZEA) by the assessment of viability (Trypan blue dye exclusion), motility (CASA), stability of chromatin structure (SCSA) and DNA fragmentation (Apo-BrdU). After 24h, all mycotoxins, at concentrations ranging from $10^{-6}$ to $10^{-4}$µM, modified the semen quality with different effects. ZEA induced DNA double-strand breaks (54%; $p< 0.05$), evaluated by flow cytometry, α-ZEA modified the sperm chromatin structure (64%; $p<0.001$), and β-ZEA provoked modification of kinetic parameters. Influences on viability, evaluated by membrane damage, were induced by higher concentrations ($10^{-2}$ to 1 µM) of mycotoxins. After 48 h of incubation, β-ZEA showed apoptosis induction (more than 50%) and increased instability of chromatin (14%) at low levels ($10^{-8}$- $10^{-6}$ µM). This is the first report on toxicity induced by ZEA and its derivatives in swine spermatozoa. Exposure to ZEA and its derivatives could influence sperm quality, considering the widespread occurrence of mycotoxins in cereals and the low concentrations found to be active in this study.

2816

**Reproductive Efficiency of Encapsulated Boar Semen for Artificial Insemination**

D. Vigo,[1] A. Riccardi,[1] S. Scocca,[1] M. Faustini,[1] S. Villani,[2] U. Conte,[3] V. Russo,[1] G. Ricevuti,[3] L. Sesso,[1] E. Benzoni,[1] M. Torre[3]; [1]Department of Veterinary Science and Technologies for Food Safety, University of Milan, Faculty of Veterinary Medicine, Milan, Italy, [2]Dipartimento di Scienze Sanitarie Applicate e Psicocomportamentali, Università di Pavia, Pavia, Italy, [3]Dipartimento di Chimica Farmaceutica, Università di Pavia, Pavia, Italy

Barium alginate controlled release capsules containing swine semen were developed to improve the preservation timespan of the spermatic cells and maximize the efficiency of a single artificial insemination procedure. Aim of this work was to evaluate the efficiency of this new technique in a swine herd: 2929 sows were artificially inseminated with a conventional dose (60.8% double/triple inseminations, control), or a single artificial insemination with controlled release capsules (39.2%) during the period autumn 2003/autumn 2004 (winter,15.7%; spring, 19.7%; summer, 20.7%; autumn, 43.8%). A multiple logistic regression model was applied, using pregnancy diagnosis and parturition rate in positively diagnosed sows as outcome variable. As independent variables, treatment, season and treatment x season interaction were considered. Pregnancy probability increase of 25% following capsule treatment with respect to conventional insemination (Odds Ratio =1.25, 95%CI=0.87-1.81, P=n.s.). Parturition probability increases of 69% (Odds Ratio =1.69, 95%CI=1.00-2.88, P<0.05) after capsule insemination with respect to control sows. Therefore, a single artificial insemination with controlled release capsules allows the same fecundity yields and higher parturition frequencies when compared to conventional artificial insemination procedures.

2817

**Screening Method of Short Term *in vitro* Assay For Nitric Oxide Scavenger Reagents**

H. Tokuda,[1] T. Akihisa,[2] R. Tanaka,[3] J. Takayasu,[1] F. Enjo,[1] H. Nishino[1]; [1]Department of Molecular Biochemistry, Kyoto Prefectural University of Medicine, Kyoto, Japan, [2]College of Science, Nihon Universty, Tokyo, Japan, [3]Department of Medicinal Chemistry, Osaka University of Pharmaceutical Sciences, Osaka, Japan

The important physiological roles of nitric oxide(NO) suggest that donation of NO may be useful for the treatment of several states, and bioactivity of NO was indistinguishable from that of endothelium derived relaxing factor. Some pharmacological NO donors, that they may serve as natural strange and transport forms for bioregulatory NO and currently in use for the biological generation of NO. Other important feature of NO is a mutagenic compounds that can cause mutations in bacteria as well as chromosomal aberrations in rat primary lung cells and it is best known as a toxic reactive free radicals. NO is emerging as an important mediator of cytotoxicity and/or mutagenicity. In order to develop a possible *in vitro* screening model of scavenger against NO, we begin to explore the potential role of treatment scavenging of malignant NO production. Chang liver cells (human derived) from in DMEM were cultured for 3 days before treatment. NOR1(NO donor, (+-) -(E)-methyl-2-[(E) -hydroxyimin]-5-nitro-6-methoxy-3-hexenamide ) was added into culture dish and incubated for 1 h under $CO_2$ incubator as control. For screening assay, test samples to culture dish were observed under light-microscopy (x 100) without stained. All observed cells count for more than 250. The inhibitory ratio was then calculated for arrangement of data. Anti-oxidative reagents tested showed moderate inhibitory effects on NOR1 activation. In present paper, we designed a short-term *in vitro* assay for detecting NO scavengers, and test is simple to perform, reproducible and should be applicable for mass-screeni g of useful substances in our environment.

2818

**Cell Culture on Nanopillar Sheet - Analysis of Hela Cells Cultured on Nanopillar Sheet**

S. Nomura,[1] R. Nagano,[1] H. Kojima,[1] Y. Ohyabu,[1] K. Kuwabara,[2] A. Miyauchi,[2] T. Uemura[1]; [1]Nanotechnology Research Institute, AIST(Natl Inst. Adv. Industr. Sci. Technol.), Tsukuba, Ibaraki, Japan, [2]Materials Research Laboratory, Hitachi Ltd., Hitachi, Japan

We have succeeded in forming high-aspect-ratio structures (nanopillars) by nanoimprinting.. In this paper, the application of the nanopillar sheet as a new type of cell culture dish is introduced. Polystyrene films with the thickness of 1.0 μm were spin-coated onto glass substrates. By pressing the nano-mold made of silicon wafer onto the films at 150 $^{o}$Cand releasing the nano-mold from the films at room temperature, nanopillar structures were formed. The diameters of the nanopillars ranged between 0.16 μm and 1.0 μm according to the patterns on the nano-molds. The height of nanopillars was 1.0 μm. HeLa cells were seeded at $1.0x10^5$ cells/$cm^2$ on the nanopillar sheet and cultured for 5 days in DMEM containing 10% FBS at 37$^{o}$C in a humidified atmosphere of 95% air with 5% $CO_2$ . Analysis were performed by cell counting, morphological observation using a phase contrast microscope and immuno-histochemical observation of F-actin and vinculin on the cells using rhodamine-phalloidin and anti vinculin monoclonal antibody, respectively. The cells cultured on nanopillar sheets were not spread, but adhered only on the head of the pillars, keeping their original round shape. They grew and proliferated on the pillars. Since the adhered area of the cells to materials was small, the cells were easily removed from the sheet and collected just only by pipetting without conventional trypsinization method. The analysis of the HeLa cells cultured on the nanopillar sheets suggested that the nanopillar sheets are able to provide a new type of cell culture dish. A damage free subculture by enzymes is possible and the cells on the sheets proliferated in the same way as on the flat dishes with different manner of adhesion to the materials.

**The Effect of Modified Media on the Expression of α-SMA and ALDH3A1 in Human Corneal Stromal Cells**

S. Rodenberg,[1] A. Tan,[1] A. Voorhees,[1] M. K. Bechtel,[1] E. J. Orwin[2]; [1]Biology, Harvey Mudd College, Claremont, CA, [2]Biology and Engineering, Harvey Mudd College, Claremont, CA

Normal human corneal stroma is composed primarily of quiescent keratocytes, characterized by expression of two water soluble proteins, aldehyde dehydrogenase 3A1 (ALDH3A1) and transketolase (TKT), which assist in corneal transparency. These cells are capable of differentiating into repair fibroblasts when injured or when grown in monolayer culture. Repair fibroblasts can be stimulated to reversibly differentiate into myofibroblasts (wound healing phenotype), characterized by increased α-smooth muscle actin (α-SMA) expression. When quiescent keratocytes become either of these cell types, there is a loss of transparency that may be attributed to the production of α-SMA, as well as the disruption of the matrix structure, resulting in an opaque cornea. The objective of this study was to determine how various culture conditions may affect the expression of ALDH3A1 and α-SMA in human corneal stromal cells. Western blot and immunofluorescence analysis demonstrated that media supplemented with transforming growth factor-β (TGF-β) increased α-SMA protein levels in these cells when cultured in monolayer. Quantitative real-time PCR analysis demonstrated that TGF-β increased α-SMA mRNA and decreased ALDH3A1 mRNA expression. Analysis via immunofluorescence confocal microscopy indicated that serum-free media supplemented with fibroblast growth factor (FGF) and heparin maintained α-SMA protein levels while decreasing ALDH3A1 protein levels. In addition, serum-free media alone was found to upregulate α-SMA and ALDH3A1 after seven days of treatment, while at eleven days α-SMA expression was found to return to normal. From these results we hypothesize that serum-free media supplemented with FGF and heparin induces differentiation of myofibroblasts to repair fibroblasts, and that serum-free media alone induces repair fibroblasts to revert to the quiescent keratocyte phenotype. Continuing studies will examine time

dependence of treatment with serum-free medium on α-SMA and ALDH3A1 protein and mRNA expression.

2820

**Continuous Cell Culture and Analysis in a Microfluidic Microbioreactor**

T. A. Holland,[1] E. Behravesh,[1] H. Sung,[1] K. Zygourakis,[2] S. R. Gonda[3]; [1]Division of Space Life Sciences, Universities Space and Research Association, Houston, TX, [2]Department of Chemical Engineering, Rice University, Houston, TX, [3]Advanced Biotechnology Section, NASA Johnson Space Center, Houston, TX

For many applications, it is desirable to sample cultured cells and medium over prolonged periods to examine the effects of a given factor on cell function. Many microbioreactor systems currently provide for continuous media sampling but, unfortunately, require experiment termination and reactor disassembly for cell sampling. The current work describes a microfluidic microbioreactor system developed in our laboratory, and a method for real-time cell sampling that eliminates the need for cell passaging or bioreactor disassembly. The microfluidic microbioreactor contains an annular designed chamber that is 3.30mm x 30.0mm x 0.25 mm (w x l x h), with multiple inlet and exit lines, and a transparent polycarbonate disk for light microscope monitoring. In this work, we investigated the effect of surface substratum and shear stress on L1210 cell adhesion by step-wise increases in flow rates at 10 min intervals to develop shear stresses of 0.13 to 0.45 dyne/cm2, followed by reversal of this trend with stepwise decreases at 10 min intervals. In addition, we examined the effect of alterations in shear stress on the size distribution of L1210 cells detached from the micro-culture chamber. Our results showed that low shear stresses (0.09-0.13 dyne/cm2) selectively detached daughter cells from a monolayer of exponentially dividing L1210 cells. Alternatively, higher shear stresses (0.22-0.45 dyne/cm2) were shown to detach a mixed population of both daughter and parent cells, while maintaining a monolayer of adherent cells in the micro-culture chamber. Accordingly, this microbioreactor design provides a cost and space efficient method of assessing the potential effects of numerous environment factors on cell behavior through controlled, real-time cell and media sampling. Supported by funding from NASA.

2821

**Mineralization Induced by Micro-Sized Pillars**

J. Justesen,[1,2] A. Fuechtbauer,[1] M. Duch,[1,2] M. Foss,[3,2] L. Andersen,[3,2] O. Hansen,[4] J. Chevallier,[3] F. Besenbacher,[3,2] F. Pedersen[1,2]; [1]Department of Molecular Biology, University of Aarhus, Aarhus C, Denmark, [2]Interdisciplinary Nanoscience Center, University of Aarhus, Aarhus C, Denmark, [3]Department of Physcics and Astronomy, University of Aarhus, Aarhus C, Denmark, [4]Department of Micro and Nanotechnology, Technical University of Denmark, Copenhagen, Denmark

Fast and stable biointegration of bone implants is important for the health and well being of patients after orthopaedic surgery. In order to identify promising surfaces, we have screened wafers with an array of multiple microstructures for mineralization properties. Silicon wafers with microstructures were coated with 250 nm tantalum. A total of 15 structures were designed on wafers with 5 different depths. MC3T3-E1 (murine preosteoblasts) were seeded onto the wafers in growth medium and stained for alkaline phosphatase after 1 and 2 weeks. Cells seeded in medium containing 50 μg/ml ascorbic acid and 10 mM β-glycerophosphate were stained with Alizarin Red after 3½ weeks for mineralisation. For actin fibre visualisation, cells were grown for 48 hrs, fixed, and stained with phalloidine. Alizarin Red staining on wafers, visualised that mineralization was enhanced by the pillar-structure D1. Neither any other structure nor the slightly different pillar-structure D2 showed enhanced staining. Mineralization studies on the different depths illustrated a decrease in the staining intensity for D1, as compared to the other structures, with decreasing depth. In contrast, no difference between the microstructures was observed for the alkaline phosphatase staining. Elongated actin fibres was observed for cells grown on flat structures (reference) and D2. However, on the D1 structure, the actin fibres were deposited around the pillars and the shape of the cells were highly influenced by the pattern of the structure. In conclusion, the structure and depth of the growth surface affect the differentiation of the cells. MC3T3-E1 cells show increased mineralization on D1, a process affected by the depth of the structure. This increase in mineralization may be connected with the observed early changes in the cytoskeleton of the cells.

2823

**Establishing a Cell Biology Model of Suppression in Epithelial Ovarian Cancer**

D. Dafou,[1] D. A. Trott,[2] R. F. Newbold,[3] J. Timms,[4] S. J. Ramus,[1] I. J. Jacobs,[1] S. A. Gayther[1]; [1]Gynaecological Oncology, UCL, Institute of Women's Health, United Kingdom, [2]Transplant Immunology, Imperial College London, National Heart and Lung Institute, United Kingdom, [3]Life Sciences, Brunel University, Institute of Cancer Genetics and Pharmacogenomics, United Kingdom, [4]Biochemistry, UCL, Ludwig Institute, United Kingdom

Epithelial ovarian cancer is the leading cause of death from gynaecological malignancy worldwide. Identifying molecular markers of disease may provide novel approaches to screening and could enable targeted treatment and/or lead to the design of novel therapies. Unfortunately, the molecular genetic events that underlie the initiation and progression of ovarian cancer are poorly understood. Previously141 primary epithelial ovarian tumours were analysed using metaphase CGH analysis to identify common regions of chromosome deletions that may indicate the presence of tumour and/or metastasis suppressor genes. Complete or interstitial deletions of chromosomes 4, 5, 6, 13, 14, 15, 18 and 21 occurred in 36-68 % of all tumours analysed, suggesting that these chromosomes may harbour suppressor gene(s). Subsequently, we have used the microcell mediated chromosome transfer (MMCT) to introduce these chromosomes into EOC cell lines in order to assess the their functional significance. *In vitro* and *in vivo* data indicate that chromosomes 5, 6 and 18 have a strong negative effect on ovarian cancer cell growth and anchorage independent colony formation. This suggests these chromosomes contain one or more genes that behave as ovarian cancer tumour and/or metastasis suppressor genes. We have mapped candidate gene locations on chromosome 18 by microsatellite repeat analysis. We have analysed RNA expression array data and 2-Dimension Differential Gel Electrophoresis data from hybrids, parentals and revertant cell lines. In doing so, we aim to identify genes and biological pathways that represent new therapeutic targets for EOC treatment.

2824

**Novel Three-Dimensional Cell Scaffold Allows Non-enzymatic Cell Release**

E. C. Elliott,[1] S. L. Snabes,[2] J. Bang,[1] S. Wang,[3] N. Kotov[1]; [1]Chemical Engineering, University of Michigan, Ann Arbor, MI, [2]Research, Aastrom Biosciences, Ann Arbor, MI, [3]Nomadics Inc., Stillwater, OK

We recently reported a new type of three-dimensional scaffold with inverted-colloidal-crystal geometry. Here we introduce a positively charged super absorbent polymeric hydrogel matrix. The cationic hydrogel is based on a crosslinked copolymer network consisting of N, N-dimethylacrlyamide and (3-Acrylamidopropyl)trimethyl-ammonium chloride. The topography of the scaffold consists of uniform spherical cavities interconnected by a network of channels with openings ranging from 104 to 300 µm. Scanning electron and confocal microscopy have confirmed that the cationic nature of the matrix allows for remarkable cell adhesion and nesting throughout the hydrophilic three-dimensional matrix without using costly or time consuming coating techniques. Furthermore, by adjusting the media multivalent ion concentration, we are able to dynamically control and manipulate swelling equilibrium and the size of the interconnecting openings during cell incubation. With up to a 10-fold increase in swelling equilibrium we are able to reversibly expand and collapse the interconnected cavities from 100-600 µm in size. Such action provides a reagent or enzyme free method of cell release from our matrix. This engineered scaffold possesses desirable optical, functional, and mechanical properties that can also facilitate tissue regeneration, continuous high-resolution optical monitoring of cell proliferation and cell-cell interaction. Biocompatibility has been demonstrated with HS-5, MSC, and OP9 cell cultures. When cultured with various feeder layers, cells appear to attach and expand normally. Cytospins, cell and viability counts, confocal microscopy, SEM and flow cytometry confirm that morphology and function are preserved during culture and harvest. This functionality, ease of production, unique 3D structure, biocompatibility, optical transparency, and the non-enzymatic alternative for cell harvest combine to make this new type of hydrogel scaffold advantageous for today's demanding cell and tissue culture field.

### Development of an Avian Expression System for Chicken 1,25$D_3$-MARRS

S. E. Safford; Biology, Lincoln University, Lincoln University, PA

1,25$D_3$-MARRS (Membrane Associated Rapid Response to Steroids)/ERp57 is a recently identified protein mediating rapid ion transport responses to vitamin D hormone, 1,25$D_3$, in chicken intestine. To acquire the full length avian protein for structural and functional analysis, we wished to express the protein in a recombinant system. To date, avian codon bias prevented efficient expression of the chicken protein in a variety of mammalian expression systems lacking essential tRNAs. To solve this problem, we transfected a plasmid encoding full length chicken 1,25$D_3$-MARRS linked to a myc-his tag at the C-terminus into a quail sarcoma (QT-6) cell line. The protein encoded by the transfected plasmid was recognized by a commercial anti-myc monoclonal antibody, and was slightly larger than endogenous 1,25$D_3$-MARRS expressed by the quail cells. Both proteins were recognized by an antibody raised against the N-terminus of chicken 1,25$D_3$-MARRS purified from basolateral membrane (Ab099). Rat intestinal epithelial cells (IEC-6 and IEC-18) transfected with the chicken 1,25$D_3$-MARRS plasmid failed to express a protein recognized by the anti-myc antibody. However, endogenous rat 1,25$D_3$-MARRS was recognized by a commercial mammalian antibody to the C-terminus of ERp57. Rat 1,25$D_3$-MARRS migrated slower in SDS-PAGE gels than did endogenous quail 1,25$D_3$-MARRS. We conclude that the quail model is superior for expression of the 1,25D3-MARRS protein for investigation of cell surface expression of 1,25$D_3$-MARRS, for studies of cell trafficking of 1,25$D_3$-MARRS under unstimulated and 1,25$D_3$ stimulated conditions, and for pharmacological study of binding of 1,25$D_3$ to the expressed 1,25$D_3$-MARRS protein.

## Cancer IV (2826-2846)

2826

### HMG-CoA Reductase is Required for the Initiation and Maintenance of MYC Induced Tumorigenesis

C. M. Shachaf,[1] O. D. Perez,[2] S. Youssef,[3] M. Chang,[1] S. V. Elchuri,[1] M. J. Goldstein,[3] L. Steinman,[3] G. P. Nolan,[2] D. W. Felsher[1]; [1]Medicine/Oncology, Stanford University, Stanford, CA, [2]Microbiology & Immunology, The Baxter Laboratory for Genetic Pharmacology, Stanford University, Stanford, CA, [3]Neurology and Neurological Sciences, Stanford University, Stanford, CA

The best therapeutic targets for cancer may not be the immediate molecular underpinnings of tumorigenesis, but key nodal proteins of metabolic signaling pathways. The 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase is a critical enzyme in the mevalonate pathway, required for the synthesis of several important bioactive compounds. We demonstrate in a defined model of oncogene induced tumorigenesis that the inhibition of HMG-CoA reductase was sufficient to not only reverse established tumors, but to prevent MYC induced tumor development. Even briefly treating adult transgenic mice with the inhibitor of HMG-CoA reductase, atorvastatin prevented tumor onset. Bone marrow from tumor affected animals could be purged by *in vitro* treatment with atorvastatin and used to reconstitute the hematopoietic system in lethally irradiated mice. To account for these findings, we defined the phospho-protein profiles associated with the inhibition of HMG-CoA reductase by treatment with atorvastatin. Atorvastatin inactivated the MYC oncogene through the inhibition of Ras and ERK1/2, resulting in the prevention of MYC phosphorylation and activation. Treatment with the down-stream metabolite of HMG-CoA reductase, mevalonate, prevented statins from reversing the phospho-protein signature and tumorigenesis associated with MYC. Also, RNAi directed at HMG-CoA reductase was alone sufficient to abrogate the neoplastic properties of MYC induced tumors. Thus, HMG-CoA reductase appears to be an example of a key regulatory protein required for both tumor initiation and maintenance of tumors induced through MYC overexpression.

### Effect of MUC-1 Expression on EGFR Endocytosis and Degradation in Human Breast Cancer Cell Lines

R. M. El Bejjani; Molecular and Cellular Biology, The University of Arizona, Tucson, AZ

EGFR overexpression and amplification have been tied to tumor formation in the mammary gland. Overexpression of MUC1 in the breast induces the formation of tumors that are able to metastasize. The mechanism by which MUC1 causes the onset of tumor formation is unknown, but studies show that MUC1 can modulate EGFR signaling. Our preliminary data shows that MUC1 and EGFR interact in breast cancer cells but not in the normal polarized mammary epithelium. Data generated in BT20 human breast cancer cell lines shows that MUC1 and EGFR interact in these cells only when treated with the EGFR ligand, EGF. Upon ligand binding, EGFR is typically endocytosed, where it is either degraded or recycled. We show that MUC1 knockdown in BT20 cells induces faster degradation of ligand-bound EGFR compared to MUC1-expressing cells. Localization of endocytosed EGFR demonstrates that it localizes to a perinuclear compartment of unknown identity where internalized MUC1 resides. To determine whether MUC1 affects the degradation of surface EGFR or previously internalized EGFR, we performed biotinylation of surface

proteins. These experiments show that MUC1 affects the degradation of ligand-bound EGFR at the cell surface. Future experiments will examine the non-clathrin mediated endocytosis pathways in order to determine the nature of the observed perinuclear organelle. We will also investigate how MUC1 overexpression affects Cbl, Grb2 and CALM association with EGFR during endocytosis (key proteins in the endocytosis and degradation of EGFR). Finally, we will investigate the effect of MUC1 overexpression and knockdown on the tumorigenic potential of human breast cancer cell lines and in mouse models.

**Effects of hTERT on Metal-induced Changes in Clonogenic Survival**

A. Glaviano,[1] D. M. Baird,[2] E. Cabuy,[3] M. A. Rubio,[4] P. Slijepcevic,[5] C. Mothersill,[6] F. Lyng,[6] C. P. Case[1]; [1]Dpt. of Orthopaedic Surgery, University of Bristol, Bristol, United Kingdom, [2]Department of Pathology, University of Cardiff, Cardiff, United Kingdom, [3]Brunel Institute of Cancer genetics and Pharmacogenomics, University of Brunel, London, United Kingdom, [4]Lawrence Berkeley National Laboratory, University of Berkeley, Berkeley, CA, [5]Brunel institute of Cancer Genetics and Pharmacogenomics, University of Brunel, London, United Kingdom, [6]Radiation and Environmental Science Centre, Dublin Institute of Technology, Dublin, Ireland

Genomic instability is considered to be an important component in carcinogenesis. Cr(VI) and V(V) can initiate long term genomic instability in generations of daughter cells from parent human primary fibroblasts exposed to metal ions for only 24 hours. This is regulated by telomerase. In wild type hTERT- cells there is a persistent increase of dicentric chromosomes. In hTERT+ cells (after ectopic transfection) there is a persistent increase in tetraploidy. In this study we have examined the clonogenic survival of these cells using the clonogenic assay. The telomere lengths were measured with telomere flow FISH and STELLA, the cell cycle with flow cytometry and the degree of senescence with B Galactosidase staining. Exposure to metals caused a persistent and dose related reduction in clonogenic survival in hTERT- cells up to 30 days post exposure. This was not seen in hTERT+ cells except at the highest doses. In contrast there was no persistent change in the cell cycle distributions of either hTERT- or hTERT+ cells after metal exposure if they were grown at non-confluent levels in flasks. Now was there a change in their proliferation rates. Only a short-term induction of apoptosis was seen. In the cells grown as colonies for the clonogenic assay there was a progressive and dose dependent increase in B galactosidase staining 30 days after metal exposure in hTERT- cells which was not seen in hTERT+ cells. A population of cells with short telomeres was present in hTERT- cells that was not seen in hTERT+ cells. However the distributions of telomere lengths were not altered by the metal exposures. This study suggests metals may alter the growth of human cells as colonies. Although this may be influenced by telomerase it may not be explained by metals changing telomere lengths.

2829

**A Possible Link Between Centrioles, Calcium Deficiency and Cancer**

J. Wells; Discovery Institute, Seattle, WA

Centrosomal defects leading to chromosomal instability appear to be an early step in the development of major human cancers, though the precise nature of the centrosomal defects remains unknown. An animal centrosome contains two orthogonally oriented centrioles, each composed of nine microtubule triplets arranged like the blades of a turbine. An engineering analysis of centriole ultrastructure based on electron microscope data leads to the hypothesis that these organelles function as dynein-driven turbines to generate a high-speed, small-amplitude oscillation in spindle microtubules that resembles the motion of a laboratory vortexer. Calculations show that the result would be a polar ejection force several times stronger than gravity that would tend to push chromosomes away from spindle poles during prometaphase and metaphase. [Rivista di Biologia / Biology Forum 98 (2005): 71-96]. The transient increase in intracellular calcium that normally accompanies the onset of anaphase would shut down the dynein-driven centriolar turbines to permit the unobstructed poleward movement of chromosomes. Under conditions of calcium deficiency or defective calcium regulation, however, centrioles could generate an increasing polar ejection force throughout anaphase that would break chromosome arms and produce chromosomal instability. Several experimental approaches are suggested to test the hypothesis, which if corroborated may contribute to a better understanding not only of cell division but also of cancer.

**Characterizing *Helicobacter pylori's* Virulence Factor, CagA, Using a *Drosophila* Model**

C. M. Botham, K. J. Guillemin; Institute of Molecular Biology, Uninversity of Oregon, Eugene, OR

*Helicobacter pylori's* virulence factor CagA is delivered via a Type IV secretion system into host cells and subsequently alters cell signaling. Inside cells, CagA is tyrosine phosphorylated by host Src kinases and activates SRC homology 2-domain phosphatase (SHP-2), a key component of receptor tyrosine kinase (RTK) pathways. Several proteins known to interact with CagA are also involved in RTK signaling. The activation of SHP-2 by CagA is hypothesized to be similar to the normal activation of SHP-2 by Grb2-associated binder (Gab) proteins. We are using a *Drosophila* model to determine if CagA functions like a Gab protein mimic. *Drosophila* are ideal for these experiments because their RTK pathways are well characterized and homologous to mammalian RTK pathways. We have generated transgenic *Drosophila* and shown that CagA activates several RTK pathways. The sevenless (SEV) RTK pathway specifies the R7 photoreceptor in the eye and CagA expression in the eye causes extra R7 photoreceptors. This phenotype mimics the expression of constitutively activated corkscrew (CSW), the *Drosophila* homologue of SHP-2. Daughter of sevenless (DOS), the only *Drosophila* homologue of Gab, normally activates CSW in the SEV RTK pathway and we are using *csw* and *dos* mutants to determine whether CagA acts solely through CSW and whether CagA mimics Gab. CagA expression in the tracheal system causes extra tracheal branches similar to expression of constitutively activated CSW in the fibroblast growth factor receptor (FGFR) RTK pathway. Downstream of FGF, scaffolding adaptor protein, normally activates the FGFR RTK pathway and we are using mutants to determine whether CagA acts as a general activator of RTK pathways. Dissecting CagA's activation of *Drosophila* RTK pathways will lead to a better understanding of the mechanisms by which CagA perturbs cell signaling.

2831

**Downregulation of Naked2 in Colorectal Cancer**

W. Ding,[1] J. Smith,[1] C. Li,[1] R. J. Coffey[1,2]; [1]Vanderbilt University, Nashville, TN, [2]Veterans Affairs Medical Center, Nashville, TN

Genetic studies in Drosophila have established that activation of canonical Wnt signaling results in upregulation of Naked Cuticle that then binds

and inactivates Dishevelled, a positive regulator of Wnt signaling. Two mammalian Naked homologs, Naked1 and Naked2, have been identified. We recently reported that Naked2, but not Naked1, interacts with the cytoplasmic tail of pro-TGFα, and escorts pro-TGFα-containing exocytic vesicles to the basolateral surface of polarized epithelial cells where these vesicles dock and fuse in Naked2 myristoylation-dependent manner (PNAS 101: 5571-5576, 2004). The present studies were designed to address whether Naked 1 and 2 were regulated like Naked Cuticle. For these studies, we utilized parental SW480 cells, a human colorectal cancer (CRC) cell line with mutant APC and active Wnt signaling as determined by nuclear β-catenin, and clones stably transfected with APC in which β-catenin is redirected to the plasma membrane and the cells revert to a non-transformed phenotype. Like Naked Cuticle, Naked1 expression by RT-PCR is high in parental SW480 cells and decreased in APC-transfected SW480 cells. In contrast, Naked2 expression is barely detectable in parental SW480 cells and both mRNA by RT-PCR and protein by western blotting are increased in APC-transfected SW480 cells. Moreover, immunohistochemical staining for TGFα is redirected from the cytoplasm to the plasma membrane in APC-transfected SW480 cells. In addition, full length 55kDa Naked2 protein is downregulated in 5 of 6 paired normal/cancer human CRC specimens by western blotting. We hypothesize that Naked2 helps to maintain normal epithelial homeostasis by regulated basolateral cell surface delivery of TGFα, and that loss of Naked2 predisposes to neoplasia.

**Regulation of the Proteasome by Yin6/int6 and an Actin Regulatory Protein, Arc21**

R. Cabrera, E. C. Chang; Breast Center, Baylor College of Medicine, Houston, TX

The “int” genes were originally identified as loci where mouse mammary tumor virus (MMTV) integration induces breast tumor formation. Nearly all “int” genes have well characterized molecular functions that are critical for oncogenesis; in contrast, the role of *int6* in tumorigenesis remains largely unknown. In order to better understand how *int6* can mediate cancer formation, we have recently uncovered a highly conserved function of *int6* by characterizing the *int6* ortholog, named *yin6*, in the genetic model system fission yeast. Our data suggest that *int6* regulates localization and assembly of the proteasome. Inactivation of *int6* weakens the proteasome leading to chromosome instability and abnormal mitosis. To further decipher how Int6 regulates proteasome localization and assembly, our lab performed a screen to isolate *S. pombe* cDNAs that, when overexpressed, rescue the growth defect of *yin6* null (*yin6*Δ) cells. This study focuses on *arc21*, encoding a potential subunit of the Arp2/3 complex, which has been implicated in the regulation of actin polymerization. My gene knock out experiments show that *arc21* is an essential gene and its inaction is associated with loss of cell polarity. Furthermore, my data show that an Arc21-GFP fusion protein colocalizes with F-actin, a pattern that can be disrupted by the actin polymerization inhibitor Latrunculin A. These results support the hypothesis that Arc21 binds actin and regulates actin function. Overexpression of Arc21 can rescue the proteasome defects observed in *yin6Δ* cells. Additionally, *yin6Δ* cells show an aberrant localization of Arc21-GFP, and, like many mutants defective in F-actin, are hypersensitive to actin polymerization inhibitors. These data support a model in which *yin6* mediates proteasome localization and assembly by acting via *arc21* and the actin cytoskeleton.

2833

**Erbb2 Disrupts Epithelial Cell Polarity by Inactivating the Par Complex**

V. Aranda,[1] T. Haire,[1] M. E. Nolan,[1] J. P. Fawcett,[2] C. D. Allred,[3] T. Pawson,[2] S. K. Muthuswamy[1]; [1]Cold Spring Harbor Laboratory, Cold Spring Harbor, NY, [2]Program in Molecular Biology and Cancer, Samuel Lunenfeld Research Institue, Mount Sinai Hospital, Toronto, ON, Canada, [3]Breast Center, Baylor College of Medicine, Houston, TX

Loss of tissue organization is a feature observed in all pre-cancerous epithelial lesions. Oncogenes such as v-Src, Ras, Myc and ErbB2 are known to disrupt epithelial cell architecture in cell culture and mouse models. Epithelial architecture is characterized by apical-basal asymmetry, referred to as cell polarity. During polarity establishment, a series of protein complexes, Scribble/Lgl/Dlg, Crumbs/PALS1/PATJ and the Par3/Par6/aPKC complex interact hierarchically to generate the organizational asymmetry. There is little information about the role of these polarity regulators in oncogenic signaling, although several studies are starting to identify them as potential tumor suppressors in mammals. The mechanisms by which oncogenes can interact with the cellular machinery involved in regulating cell architecture remain unknown. We have developed a system to model the early stages of oncogene-induced transformation by overexpressing ErbB2 in MDCK cells. Using an inducible receptor, we have characterized the time course of events that leads to the disruption of apical-basal polarity upon ErbB2 activation. This phenotype resembles the alterations observed in early cancerous lesions and has lead us to identify tight junctions as the earliest target of oncogene action. In order to characterize ErbB2-induced disruption of TJ, we focused on the Par3/Par6/aPKC complex, known to play critical roles during TJ formation. We found that activation of ErbB2 induces the dissociation of Par3 from Par6/aPKC, and formation of an ErbB2-Par6/aPKC complex. This induces a decrease in Par6-associated aPKC activity, in contrast with aPKC upregulation described in polarity formation and transformation of non-polarized cells. Moreover, overexpression of a kinase dead version of aPKC phenotypically cooperates with ErbB2. Thus we identify a new pathway for ErbB2 oncogenic signaling in polarized cells that involves inactivation of the Par complex and promotes disruption of epithelial architecture.

2834

**Caspase-mediated Proteolysis of Neurofibromin**

M. K. Kuechle,[1] M. M. Shinohara,[1] K. G. Stephens[2]; [1]Medicine/Dermatology, University of Washington, Seattle, WA, [2]Medicine and Laboratory Medicine, University of Washington, Seattle, WA

Neurofibromatosis type 1 (NF1) is a common autosomal dominant disorder with diverse clinical features that results from mutations in the NF1 gene. Neurofibromin, the NF1 protein product, is a large (2818 amino acids), multidomain protein, that functions in part as a tumor suppressor through its Ras-GTPase activating domain. The Gap-related domain (GRD) of neurofibromin accounts for only 10% of this large protein. The presence of multiple splice variants and the existence of pathogenic missense mutations outside the GRD suggest functions other than those related to the Ras pathway. Recently, NF has been shown to be actively transported to the nucleus via the presence of a bipartite nuclear localization signal in an exon located at the distal c-terminus. Nuclear staining for NF has been reported in developing neurons and in differentiating keratinocytes. Furthermore, altered nuclear localization of neurofibromin has been reported in psoriasis, a disorder of epidermal differentiation. These observations suggest that neurofibromin species found in the nucleus function to influence differentiation and/or development in certain tissues. A database screen identified neurofibromin as a potential caspase substrate with two consensus sites. In this study, we demonstrate that neurofibromin is proteolytically cleaved during Fas-mediated apoptosis in BJAB cells, and is due to a caspase-6 like protease. Furthermore, the cleavage pattern is

compatible with the predicted caspase sites. These findings identify neurofibromin as a novel caspase target, and provide the first evidence that neurofibromin is an important contributor to cell death as well as cell survival. Based on these studies, we hypothesize that caspase-mediated cleavage of neurofibromin releases the nuclear localization domain, allowing transport to the nucleus, where it functions to signal downstream events of cellular differentiation.

**Vav2 Modulates Cellular Invasion Through the Rac1 Signaling Pathway**

S. Y. Lai,[1] A. F. Ziober,[2] M. N. Lee,[2] E. M. Falls,[2] B. L. Ziober[2]; [1]Otolaryngology, University of Pittsburgh, Pittsburgh, PA, [2]Otorhinolaryngology, University of Pennsylvania, Philadelphia, PA

The Rho family of GTPases regulate cellular adhesion and motility. Guanine nucleotide exchange factors (GEFs) in turn regulate the activity of GTPases by promoting nucleotide exchange from GDP to GTP. We have determined that GTP-bound Rac1 is elevated in invasive oral squamous cell carcinoma (OSCC). Furthermore, expression of Vav2, a Rho family GTPase for Rac1, Cdc42 and RhoA was also up regulated in OSCC. Although Vav2 may regulate a number of cellular functions the specific signaling pathways remain incompletely defined in OSCC. Because of the critical role of cellular invasion in the progression and metastasis of OSCC, we investigated if Vav2 modulated Rac1 and Cdc42 activation and thus influenced cellular invasion in OSCC. Transient expression of Vav2 in UM-22B-SCC, a highly invasive OSCC cell line, resulted in an increase in GTP-bound Rac1, but not Cdc42. Stable expression of Vav2 in UM-22B-SCC and HaCaT cells resulted in an increase in GTP-bound Rac1, and to a lesser extent, GTP-bound Cdc42. Increased levels of GTP-bound Rac1 correlated with increased cellular invasion. Adenovirus-mediated expression of a dominant-negative Rac1 in the HaCaT-Vav2 cells and invasive OSCC cells resulted in an inhibition of cell invasion This effect appeared to be specific for Rac1, as a dominant-negative Cdc42 affected cellular invasion to a lesser extent. Thus, Vav2 appears to modulate cellular invasion through specific regulation of Rac1 activity in OSCC.

2836

**Identification of a Gene Expression Signature Associated with Oral Squamous Cell Carcinoma**

A. F. Ziober,[1] P. A. Gimotty,[2] J. L. Hunt,[3] K. R. Patel,[1] M. Feldman,[4] B. L. Ziober[1]; [1]Otorhinolaryngology, University of Pennsylvania, Philadelphia, PA, [2]Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, PA, [3]Pathology, University of Pittsburgh, Pittsburgh, PA, [4]Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA

Attempts to find biomarkers that distinguish OSCC lesions from normal oral epithelium have resulted in several candidate genes associated with OSCC tumor progression including p53, cyclin D1, and EGFR. However, to date, no single gene has shown sufficient diagnostic utility in OSCC. In an effort to identify a gene expression signature that may serve as biomarkers for OSCC we analyzed 12 non-cancerous and OSCC matched specimens from the University of Pittsburgh and the University of Pennsylvania using Affymetrix U133A GeneChip arrays. A *t* test of the normalized values for each gene with an adjusted p-value of $p < 0.001$ and the Benjamini-Hochberg false discovery correction yielded a list of 63 genes. Expression of selected genes was validated by real-time PCR and immunohistochemistry. Hierarchal clustering and Treeview imaging software were used to visualize the gene signature. Comparison of the paired non-cancerous tissue with the corresponding OSCC tumors identified several gene signatures including those associated the extracellular matrix, proliferation and signal transduction. Interestingly, cluster analysis identified primary OSCC samples that were lymph node positive and a gene signature for site specific expression in the oral cavity. Using Prediction Analysis of Microarrays (PAM) and the 12 non-cancerous and OSCC matched specimens, we identified a set of genes that, on cross-validation, were 83-88% accurate at classifying non-cancerous and OSCC specimens. This gene set was able to predict two independent non-cancerous and OSCC mismatched groups of 27 and 21 specimens with accuracies of 93% and 90%, respectively. These data provide evidence for gene expression-based biomarkers in OSCC.

2837

**Targeting TACE-Dependent Growth Factor Shedding in Breast Cancer**

P. A. Kenny, M. J. Bissell; Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA

The ability to proliferate independently of signals from other cell types is a fundamental characteristic of tumor cells. Tumors resulting from inappropriate activation of the EGFR are common in multiple tissues and are, for the most part, refractory to current targeted therapies. Using a 3D culture model of human breast cancer progression, we have delineated a protease-dependent autocrine loop which provides an oncogenic stimulus to this pathway in the absence of proto-oncogene mutation. Inhibition of this protease, TACE/ADAM17, reverts the malignant phenotype by preventing mobilization of two crucial growth factors, Amphiregulin and TGFα. We show further that the efficacy of EGFR inhibitors is overcome by physiological levels of growth factors and that successful EGFR inhibition is dependent on reducing ligand bioavailability. Using existing patient outcome data, we demonstrate a strong correlation between TACE and TGFα expression in human breast cancers that is predictive of poor prognosis**.** These data implicate TACE as a therapeutically tractable enzyme, the inhibition of which effectively blocks EGFR signaling by preventing mobilization of ligands for this receptor. Furthermore, the data provide mechanistic insight into the insensitivity of EGFR-overexpressing tumors to anilinoquinazoline inhibitors and suggest that co-ordinate inhibition of TACE might augment the activity of EGFR inhibitors in a clinical setting.

2838

**The Neurotrophin Receptor p75 Mediates Glioma Invasion**

A. L. M. Johnston,[1] X. Lun,[1] M. Slovack,[1] B. L. Hempstead,[2] S. M. Robbins,[1] D. L. Senger,[1] P. A. Forsyth[1]; [1]University of Calgary, Calgary, AB, Canada, [2]Cornell University Medical College, New York, NY

The invasive nature of cancers in general and malignant gliomas in particular is a major clinical problem and renders tumors incurable by “local” therapies (e.g. surgery, radiotherapy). To better understand invasion in glioma, we used serial *in vivo* selection to isolate highly invasive glioma cells from a non-invasive human glioma cell line, U87. Gene expression profiles of highly invasive cells were compared to their non-invasive counterparts using DNA microarrays. We found that the p75 neurotrophin receptor was significantly upregulated in the invading glioma cells. p75 was functional and ligand binding increased both migration and invasion *in vitro.* Ectopic expression of p75 in the original U87 cell line conferred

an increased migratory and invasive ability *in vitro* and upon implantation into SCID mouse brains. Conversely, down-regulation of p75, in a human glioma cell line expressing high levels of p75, decreased the migration and invasion of these cells *in vitro*. These data suggest that p75 is present, functional, and involved in glioma migration and invasion. In addition, high levels of p75 were common in patient specimens from highly invasive glioblastomas multiforme. Finally, as a beginning to understanding the mechanism behind p75's invasive effects, we have demonstrated that these cells also express the p75 ligand BDNF and may be setting up an autocrine loop. Future experiments are aimed at further elucidating p75's mechanism of action in this system. In glioma cells, reports have hinted at roles for p75 in growth and apoptosis; however, data presented here supports a much different role for p75, that of mediating glioma cell invasion.

2839

**3D Morphologies of Breast Tumor Cell Lines Cluster by Gene Expression Patterns**

C. Myers; Lawrence Berkeley National Lab, Berkeley, CA

Previous studies from the Bissell laboratory have shown that non-malignant and malignant cells can be distinguished easily by their morphological architecture when cultured in a three dimensional, laminin-rich extracellular matrix gels(3DlrECM) but not when cultured on traditional tissue culture plastic (2D)(1). In addition we have shown that cellular response to signaling inhibitors and apoptotic agents differ in cells cultured in 2D vs 3D(2-4). We asked whether the 3D morphology could be used as a reasonable surrogate for gene expression profiles for a panel of breast cancer cell lines. The 16 cell lines examined so far fell into 6 distinct morphologies termed round, round mass, irregular mass, grape-like, grape-like stellate and invasive stellate. Hierarchical clustering of 3836 genes with statistically significant differential expression clustered into 2 major groups: Stellates in one, and round/ mass/ and grape-like in the other. The 3D cluster analysis is similar to the 2D cluster analysis. However, the 3D morphological assignments allowed for finer subcatorgorization in that representatives from each of the 6 morphologies clustered together. We are currently analyzing these expression profiles to identify common signaling themes and/or morphological regulators as well as performing studies correlating morphology and expression profiles with therapeutic response to Herceptin and other therapeutic agents. 1. **Asbestos Produces Aneuploidy by Preferential Binding to Cell-Cycle Regulatory Proteins**

R. A. MacCorkle, S. D. Slattery, D. R. Nash, B. R. Brinkley; Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX

Asbestos is lightweight and chemically durable construction material commonly used in the USA until the 1970's and still used throughout the world today. Asbestos has been formally linked to the development of pleural mesothelioma, other lung cancers and lung-damaging fibrosis. The latency period for asbestos-linked lung cancer is 30-45 years after exposure, thus the incidence of asbestos-linked cancers is currently peaking in the USA and on the rise in other parts of the world. Unfortunately, our incomplete understanding of the carcinogenic mechanisms of asbestos has limited our ability to effectively prevent and treat disease caused by asbestos exposure. Studies have shown that the two common types of asbestos, amphibole and serpentine, can both physically interfere with chromosome segregation in human lung cells. This interference has been proposed to be responsible for the generation of a genetically unstable aneuploid cell population which has been linked to cancer progression. However, some cells still become aneuploid when exposed to asbestos in the absence of this physical interference mechanism. We hypothesized that an additional biochemical mechanism, such as sequestration of critical cell-cycle regulatory proteins, may contribute to asbestos-induced aneuploidy. To test this hypothesis we exposed asbestos fibers to human lung cell extracts and identified proteins that bound to them. We found that asbestos fibers preferentially bound proteins with known functions in regulation of the cell cycle, cytoskeleton and mitotic apparatus. This protein binding was functionally important because pre-coating of fibers with microtubule-associated protein (MAP)/ Tubulin complexes, effectively blocked cellular protein binding and aneuploidy generation in human lung cells. These results show a novel biochemical mechanism of protein sequestration by asbestos fibers that accounts for both amphibole and serpentine asbestos-induced aneuploidy. These results also show that precoating asbestos fibers with specific protein reduces their genotoxicity.

2841

**Altered Trafficking and Signaling of EGFR in Iressa-Sensitive Human Cell Lines**

P. J. Jasper, M. Lazzara, G. Lu, D. Lauffenburger, P. Sorger; Biology, MIT, Cambridge, MA

The small-molecule tyrosine kinase inhibitor Iressa belongs to a class of therapeutics aimed at interrupting dysregulated signaling by ErbB receptors (e.g., EGFR/ErbB1, HER2/ErbB2) in cancer. Recently, a strong correlation was established between patients who are responsive to Iressa and the presence of specific EGFR mutations. The relationship between mutation and Iressa sensitivity is not simple however; cells with WT receptor can be highly sensitive and even in mutants, sensitivity is not associated with tighter binding to the drug. The biology of WT and mutant ErbB receptors represents an opportunity to elucidate factors in the ErbB signal transduction pathway whose alteration leads to cancer, and to determine the precise mechanisms of action of anti-EGFR therapeutics. To gain quantitative, mechanistic understanding of ErbB1 mutations leading to Iressa-responsiveness, we employ a systems approach to investigating receptor trafficking, intracellular signaling, and cell death response in a panel of cell lines with wild type and mutant forms of EGFR. We are using this information to train physicochemical models of EGFR signaling under normal growth conditions and in the presence of Iressa or other kinase inhibitors. Analysis of EGFR trafficking reveals a striking pattern of lowered rate of internalization in Iressa-sensitive lines, regardless of whether EGFR is wild type or mutant. By probing for the phosphorylation of key downstream kinases, we have demonstrated differences in the signaling patterns of sensitive and insensitive cell lines. These differences are consistent with differential receptor trafficking. Ongoing research is aimed at the use of mathematical models to explain sensitivity and resistance, and eventually to develop design principles for second generation therapies.

2842

**Folate Receptor Targeting of a Transcription Factor Decoy for Hypoxia Induced Factor (HIF) for Treatment of Renal Cell Carcinoma**

Y. Li, C. Parham, E. Shocron, P. Nhonthachit, L. Komuves, J. Wilken, T. Flaherty, M. Garcia, J. Braisted, L. Beviglia, L. Powell, L. McEvoy, S. Hudak; Research, Corgentech Inc., South San Francsico, CA

The transcription factor Hypoxia-inducible Factor (HIF) controls expression of multiple genes involved in cancer biology, including angiogenesis, tumor growth, survival and invasion. Inhibition of HIF activity has marked effects on tumor growth. We generated a double-stranded oligonucleotide HIF Decoy that specifically binds to and inhibits HIF binding to target gene promoters. In previous work, we demonstrated that HIF Decoy blocks target gene expression in human tumor lines and reduces tumor growth by HIF Decoy in multiple murine xenograft tumor models. Efficacy equivalent to Avastin was seen in several xenograft tumor models where only 50% of the HIF activity was blocked, suggesting that improved delivery to the tumor is key to increased efficacy. Folate receptor is a highly selective tumor marker that has been utilized to deliver a wide variety of therapeutic agents. We developed a folate conjugate of our HIF Decoy in an effort to improve delivery to tumor cells. The renal tumor cell line 786-0 lacks HIF-1α but constitutively expresses HIF-2α, which is known to stimulate a number of hypoxia-inducible genes. We have demonstrated both the constitutive expression of HIF-2α and the binding of nuclear HIF2α by HIF Decoy in 786-O cells, as well as expression of folate receptor by flow cytometry. Folate-HIF Decoy demonstrates high affinity, specific binding and blocking of HIF-1α and HIF-2α activity. Folate conjugated HIF decoy showed a significant improvement in cellular and nuclear uptake compared to naked decoy, suggesting the potential for improved efficacy *in vivo. In vivo* experiments utilizing the 786-O xenograft tumor model are underway.

**HoxA9 Modulates the Tumor Phenotype by Regulating BRCA1 Expression**

P. M. Gilbert,[1] M. K. Gbegnon,[1] J. N. Lakins,[1] M. A. Unger,[2] B. L. Weber,[3] V. M. Weaver[1]; [1]IME/Pathology and Lab Medicine, UPENN, Philadelphia, PA, [2]Abramson Family Cancer Research Institute, UPENN, Philadelphia, PA, [3]Abramson Family Research Center/MERCK, UPENN, Philadelphia, PA

The tumor suppressor BRCA1 is known to play a critical role in familial and sporadic breast cancers. While genomic deletions and mutations in BRCA1 are known to underlie the loss of BRCA1 expression in familial breast cancers, less is known about what contributes to down-regulation and/or loss of function of this tumor suppressor in sporadic breast tumors. We previously identified HoxA9 as a gene whose expression is often lost during malignant transformation of the mammary gland. HoxA9 re expression in mammary epithelial tumor cells (METCs) resulted in decreased cell migration, proliferation, invasion, and anchorage independence *in vitro* as well as reduced tumor burden, growth, metastases, and viability *in vivo*. In addition, we found that HoxA9 re expression regulates adhesion through altering integrin expression and adhesion activity resulting in morphogenic reversion of tumors grown within a three-dimension reconstituted basement membrane (3D rBM). Subsequent studies showed HoxA9 directly binds to and activates the promoter of BRCA1. To determine which tumor modulator effects were dependent on HoxA9 mediated BRCA1 up regulation we utilized a full length BRCA1 expression construct in METCs and a dominant negative BRCA1 expression construct in METCs re-expressing exogenous HoxA9. Using soft agar and wound closure assays we showed BRCA1 is responsible for HoxA9 mediated effects on anchorage independence and migration. In addition, growth of these cells within a 3D rBM revealed that BRCA1 represses cell proliferation and promotes mammary morphogenesis by inducing apical polarity. *In vivo* studies demonstrated HoxA9 mediated effects on tumor metastases are exerted in part through up regulation of BRCA1. These data suggest that HoxA9 may function as a novel tumor modulator in mammary epithelial cells through regulation of tumor suppressors such as BRCA1, and by altering stromal-epithelial interactions. (Supp: DISS0402407, DODW81XWH-05-1-330, NCI CA078731 and DAMD17-01-1-0368).

**Quantitative Analysis of Energy Metabolism Pathways in Breast Cancer Cells Using Native NAD(P)H**

R. P. Walvick, A. A. Heikal; Department of Bioengineering, Pennsylvania State University, University Park, PA

The concentration of intrinsic NAD(P)H in live cells or tissues is a sensitive reporter of mitochondrial function. Conventional biochemical techniques require lysing the cell in order to measure the concentration of any biomolecules. In contrast, fluorescence measurements provide a noninvasive approach for qualitative imaging of NAD(P)H in vivo. However, standard fluorescence microscopy does not take into account the sensitivity of the fluorescence dynamics of NAD(P)H to its cellular environment and the physiological conditions of live cells. Here we report on quantitative analysis of NAD(P)H as a reporter of the cell physiology using a combination of steady-state and time-resolved two-photon (2P) fluorescence imaging microscopy. Our preliminary results on breast cancer (Hs578T) and normal (Hs578Bst) cells, which are derived from the same patient, indicate quantitative differences between the intrinsic NAD(P)H in these two cell lines under 740-nm illumination. Of particular interest here is the exact concentration and the spatial distribution of native NAD(P)H to quantify the partitioning of the energy budget between oxidative phosphorylation and glycolysis in cancer cells. We have also used 2P-fluorescence polarization imaging microscopy to map out the dipole-moment orientation of native NAD(P)H in the heterogeneous environment of live cells. These results will ultimately help understanding of the underlying molecular differences in energy metabolic pathways in cancer cells and may lead to the development of a sensitive and intrinsic diagnostic probe.

**nSMase2 is Modulated by Oxidative Stress and Induces Apoptosis in Lung Epithelial Cells**

M. Levy, S. S. Castillo, C. Wang, T. T. Goldkorn; Internal Medicine, UC Davis School of Medicine, Davis, CA

Our laboratory demonstrated that exposure of lung epithelial cells to oxidative stress via hydrogen peroxide (H2O2) directly activates an endogenous membrane neutral sphingomyelinase (nSMase) to induce ceramide accumulation followed by apoptosis. Additionally, we found that glutathione negatively regulated nSMase and inhibited apoptosis. Purification studies of nSMase from the lung (of monkey or pig) indicated that there is more than one isoform of nSMase present in the lung epithelium. Cloning approaches based on homology with bacterial SMases identified two mammalian enzymes, nSMase1 and nSMase2 as putative nSMases capable of hydrolyzing spingomyeline in-vitro. In order to determine the role of nSMase2 in lung epithelial cells we first demonstrated that nSMase2 is present and functional in lung epithelial cells. Then, using 3 overlapping sets of primers based on identical regions between human and mouse cDNA for nSMase2, we cloned nSMase2 from human A549 lung epithelial cells and from rhesus monkey lung tissue. We then transfected A549 cells with the cloned nSMase2. The over-expression of nSMase2 resulted in 16-fold increase in basal enzyme activity, which could be quenched by the addition of 10 mM glutathione. When 100 μM H2O2 was added to cells over-expressing nSMase2, an additional increase of 8-fold in enzyme activity was obtained. Both basal and inducible activation of nSMase2 were impaired by siRNA knockdown of nSMase2. In addition, H2O2-Induced apoptosis was examined before and after silencing. While

H2O2 enhanced early apoptosis 1.6-fold, silencing of nSMase2 canceled this induction. Our results suggest that the nSMase isozyme nSMase2 is modulated by oxidative stress and is a key player in lung epithelial cell death.

**The Tetraspanin CD151 Regulates Rumor Cell Intravasation by Mediating Matrix Interactions During Migration and Invasion of the Tumor Stroma**

A. Zijlstra, J. Lewis, H. Stuhlman, J. P. Quigley; Cell Biology, The Scripps Research Institute, La Jolla, CA

In vivo, metastatic dissemination is a process involving multiple sequential rate-limiting steps which ultimately result in the colonization of secondary sites. Matrix interactions mediated by integrin complexes are thought to play a key role in the adhesion, migration and invasion of tumor cells at multiple steps in the metastatic cascade. The tetraspanin CD151 associates with the α3β1 integrin complex on the cell surface and is thought to regulate ligand interactions. Using a CD151 function blocking antibody, we have demonstrated that CD151 regulates migration of tumor cells on multiple ECM components, not only those bound by α3β1. As a consequence CD151 can regulate tumor cell motility in the complex matrix of tissue stroma. Cell surface CD151 clusters into micro-domains in response to antibody binding. The clustered CD151 exhibits improved association with the β1 integrin complexes and facilitates an increased formation of Paxillin containing adhesion complexes. Intravital imaging of tumor cell motility demonstrates that antibody ligation results in diminished migration due to the inability of the tumor cell to detach the trailing end of the cell body. Using high-throughput quantitative analysis of individual steps in the metastatic cascade, we have demonstrated that this failure to migrate does not affect primary tumor growth nor tumor cell arrest, extravasation or growth at the secondary site. In contrast, the inhibition of CD151 mediated migration prevents invasion of the tumor stroma and migration along the stromal vasculature. Quantitative assessment of intravasation demonstrates that the inhibition of CD151 mediated migration specifically prevents intravasation at the site of the primary tumor. Thus CD151 regulates migration in the stroma of tumor tissue. The inhibition of CD151 mediated migration prevents entry into the tumor vasculature and subsequent colonization of secondary tissues.

**Curing of Yeast [*PSI*$^+$] Prion by Guanidine Inactivation of Hsp104 Does Not Require Cell Division**

Y. Wu,[1] L. E. Greene,[1] D. C. Masison,[2] E. Eisenberg[1]; [1]Laboratory of Cell Biology, NHLBI, National Institutes of Health, Bethesda, MD, [2]Laboratory of Biochemistry and Genetics, NIDDK, National Institutes of Health, Bethesda, MD

Propagation of the yeast prion [*PSI*$^+$], a self-replicating aggregated form of Sup35p requires Hsp104. One model to explain this phenomenon proposes that, in the absence of Hsp104, Sup35p aggregates enlarge but fail to replicate thus becoming diluted out as the yeast divide. To test this model, we used live imaging of Sup35p-GFP to follow the changes that occur in [*PSI*$^+$] cells after addition of guanidine to inactivate Hsp104. Following guanidine addition there was initially an increase in aggregation of Sup35p-GFP. But then, before the yeast divided, the aggregates began to dissolve, and after about 6 hours the Sup35-GFP looked identical to the Sup35-GFP in [*psi*$^-$] cells. Although plating studies showed that the yeast were still [*PSI*$^+$], this reduction in aggregation suggested that curing of [*PSI*$^+$] by inactivation of Hsp104 might be independent of cell division. This was tested by measuring the rate of curing of [*PSI*$^+$] cells in both dividing and non-dividing cells. Cell division was inhibited by either adding either alpha factor or farnesol. Remarkably, with both of these methods, we found that the rate of curing was not significantly affected by cell division. Thus cell division is not a determining factor for curing [*PSI*$^+$] by inactivating Hsp104 with guanidine. Rather, curing apparently occurs because Sup35-GFP polymers slowly depolymerize in the absence of Hsp104 activity. Hsp104 then counteracts this curing possibly by catalyzing formation of new polymers.

**Prion Proteins [PrP] of Mammals, Yeast, Fungi and Others Are Related in Conserved Homologous Domains for Binding *Endogenous* Redox- and Metalloregulated *"Non-Coding"* Small RNA Bioaptamers: Codes for Epigenetic Reprogramming Cell Fate in Conformation Phase Pathway-Locked Loops [CPLL]**

J. H. Wissler, J. E. Wissler; ARCONS Institute for Applied Research & Didactics, Postfach 1327, D-61231 Bad Nauheim, Germany

OBJECTIVE: Relations of different PrP in interaction with entitled structurally defined *endogenous* nucleic acids to epigenetic [non-Mendelian] phenotype alterations [EPA] in reprogramming metabolic and developmental cell fate and proteinaceous transmission ["infection"] of conformational disease. METHODS: Isolation of such nucleic acids from wound and supernatant fluids of cells cultured in serum-free synthetic media. Purification guided by bioassays of cellular differentiation and tissue morphogenesis [Wissler et al., Protides Biol.Fluids 34:517-536,1986; Materialwiss.Werkstofftech.32:984-1008,2001; Ann.N.Y.Acad.Sci.991:333-338,2003; 1022:163-184,2004; FASEB J.19:A621,2005; FEBS J.272-s1:N1-06-4P,2005]. RESULTS: Bioactive *endogenous* complexes of nucleic acid bioaptamers and conformers of PrP-surrogate [S100-EF-hand] proteins were isolated. Some sequence-defined bioaptamers are redox- and metalloregulated, edited and modified *"non-coding"* small RNA [<200 bases] as regulators and messengers of protein structure [folding] at cellular translation and transcription levels. They address conserved homologous metalloregulated nucleic acid-binding domains in proteins, termed K/R3H-[K/RxxxH], i.e. -t/s/xK/R/q/nxxxH/y/n/q/e/dx$_{7-9}$h/xx$_{7-9}$h/xx$_{5-20}$K/R/q/n/e/h- with accessory basic [R/K]$_n$, R/K-zipper, SR/K/RS and/or HxxxH/y/n/q segments. Highly conserved homologous domains in mammalian PrP were found characteristically patterned in prions of yeast, fungi and other species, e.g. Ure2p-URE3, Sup35p-ERF3-PSI+, Rnq1p-PIN+, New1p-NU+, Prb1p-[vacuolar protease-B], HET-s-[Small-s]. In latter HET-S-[Big-S] allelic variants, different domain patterns comprise accessory R/K-zipper. Sequences and positions suggest that only some EPA are transmissible, confined to species barriers or prone to *"bioaptamer disease"*. CONCLUSIONS: Since not directly retranslatable to heritable genome codes by sequence edition, base modification, redox- and metalloregulation, i.e. code extensions/alterations, entitled *"non-coding"* RNA bioaptamers as products of overwhelming portions [~98%] of transcriptional output apparently represent codes for EPA. RNA-, redox- and metal ion-orchestrated CPLL are suggested reprogramming cell fate in searched concepts [Wickner et al., Genes Develop.18:470-485,2004]: "Proteins as genes and infectious entities".

**Identification and Characterization of a Novel Protein Associated with Early-Onset Dystonia Protein TorsinA**

L. M. Imboden, L. Chin, L. Li; Department of Pharmacology, Emory University School of Medicine, Atlanta, GA

Early-onset generalized dystonia (DYT1) is a movement disorder characterized by involuntary movements and prolonged muscle contraction, resulting in twisting body motions, tremor, and abnormal posture. DYT1 has been linked to two mutations (ΔE302 and ΔF323-Y328) in the AAA+ protein torsinA. To identify additional players in the torsinA pathogenic pathway, we performed yeast two-hybrid screens to search for torsinA-interacting proteins in the brain. Here we report the identification of a novel protein named printor (protein interactor of torsinA). Printor is a 70-kDa protein with no apparent signal sequence or transmembrane domain. Western blot analysis reveals that printor is expressed in brain as well as other tissues, suggesting that printor has a functional role important to many cell types, including neurons. Subcellular fractionation studies indicate that printor exists in both cytosolic and membrane-associated pools. Immunofluorescence confocal microscopic analysis demonstrates that, like torsinA, printor is localized to endoplasmic reticulum and nuclear envelope, but not early endosome, lysosome, or mitochondria. We have confirmed the interaction of printor with torsinA by coimmunoprecipitation and shown that printor colocalizes with torsinA in cells by double immunofluorescence labeling. These results provide compelling evidence that printor and torsinA associate *in vivo* and suggest a potential role for printor in the molecular pathogenesis of DYT1. Supported by NIH Grant NS047575

**Mutations Identified in Myoclonus-Dystonia Patients Alter Epsilon Sarcoglycan Protein Localization**

L. LIU, L. J. Ozelius; Molecular Genetics, Albert Einstein College of Medicine, Bronx, NY

Epsilon-sarcoglycan (SGCE) is an N-glycosylated transmembrane protein expressed ubiqitously. It is functionally related to the other sarcoglycans including alpha-, beta-, delta-, gamma- and zeta- sarcoglycans. Evidences showed a tight interaction of beta-, delta- and epsilon-sarcoglycan in the dystroglycan complex in muscles. Mutations in the SGCE gene cause Myoclonus Dystonia (M-D), a neurologic movement disorder characterized by lightening-like jerks (myoclonus) and sustained twisting and repetitive movements, resulting in abnormal postures (dystonia). The function of SGCE remains unknown. Using site directed mutatgenesis, SGCE mutations found in M-D patients were generated, cloned into a mammalian expression vector and expressed in neuronal like cell lines. Immunohistochemical analysis of wild type and mutant SGCE protein showed significant differences in the localization patterns in the cells with the mutant proteins failing to be transported to the membrane. Protein expression studies suggest that various mutant SGCE proteins interact with wild type protein and partially interfering with targeting of the wild type protein to the membrane. Studies to determine whether the tight interaction of beta-, delta- and epsilon- sarcoglycan might be disrupted due to the mislocalization of mutant SGCE proteins are ongoing. Characterization of mutant SGCE protein will help to better understand the mechanism of myoclonus dystonia and may suggest possible treatment strategies.

**Drug Screening for Potential Therapeutic Development in a *C elegans* Dystonia Model**

A. K. Clark, S. Cao, K. A. Caldwell, G. A. Caldwell; Biological Sciences, The University of Alabama, Tuscaloosa, AL

Dystonia is a human movement disorder that is estimated to affect over 500,000 people in North America and is more prevalent then Huntington's Disease, ALS, and Muscular Dystrophy - combined. The most severe, early-onset form of dystonia is a dominant disorder caused by a single codon deletion in a gene termed *DYT1 (TOR1A)* that encodes a protein called torsinA. A logical route toward therapeutic intervention for dystonia involves the identification of small molecules that have the ability to alter the function of mutant torsinA. We have established the nematode *C. elegans* as a model system by which the activity of torsins can be examined in the context of their putative role as molecular chaperones. Previous work has shown that torsin proteins have the capacity to suppress misfolding of proteins and can protect dopaminergic neurons from toxic insults such a 6-hydroxydopamine treatment in worms. We are conducting a screen for compounds that alter the functional consequences of co-expressing both wildtype and mutant human torsinA in vivo. Here we report use of a set of 240 chemically diverse small molecules, representing off-patent drugs approved for human use, and prescreened for toxicity to *C. elegans*, that we have assayed for reversal of mutant torsin activity in two distinct assays for bioactivity in altering: 1) protein misfolding and 2) dopaminergic neurotoxicity. We have identified 8 drugs that show over 20% increase in blocking protein misfolding and 3 compounds that exhibit a similar enhancement of neuroprotection. 2 of these compounds were overlapping in both assays. These are being examined for torsin-specific effects and will be further investigated as potential lead compounds for chemical modification toward therapeutic development.

2852

**The SPG3A Hereditary Spastic Paraplegia Protein Atlastin-1 is Enriched in Axonal Growth Cones**

P. Zhu,[1] S. J. H. Tao-Cheng,[2] C. L. Smith,[3] J. Stadler,[1] S. M. Yang,[1] C. Blackstone[1]; [1]Cellular Neurology Unit, NIH / NINDS, Bethesda, MD, [2]NINDS Electron Microscopy Facility, NIH / NINDS, Bethesda, MD, [3]NINDS Light Imaging Facility, NIH / NINDS, Bethesda, MD

Mutations in the atlastin-1 gene have been identified in SPG3A, one of the more common forms of autosomal dominant “pure” hereditary spastic paraplegia (HSP), likely resulting in the functional impairment of the atlastin-1 protein. The HSPs are a group of over 25 inherited neurological disorders with the cardinal feature of lower extremity spasticity and weakness resulting from a length-dependent axonopathy of the upper motor neurons. An interesting feature of SPG3A is its very early onset, raising the possibility that developmental abnormalities may be involved in its pathogenesis. We have previously found that atlastin-1 is a large oligomeric GTPase in the dynamin superfamily that is an integral membrane protein localized predominantly to the *cis*-Golgi apparatus in neurons (Zhu et al., J Biol Chem 278:49063-71, 2003), though smaller amounts are also found in the endoplasmic reticulum (ER). Yeast two-hybrid, gel exclusion chromatography, and chemical cross-linking studies have revealed that SPG3A mutations do not affect formation of atlastin-1 oligomers, indicating that these mutant subunits may interfere with the atlastin-1 GTPase complex function in a dominant-negative fashion. Immunoblotting experiments reveal extensive expression of atlastin-1 in the brain and spinal cord in rats, and the level of expression in brain increases from embryonic through adult ages. Unexpectedly, using confocal and electron microscopy we have also found that atlastin-1 is highly enriched in vesicles within axonal varicosities and growth cones in rat cortical neurons in culture, prefiguring a functional role in axonal development. On the other hand, multiple protein markers for the Golgi apparatus and ER are not detected in these compartments. Thus, the "long axonopathy" in SPG3A may result from abnormal ER-Golgi membrane trafficking and/or the

proper development of axons.

2853

**Localization of Spastin and Spartin to Cellular Organelles, and Analysis of their Interaction Proteins**

J. Lu, P. C. Byrne; Pathology, UCD, Dublin, Ireland

Hereditary spastic paraplegia (HSP) describes a diverse group of disorders characterized by length dependent axonal degeneration that causes progressive paralysis affecting the lower limbs. HSP is due to mutations in a number of genes, including SPG4, which encodes spastin and SPG20 which encodes spartin. Both proteins have an MIT (microtubule interacting and trafficking) domain in the amino terminal of the protein and an AAA (ATPases Associated with diverse cellular Activities) domain in the carboxy terminal. Through subcellular localisation studies of fluorescent tagged full-length, NH2-terminal deleted and prematurely truncated spastin and spartin, we identified a novel site of spastin expression -the endoplasmic reticulum, and the localization of spartin in mitochondria. The findings were not reported previously. We have also confirmed that spastin is also expressed in multiple cellular locations including endosomes. Using NH2-terminal deleted and prematurely truncated spastin/spartin constructs we found that sequences at the NH2-terminal region of spastin and C-terminal region of spartin contain the primary determinants for ER and mitochondria localisation respectively. Through acceptor quenching FRET analysis of cultured cells co-expressing EYFP -alpha tubulin and ECFP-spastin, we showed the interaction of tagged spastin and spartin with the alpha-tubulin, indicating the interaction of these proteins with microtubule structures.

2854

**Axons Sever to Survive: Spastin, Atlastin, and Microtubule Severing in Hereditary Spastic Paraplegia**

B. P. Lauring; Pathology, Columbia University, New York, NY

Mutations in the AAA ATPase Spastin (SPG4) cause an autosomal dominant form of hereditary spastic paraplegia (HSP) a retrograde axonopathy primarily characterized pathologically by degeneration of long spinal neurons in the corticospinal tracts and the dorsal columns. Using purified components with real-time videomicroscopic and sedimentation assays we show that recombinant Spastin severs taxol-stabilized microtubules. We find that six mutant forms of Spastin including three disease-associated forms are severely impaired in ATPase and severing activities. Like other AAA ATPases, Spastin oliogomerizes in response to ATP, and some disease-associated mutations abolish assembly whereas others may prevent disassembly. Using a yeast two hybrid screen we identified Atlastin, another HSP gene encoding a golgi-localized integral membrane protein GTPase, as a Spastin binding protein. We show that the two recombinant proteins bind one another in vitro, can be co-immunoprecipitated from cell lysates, and that one protein appears to localize the other in cells. The domain of Spastin binding Atlastin is dispensable for microtubule severing, and recombinant Atlastin does not alter the ATPase activity of Spastin. Instead, Atlastin may recruit Spastin to the golgi apparatus. In cultured hippocampal neurons Spastin expression appears to result in increased dendrite numbers and branching, perhaps indicating a role for microtubule severing in branch formation. We further show that a putative C. elegans orthologue of Spastin indeed severs microtubules and that motor axons terminate prematurely in C. elegans null for Spastin. These studies suggest that defects in microtubule severing are a cause of axonal degeneration in human disease, and that multiple HSP genes may function in a common cell biological pathway important in axonal maintenance.

2855

**Gemin4: A Potential Modifier of Spinal Muscular Atrophy?**

M. P. Walker, K. B. Shpargel, A. G. Matera; Genetics, Case Western Reserve University, Cleveland, OH

Spinal muscular atrophy (SMA) is the leading monogenetic cause of infant morbidity and mortality. Deletion and/or mutations of the survival of motorneurons gene 1 (SMN1) causes SMA. SMN is part of a macromolecular structure known as the SMN complex which is involved in the biogenesis of the essential pre-mRNA splicing factors, the UsnRNPs. The SMN complex is comprised of SMN and seven other core proteins, collectively called Gemins. SMN has been extensively characterized because of it's involvement in SMA. However, detailed functional studies of the other members of the SMN complex are lacking. Our lab is interested in deciphering the role of these Gemin proteins in the complex which in turn may better help us to understand the molecular mechanisms involved in SMA disease. Here we describe the creation and characterization of a mouse model of Gemin4. Gemin4 is a 1058 aa polypeptide that has no known homology to other proteins. Initial studies of Gemin4 revealed that it interacts with the SMN complex via its direct contact with the putative RNA helicase, Gemin3. We have found that disruption of Gemin4 function is lethal. No homozygous mutant neonatal (P1) or mid-gestation (E13.5) animals were recovered, indicating an early embryonic lethal phenotype. We are currently analyzing early-gestation embryos and investigating Gemin4's potential as a modifier of the SMA phenotype. These results indicate that Gemin4 is an essential member of the SMN complex.

2856

**Role of the Survival of Motoneuron (SMN) Protein in Neurite Outgrowth**

J. van Bergeijk,[1] A. F. Bruns,[1] C. Grothe,[1,2] P. Claus[1,2]; [1]Neuroanatomy, OE 4140, Hannover Medical School, Hannover, Germany, [2]Center for Systems Neuroscience (ZSN) Hannover, Hannover, Germany

Spinal muscular atrophy (SMA) is a neurodegenerative disease affecting motoneurons in the spinal cord. SMA is caused by mutations or a deletion of the survival of motoneuron (SMN) gene 1. SMN has a functional role as an assembly protein for small nuclear ribonucleoprotein particles (snRNP) involved in splicing. SMN dissociates from snRNPs in the nucleus and localizes to certain nuclear bodies called nuclear gems. Patients with SMA display significantly less or no nuclear gems. In this study, we performed a functional domain mapping of the SMN protein with respect to differential nuclear localization and effects on neurite outgrowth in PC12 cells. SMN deletions were fused to green fluorescent protein (GFP) and their localization analyzed. A mutant without the C-terminus lost the ability to form nuclear gems and located instead diffusely to the nucleoplasm. In the neurite outgrowth assay, full-length SMN enhanced neurite outgrowth. Interestingly, a mutant displaying the C-terminus only demonstrated the same effect, whereas its ability to assemble snRNPs was impaired. These data argue for a splicing-independent contribution of SMN to neurite growth. We have recently shown a direct interaction between SMN and the neurotrophic fibroblast growth factor - $2^{23}$ (FGF-$2^{23}$). FGF-2 is not only an extracellular signaling molecule, but also a protein found in the nucleus. With regard to function, this interaction suppresses the promoting effect of SMN on neurite outgrowth in PC12 cells. Interestingly, on a molecular level FGF-$2^{23}$ can compete with Gemin2, a

component of the SMN complex in nuclear gems, for binding to SMN. As a functional consequence on a cellular level, the number of nuclear gems is significantly decreased. The results demonstrate the importance of the C-terminus of SMN for regulation of neurite outgrowth and a possible involvement of FGF-2 in this process.

2857

**Visualization of Dimer/Oligomer Formation by Polyglutamine Stretches in Living Cells**

T. Takahashi,[1] S. Kikuchi,[2] M. Nishizawa,[2] O. Onodera[3]; [1]Health Science, Faculty of Medicine, Niigata University, Niigata, Japan, [2]Neurology, Brain Research Institute, Niigata University, Niigata, Japan, [3]Clinical Neuroscience Branch, Brain Research Institute, Niigata University, Niigata, Japan

Polyglutamine diseases are inherited neurodegenerative disease with intranuclear aggregate formation caused by the expansion of a homopolymeric glutamine stretch in various genes. Recent works revealed that the aggregate formation showed protective activity against expanded polyglutamine cytotoxicity. Therefore one of the hypotheses is intermediates, such as dimers or oligomers of expanded polyglutamine stretches might cause cell dysfunction. To clarify this possibility, it is important to visualize the dimer or oligomer formation in living cell. For this purpose, we generated fusion proteins of monomeric-YFP(mYFP) or monomeric-CFP(mCFP) and polyglutamine stretch. We cotransfected COS7 or SH-SY5Y with these in several different combinations. If two fluorescent proteins are close enough to produce fluorescence resonance energy transfer (FRET), we can detect them by fluorescence confocal microscopy. FRET was only observed in combination with mCFP-poly(Q) / mYFP-poly(Q) or poly(Q)-mCFP / poly(Q)-mYFP. The number of the cells which showed FRET increased in a length dependent manner (Q12-9.5%, Q36-24.2%, Q56-27.2%, Q80-36.7%). By construct, in combination with mCFP-poly(Q) / poly(Q)-mYFP or poly(Q)-mCFP / mYFP-poly(Q), we could not detect any FRET. This result indicated that polyglutamine stretch made dimer in a parallel manner, not in an anti-parallel manner in living cell. Furthermore, the intensity of FRET increased in a length dependent manner. It suggested that the stability of dimer formation increased by a length-dependent manner. This new technique to visualize the dimmer/oligomer of expanded polyglutamine stretches in living cell will tell us a new aspect of pathogenesis of polyglutamine diseases.

**Alsin Mediates IGF-1 Receptor Signaling and Cell Survival**

J. D. Topp,[1] S. R. Severson,[1] B. F. Horazdovsky,[1] P. C. Orban,[2] M. R. Hayden,[2] R. S. Devon[2]; [1]Biochemistry & Molecular Biology, Mayo Clinic College of Medicine, Rochester, MN, [2]Centre for Molecular Medicine and Therapeutics, Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada

Amyotrophic lateral sclerosis (ALS) is a heterogeneous group of neurological disorders that result in motor neuron degeneration and usually leads to death. Although ALS is predominantly sporadic, familial ALS accounts for approximately 10% of patients with this illness. Eight independent chromosomal loci have been linked to ALS, and three specific genes have been identified that are mutated in familial forms: *SOD1, SETX* and *ALS2. ALS2* is mutated in a recessive juvenile-onset form of ALS and has also been linked to juvenile primary lateral sclerosis (JPLS) as well as infantile-onset ascending hereditary spastic paraplegia (IAHSP). We have previously shown that the *ALS2* gene product (Alsin) is a Rab5 and Rac1 guanine nucleotide exchange factor (GEF). In an effort to understand the molecular basis of juvenile ALS, we have chosen to examine the functional role of Alsin in neuron maintenance and survival using a cell culture model system. Insulin-like growth factor 1 (IGF-1) signaling was significantly impaired in cells expressing mutant Alsin lacking an intact Rab5 GEF domain. Though IGF-1 receptor activation and internalization were unaffected, trafficking of activated receptors to early endosomes was severely compromised. Since IGF-1 plays an important role in mediating cell survival, we examined IGF-1 anti-apoptotic activity in cells expressing the mutant form of Alsin. The IGF-1 signaling defect observed in Alsin defective cells also resulted in reduced IGF-1 protection from serum withdrawal-induced apoptosis. We conclude that mutant Alsin proteins compromise IGF-1 receptor trafficking, IGF-1 signaling, and IGF-1 mediated cell survival, identifying a potential mechanism for motor neuron degeneration observed in juvenile ALS.

2859

**Identification of Chemical Compounds that Rescue the BDNF Vesicular Transport Defects in Huntington's Disease**

J. P. Dompierre, J. Godin, B. Charrin, S. Humbert, F. Saudou; Cnrs umr 146, Institut Curie, Orsay, France

Huntington's disease (HD) is a fatal neurodegenerative disorder that is characterized by involuntary movements, personality changes and dementia. The neuropathology of HD involves neuronal dysfunction and the selective death of striatal neurons in the brain. The mutation that causes disease is an abnormal expansion of a polyglutamine (polyQ) stretch in the N-terminus of the 350 kD protein huntingtin. The mechanisms by which huntingtin induces dysfunction and death of neurons in the brain are not clearly understood. These could involve the gain of a new toxic function as well as the loss of the beneficial activities intrinsic to wild type huntingtin. Indeed, huntingtin possesses anti-apoptotic properties as observed in cell culture and animal models. We have used 3D fast video microscopy techniques to study the intracellular dynamics in normal and pathological situations. Using this approach we have unravelled a function of huntingtin in the microtubule-based transport of neurotrophic factors such as BDNF. In the pathological situation, huntingtin-stimulated BDNF transport is altered. We demonstrated that polyQ-huntingtin *via* the huntingtin-associated protein-1, HAP1 disrupts the association of key components of the motor machinery to microtubules. Reduced BDNF transport leads to a decrease in neurotrophic support and to neurotoxicity that are both rescued by wild-type huntingtin. Our results demonstrate that the anti-apoptotic properties of huntingtin are linked to the ability of huntingtin to promote transport of BDNF in the brain. We will report recent findings that identify compounds that rescue huntingtin's dysfunction in intracellular dynamics and how they act to inhibit the toxicity of mutant polyQ-huntingtin in disease.

**Glucocorticoid Receptor Antagonists Are Effective in Eliminating Allodynia and Hyperalgesia in Mouse Model of Neuropathic Pain**

T. Tanabe, I. Takasaki, T. Kurihara, H. Saegusa, S. Zong; Pharmacology & Neurobiology, Tokyo Medical & Dental University Graduate School of Medicine, Tokyo, Japan

We have previously demonstrated that mice lacking N-type voltage-dependent Ca channels (VDCCs) show markedly reduced symptoms of

neuropathic pain-related behavior induced by spinal nerve injury, suggesting the critical role of N-type VDCCs in the development of neuropathic pain. Although several lines of studies demonstrated that blockade of this channel is effective on neuropathic pain, it has been reported that clinical application of an N-type VDCC blocker has a limitation due to its serious side effects. Our results of cDNA microarray analysis suggest that glucocorticoid receptor (GR) mRNA is up-regulated in the spinal cord of mice with spinal nerve injury as compared with sham operated mice, whereas GR mRNA expression is decreased in N-type VDCC deficient mice by nerve injury. These results suggest that GR in the spinal cord contributes to the development and/or maintenance of neuropathic pain induced by nerve injury. GR is widely expressed in the central nervous system including the regions involved in the control of pain transmission. However, the contribution of GR to neuropathic pain remains unknown. Thus we examined the effects of GR antagonists on neuropathic pain-like responses in mice. Injury to spinal nerves of mice induced mechanical allodynia and thermal hyperalgesia, and these responses were ameliorated by intrathecal injection of the GR antagonists. Intraperitoneal injection of GR antagonists also produced antinociceptive effects, whereas intracerebroventricular injection was without effects. These results suggest that spinal GR plays important roles in neuropathic pain, and controlling the activity of GR can be of great importance for the treatment of neuropathic pain.

2861

### Intracellular Calcium-activated Protein Kinase $C_{\beta II}$ and Mitochondrial $Ca^{2+}$-mediated Oxidative Stress Are Essential for the Geldanamycin-Induced Synthesis of GRP78

F. Sun, H. Shyn, Y. Lai; National Tsing Hua University, Hsinchu, Taiwan Republic of China

The molecular mechanism whereby antitumor drug geldanamycin (GA) impacts ER stress pathway is partially known to be involved with the activation of calcium, oxidative stress and protein kinase C. Here, we investigated the roles of calcium, oxidative stress and their causal relationship in GA-induced expression of ER chaperone GRP78 in 9L rat brain tumor cells. GA treatment leads to an immediate suppression of general protein synthesis followed by an enhanced synthesis of the GRP78. GA-exerted calcium signaling was completely blocked by altering mobilization of calcium in organelles with intracellular or extracellular calcium chelator, BAPTA/AM and EGTA. GA-induced increase of $[Ca^{2+}]_i$ is also 50% prevented in the presence of thapsigargin (TG) and ruthenium red (RuR). These data lead us conclude that extracellular $Ca^{2+}$ are the major sources of GA-evoked calcium signaling, and the calcium store in ER and mitochondria are also involved in the process. Furthermore, U73122 as a phospholipase C inhibitor decreased GA-induced GRP78 expression, suggesting the dependence of phospholipase C in the process. In specific kinase inhibitors screening assay, we identify $PKC_{\beta II}$ as a possible PKC subtype specifically involved in GA-induced synthesis of GRP78. GA-induced ROS formation was shown to be dependent on the presence of extracellular $Ca^{2+}$ and was further reduced when cytosolic $Ca^{2+}$ was chelated by BAPTA/AM and EGTA. To delineate the causal effects, we showed that the increase of intracellular calcium activating $PKC_{\beta II}$ preceds the generation of ROS. We further concluded that inductive GRP78 expression by GA requires consecutive mediators of calcium, $PKC_{\beta II}$ and ROS to concert this induction.

### Crosstalk Between Huntingtin N-terminal Fragments and Syntaxin 1A Regulates N-type Calcium Channels

L. Swayne, L. Chen, G. W. Zamponi, J. E. Braun; Physiology and Biophysics, University of Calgary, Calgary, AB, Canada

We have identified a novel interaction between N-terminal huntingtin fragments ($huntingtin^{exon1}$) and the synaptic protein interaction (synprint) region of the $Ca_v2.2$ subunit of the N-type calcium channel, which is a voltage-gated calcium channel important for neurotransmission. The synprint region associates with $huntingtin^{exon1}$ containing both wildtype and mutant numbers of glutamine repeats and the native proteins interact in mouse and brain homogenates. The interaction of $huntingtin^{exon1}$ with N-type calcium channels results in the disruption of syntaxin 1A-mediated effects on both channel inactivation and regulation by G proteins. To begin to address the mechanism through which htt disrupts syntaxin 1A effects on the N-type channel, we examined the $huntingtin^{exon1}$- and syntaxin 1A-binding properties of $Ca_v2.2$ synprint, and demonstrate that these proteins bind to overlapping sites of $Ca_v2.2$ synprint. We further show that $huntingtin^{exon1}$ and syntaxin 1A compete for synprint binding *in vitro*, suggesting that huntingtin exerts its effects through competition with syntaxin 1A for synprint binding. These results identify the regulation of N-type calcium fluxes as a novel role of huntingtin.

### Signaling Pathway of Ginsenoside-Rg1 Leading to Nitric Oxide Production in Endothelial Cells

K. Leung,[1] N. Mak,[1] T. Fan,[2] R. Wong[1]; [1]Department of Biology, Hong Kong Baptist University, Hong Kong, China, [2]Department of Pharmacology, University of Cambridge, Cambridge, United Kingdom

The pharmacological activity of *Panax ginseng* has been ascribed to a group of steroidal saponins known as ginsenosides, of which more than 30 members have been isolated and characterized from the *Panax* species. We here provide evidence that Rg1, one of the major ginsenosides of ginseng, is a functional ligand of the glucocorticoid receptor as determined by fluorescence polarization assay ($IC_{50}$ = 140 nM; $K_d$ = 43 nM). Rg1 increased the phosphorylation of the glucocorticoid receptor, phosphatidylinositol-3 kinase, Akt/protein kinase B, endothelial nitric oxide synthase (eNOS) and NO output in human umbilical vein endothelial cells. Phosphorylation of eNOS and the production of nitric oxide were significantly reduced either by RU486 (glucocorticoid receptor antagonist), LY294002 (phosphatidylinositol-3 kinase inhibitor), SH-6 (Akt/protein kinase B inhibitor), or L-NMMA (nitric oxide synthase inhibitor). The Rg1-induced phosphorylation and the subsequent translocation of the glucocorticoid receptor to the nucleus were also abolished by RU486. This study revealed that Rg1 can indeed serve as an agonist ligand for the glucocorticoid receptor and the activated glucocorticoid receptor can induce rapid nitric oxide production from endothelial nitric oxide synthase via the non-transcriptional phosphatidylinositol-3 kinase /Akt pathway.

### The Inhibition of Glucose Transporter-4 (Glut4) by Down Syndrome Critical Region-1 (DSCR1)

S. Lee, H. Youn; Biochemistry and Molecular Biology, Seoul National University College of Medicine, Seoul, Republic of Korea

Down syndrome (DS) has been caused by trisomy of human chromosome 21. The study of patients with partial trisomy 21 has defined an area of approximately 3 Mb at chromosomal region 21q22 as Down syndrome candidate region. In particular, since the gene of Down syndrome critical

region-1 (DSCR1) is located in human chromosome 21q22.1-q22.2 and encodes a 197aa-long protein, DSCR1 has been suggested as one of candidate genes involved in DS. It was initially proposed that DSCR1 negatively regulated the calcineurin activity because DSCR1 was found as a calcineurin inhibitory protein. On the other hand, an increasing number of degenerative diseases, including DS, are known to be associated with increased insulin resistance. Thus we investigated whether DSCR1 influences glucose uptake upon insulin stimulation. Ectopically-expressing DSCR1 markedly inhibited the translocation of Glut4 into plasma membrane, and also inhibited [C]$^{14}$-glucose uptake upon insulin stimulation. When the effective domain of DSCR1 was narrowed down, N-terminal domain of DSCR1 (1-90 amino acid) inhibited the translocation of Glut4. Taken together, we suggest that the intrinsic function of DSCR1 may negatively regulate Glut4 translocation to block glucose uptake in neuronal cell.

**Myelin Protein Zero Trafficking and Quality Control in Charcot-Marie-Tooth Neuropathies**

M. D'Antonio,[1] M. Pennuto,[1] E. Tinelli,[1] A. Quattrini,[2] M. L. Feltri,[1] L. Wrabetz[1]; [1]San Raffaele Scientific Institute, DIBIT, Milano, Italy, [2]Department of Neurology, Ospedale San Raffaele, Milano, Italy

Myelin is a multilamellar membrane that surrounds and supports axons, and facilitates rapid saltatory conduction of impulses. Myelin Protein Zero (MPZ, P0) is the most abundant glycoprotein of peripheral myelin. Several human inherited neuropathies with defects in peripheral nerve myelin are caused by mutations in the MPZ gene. Diverse mutations produce different phenotypes, ranging from mild Charcot-Marie-Tooth (CMT) disease type 1B to the more severe forms Dejerine-Sottas syndrome (DSS) and Congenital Hypomyelination or even axonal neuropathy, suggesting gain of function mechanisms. Deletion (S63del) or conversion of serine 63 to cysteine (S63C) results in CMT1B or DSS, respectively. We show that when expressed in mouse together with wild type P0, either mutant P0 produces a demyelinating neuropathy that mimics the corresponding human disease. In parallel with diverse nerve phenotypes, S63C is mostly trafficked to myelin where it creates a packing defect, while S63del is retained in the endoplasmic reticulum (ER)-Golgi complex. Protein quality control in the ER ensures that only correctly synthesized proteins are delivered to the final destination. Indeed, accumulation of P0S63del in the ER triggers an unfolded protein response (UPR) in a dose-dependent fashion, indicating a toxic gain of function. Preliminary data suggest that the UPR mediator CHOP transcription factor modulates neuropathy in Ser63del mice. Systematic analysis of gene expression is underway in these mice. These data suggest that different forms of protein quality control contribute to diverse demyelinating phenotypes in CMT neuropathies.

**DISC1 Regulates the Localization of Grb2 into the Axon via Kinesin-1**

T. Shinoda, S. Taya, K. Kaibuchi; Department of Cell Pharmacology, Nagoya University, Nagoya, Japan

*Disrupted-In-Schizophrenia-1* (*DISC1*) is identified at the breakpoint of a chromosomal translocation associated with schizophrenia in a large Scottish family. The physiological functions of DISC1, however, have been not well understood. Here, we identified Grb2 as a novel DISC1-interacting molecule by using affinity column chromatography. Grb2 is crucial for the activation of various intracellular signaling pathways. Grb2 is composed of one Src-Homology-2 (SH2) domain and two Src-homology-3 (SH3) domains. The N-terminal SH3 domain of Grb2 directly recognized DISC1. In cultured hippocampal neuron, both DISC1 and Grb2 accumulated in the distal part of axon. The knockdown of DISC1 by RNA-interference resulted in the delocalization Grb2 from axonal tips. As we previously identified Kinesin-1 as a DISC1-interacting molecule, we investigated the possibility that DISC1 is involved in the Grb2 transport or localization via Kinesin-1. Kinesin-1 is a molecular motor on microtubules, composed of two kinesin heavy chains (KIF5A, 5B or 5C) and two kinesin light chains (KLC1 or KLC2). Grb2, DISC1 and KIF5A formed a trimolecular complex both in vivo and in vitro. The functional blocking of Kinesin-1, by using a dominant-negative form of KIF5A or by the knockdown of kinesin light chains, resulted in the misloalization of Grb2 as well as DISC1 from the distal part of axon. These results suggest that the localization of Grb2 is regulated by DISC1 and Kinesin-1.

**Mimicking in-vivo Conditions at the Rim of an Ischemic Infarct Core**

H. Yao,[1] Y. Shu,[2] G. G. Haddad[1]; [1]Department of Pediatrics, Albert Einstein College of Medicine, Bronx, NY, [2]Department of Neurobiology, Yale University School of Medicine, New Haven, CT

Acute reduction of blood supply to an area in the brain can create immediately an ischemic infarct, a core that harbors dead cells. Due to processes of release or secretion from dead or dying cells, the biochemical and ionic alterations within the core are dramatic. Hence, adjacent cells are generally exposed to these changes and may be affected deleteriously, enlarging the core into the penumbra. To develop an in-vitro model that mimics some of these conditions, we have developed an ischemic solution (IS) that resembles the extracellular fluid in the infarct core “territory”. Compared to normal solutions (ACSF), IS is characterized by a) low $O_2$ (1.5%); b) low glucose (3 mM); c) low pH (6.4); d) excitotoxic (100 µM glutamate); and e) ionic alterations (64 mM $K^+$, 51 mM $Na^+$, 0.13 mM $Ca^{2+}$, 81.5 mM $Cl^-$ ). We have examined cell injury/death using propidium iodide (PI) uptake in organotypic hippocampal slice cultures after exposure to IS. Our preliminary data have shown a significant PI uptake (mean fluorescent intensity: MFI) starting 4 hours after IS treatment in CA1, CA3 and DG regions in hippocampal slices (for example, MFI in CA1: 67±5, n=36 in IS group vs 38±2, n=19 in ACSF group, $p < 0.001$). PI uptake continued to increase with continued exposure (at 24 hour for example, MFI in CA1: 596±34, n=36 in IS group vs 192±23, n=20 in ACSF group, $p < 0.001$). These data suggest that a direct exposure to IS can cause neuronal degeneration and the underlying mechanisms of cell death may resemble those in the territory between the infarcted core and the penumbral area following focal ischemia.

2868

**Inactivation of Calcineurin by Redox-mediated Proteolysis**

J. Lee, H. Kim, H. Youn; Department of Biochemistry and Molecular Biology, Seoul National University College of Medicine, Seoul, Republic of Korea

An increase in reactive oxygen species (ROS) is correlated with the loss of calcineurin activity under oxidative or neuropathologic conditions. However, the detailed molecular mechanism of ROS-mediated calcineurin inactivation is still obscure. Here we describe a novel mechanism by

which hydrogen peroxide inactivates calcineurin by cleaving the specific sequence within the catalytic domain. The cleavage form of calcineurin completely lost its enzymatic activity. The post-treatment of antioxidant *in vivo* did not recover the calcineurin activity damaged by hydrogen peroxide, suggesting that hydrogen peroxide irreversibly inactivates calcineurin *in vivo* by proteolytic cleavage rather than by the alteration of redox state of metal center. Furthermore, calcineurin was markedly cleaved in brain tissues of Alzheimer disease patients. Thus, our findings provide a new insight into how redox insult inactivates calcineurin and accumulates hyperphosphorylated tau in Alzheimer disease.

2869

**RING Finger Protein 11 Localizes to Mitochondria and Interacts with Mitochondrial Proteins**

B. R. Whatley, L. Chin, L. Li; Pharmacology, Emory University, Atlanta, GA

Dysregulated ubiquitin/proteasome-mediated protein degradation and impairment of mitochondrial function have both been implicated in the pathogenesis of several neurodegenerative diseases, including Parkinson's and Alzheimer's disease. However, the interplay between these two processes is not understood. Among the molecular components of the ubiquitin-proteasome pathway, the E3 ubiquitin-protein ligase is perhaps the most important player because it recruits the substrates for ubiquitination and determines the specificity of protein degradation. RING finger protein 11 (RNF11) is a ubiquitously expressed protein originally identified in a search for novel proteins containing the RING finger, a motif that has been implicated as a key determinant of the E3 ligase activity. The biochemical function and cellular role of RNF11 remain poorly characterized. To identify protein interactors of RNF11, we performed yeast two-hybrid screens of a rat brain cDNA library using full-length and C-terminally truncated (deletion of the RING finger motif) forms of RNF11 as bait. We isolated two different clones that encode mitochondrial proteins. Immunofluorescence confocal microscopic analysis reveals that, in transfected HeLa cells, RNF11 exhibits significant colocalization with mitochondrial markers TIM23 and Mitotracker. To confirm the mitochondrial localization of RNF11, crude mitochondrial fractions were prepared from lysates of transfected HeLa cells and further fractionated on a 10-30% OptiPrep gradient. Immunoblot analysis of the obtained fractions shows clear co-fractionation between RNF11 and mitochondrial markers. These results suggest that RNF11, a putative E3 ubiquitin-protein ligase in brain, may play a role in the regulation of mitochondrial function.

**Manipulating the Intracellular Fate of a Protein: Making an Aggregate-Prone Mutant Rhodopsin to Fold**

S. Kaushal, B. Noorwez, S. Noorwez; Ophthalmology, University of Florida, Gainesville, FL

Like many other acquired and genetic protein conformational diseases (PCDs), P23H opsin associated with Autosomal Dominant Retinitis Pigmentosa (ADRP) is a misfolded protein retained within the cell and forms inclusion bodies. We had previously described a set of pharmacological chaperones, including the native chromophore 11-*cis* retinal, that promoted the *in vivo* folding and stabilization of P23H opsin. Like the wild-type protein, the rescued mutant formed pigment and was transported to the cell surface. In this study, we investigate the effect of inhibitors of various cellular enzymes and pathways that may participate in the intracellular fate of P23H opsin. Mutant and WT and P23H opsins were expressed separately in HEK293 stable cell lines in the presence or absence of 11-*cis* retinal and various inhibitors. At 48 hrs, the amounts of folded protein were selectively immunoaffinity purified and quantitated by UV-visible spectroscopy. Strikingly, we demonstrate that inhibitors of the proteasome or autophagy led to significant increases (2.5-4.0 X) in the amount of folded P23H rhodopsin while their effect on the WT protein was minimal. We also demonstrate that by inhibiting the endoplasmic reticulum (ER) glucosidases I and II with castanospermine or inhibiting ER to Golgi transport by Brefeldin A increased the yields of the folded mutant protein by 1.2-2X. This is the first demonstration that by titrating the inhibition of various cellular processes, including the major quality control systems of the cells, the amount of a mutant folded protein can be increased to wild-type levels. Further, we clearly establish the importance of both major degradative pathways in the steady-state levels of a mutant protein. In conjunction with chemical and pharmacological chaperones, this approach may be useful as an adjuvant therapy for PCDs like ADRP.

2871

**CLN3 and CLN6 Mutations Lead to Trafficking Defects in Lysosomal-targeted Pathways**

Y. Cao, J. A. Espinola, M. E. MacDonald, S. L. Cotman; Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA

The *CLN3* and *CLN6* genes encode novel membrane proteins disrupted in two forms of neuronal ceroid lipofuscinosis (NCL), juvenile and variant late-infantile NCL, respectively. The *CLN3*-encoded protein, CLN3 or battenin, localizes to endosomal/lysosomal membranes, and the *CLN6*-encoded protein, CLN6 or linclin, localizes to the endoplasmic reticulum membrane. Despite these differing subcellular localizations, both forms of NCL exhibit autolysosomal accumulation of subunit c of the mitochondrial ATPase $F_0$ complex, suggesting battenin and linclin may function in the autophagic turnover of mitochondria. To further study the effects of the *CLN3* and *CLN6* NCL mutations on the autophagic pathway and other membrane trafficking pathways, we have established genetically accurate cerebellar neuronal precursor cell lines from *Cln3*$^{\Delta ex7/8}$ knock-in mice and *Cln6*$^{nclf}$ spontaneous mutant mice. We have previously shown that homozygous Cb*Cln3*$^{\Delta ex7/8}$ cerebellar cells exhibit defects in endocytic membrane trafficking, and more recent studies indicate an upregulation of autophagy. Moreover, changes are observed in two enzymes whose deficiencies also lead to autolysosomal subunit c accumulation, specifically the cathepsin D and tripeptidyl peptidase-I (TPP-I) enzymes. In preliminary studies of homozygous Cb*Cln6*$^{nclf}$ cerebellar precursor cells, we likewise have observed changes in cathepsin D and TPP-I enzymes. In the case of cathepsin D, both battenin and linclin deficiency lead to altered processing of the enzyme. However, TPP-I enzyme is altered differently in each case, with battenin and linclin deficiency leading to increased or decreased levels, respectively. These data support the hypothesis that the *Cln3* and *Cln6*-encoded proteins act at different levels in the same pathway, a notion consistent with their different subcellular localizations and the variable but related NCLs to which they are linked. Future studies will provide further comparative analyses and will further explore the specific membrane trafficking pathways that require battenin and linclin function.

2872

**Glutamate-induced Oxidative Stress Activates a Novel Cell Death Signaling Pathway Where Extracellular Signal Regulated Kinases-1/2 (ERK1/2) Activation Is Downstream of a Caspase-1-like Protease and Upstream of Calpain Activation**

R. Stetler, D. B. Defranco; Neuroscience and Pharmacology, University of Pittsburgh, Pittsburgh, PA

Glutamate-induced oxidative stress in immature neurons and hippocampal-derived HT22 cells occurs independently of excitotoxicity, as these cells

lack ionotropic glutamate receptors. Previous studies have found that inhibition of the mitogen-activated protein kinase (MAPK) pathway, calcium influx, and caspase-1-like protease(s) are protective against cell death caused by glutamate-induced oxidative stress, and the persistent activation of ERK1/2 is necessary for glutamate-induced oxidative toxicity in HT22 cells. However, the interactions between the cell death machinery responsible for glutamate-induced oxidative toxicity and ERK1/2 activation are as yet unknown. We sought to further characterize proteases activated following glutamate-induced oxidative stress in HT22 cells, and determine their interactions with the MAPK pathway. Inhibition of caspase-1- or -2-like proteases by YVAD.fmk or VDVAD.fmk blocked glutamate-induced toxicity and ERK1/2 activation, suggesting that ERK1/2 activation is downstream of a caspase-1- or -2- like protease. We have also found that calpain activity was significantly increased in HT22 cell lysates at 11h following 5mM glutamate treatment. Furthermore, overexpression of the endogenous calpain inhibitor, calpastatin, in transiently transfected HT22 cells delayed glutamate-induced cell death. However, unlike caspase-1- or -2- like inhibitors, calpain inhibition had no significant effect on phospho-ERK1/2 activation. Inhibition of ERK1/2 activation with U0126 blocked glutamate-induced calpain activation, further corroborating the ERK1/2 requirement for activation of calpain. Taken together, these results suggest that two distinct proteases are involved in ERK1/2-dependent oxidative toxicity, where a caspase-1- or -2-like protease appears to lie upstream of ERK1/2 activation, while calpain activation is triggered by chronically active ERK1/2.

2873

### Receptor Usage of Herpes Simplex Virus Type 1 (HSV-1) for Entry of Neurons

M. Yoon, P. G. Spear; Microbiology-Immunology, Northwestern University Medical School, Chicago, IL

Herpes simplex virus type 1 (HSV-1) can enter cells expressing one of multiple entry receptors, including herpesvirus entry mediator (HVEM), nectin-1, nectin-2 and sites in heparan sulfate generated by specific 3-O-sulfotransferases (3-O-S-HS). The viral ligand for these receptors is glycoprotein D (gD). Given that multiple cell surface receptors can be used by HSV-1 to enter cells, which ones are actually used to infect epithelial cells at the portal of entry and to spread to neurons? Usage of alternative receptors can enable a virus to infect multiple cell types that differ in receptor expression. In this study, we have generated a panel of recombinant viruses with altered receptor usage: viral mutants which cannot use HVEM and 3-O-S-HS as entry receptors, while preserving ability to use nectin-1;viral mutants which cannot use HVEM and 3-O-S-HS, while preserving ability to use nectin-1 and conferring its ability to use nectin-2; viral mutants which can not use nectin-1 and 3-O-S-HS as entry receptors, while preserving ability to use HVEM; viral mutants which can not use nectin-1 as entry receptors, while preserving ability to use HVEM and 3-O-S-HS. Viral mutants that can only use HVEM as an entry receptor were unable to infect human neuronal cell lines, including IMR5 and SH-SY5Y, whereas other viral mutants that can use nectin-1 as an entry receptor can infect these cells, suggesting that nectin-1 is the principal receptors for HSV-1 entry. Recombinant viruses use receptors other than nectin-1 may establish transient infections in neurons, but perhaps not latent infections, and are therefore candidates for development of safe live virus vaccines.

### Immunization with Pemphigus Anti-idiotype F(ab)'$_2$ Fragments Elicit Anti-epithelial Antibodies in Balb/c Mice

E. Avalos-Díaz,[1,2] G. Pacheco-Tovar,[1] J. Bollain-y-Goytia,[1] E. López-Robles,[1] E. Alvarado-Flores,[2] R. Herrera-Esparza[1]; [1]Immunology, Universidad Autónoma de Zacatecas, Zacatecas, Mexico, [2]Servicios de Salud de Zacatecas, Zacatecas, Mexico

Theoretically the immunization with anti-idiotype antibodies would elicit antibodies capable to recognize epitopes like the original idiotype. In present studies adult Balb/c mice were used to produce anti-epithelial antibodies based in internal images of pemphigus anti idiotype antibodies, which were previously produced in rabbits (Cre anti-idiotype), IgG was digested with pepsin to obtain Cre anti-idiotype F(ab)'$_2$ fragments, which were purified by gel filtration chromatography. Control Balb/c mice were weekly immunized with normal F(ab)'$_2$ fragments; another group was immunized with anti-idiotype F(ab)'$_2$ fragments. Animals immunized with anti-idiotype F(ab)'$_2$ fragments develop anti-epithelial antibodies within two months; they had anti-desmoglein 1 specificity demonstrated by ELISA. These animals had epidermal deposition of IgG along inter-cellular spaces. Control Balb/c mice group was negative. Main observation of this work is that internal images of pemphigus anti-idiotype antibody would elicit anti-epithelial antibodies; this immunological approach can be used to understand pathogenic mechanisms in pemphigus.

2875

### Neutrophil Function Is Not Compromised in Mice with Deficiency of the Shwachman-Diamond Syndrome Gene in Myeloid Lineages

S. Zhang,[1,2] J. Zhong,[2] M. Glogauer,[3] J. Rommens[1,2]; [1]Department of Molecular and Medical Genetics, University of Toronto, Toronto, ON, Canada, [2]Genetics & Genomic Biology, The Hospital for Sick Children, Toronto, ON, Canada, [3]CIHR Group in Matrix Dynamics, University of Toronto, Toronto, ON, Canada

The reported neutrophil deficiencies in Shwachman-Diamond syndrome include problems with cell numbers as well as migration responses to chemotactic agents. A novel and highly conserved gene with poorly characterized function, called SBDS, has been identified as being responsible for this genetic disorder with loss of function mutations. Complete loss of Sbds leads to embryonic lethality, so a gene targeting methodology with a Cre-Lox strategy was used to generate Sbds alleles that could be ablated in selected tissues. To characterize the role of Sbds in neutrophil function, breeding with a transgenic mouse with Cre under control of the Lysozyme M promoter, produced mice deficient in Sbds in their monocyte and myeloid lineages. Sbds was confirmed to be markedly reduced in mature neutrophils isolated from mutant mice by Percoll gradient centrifugation using Western blotting. However, circulating cell counts of blood lineages, including neutrophils, were normal in adult mice. In an in vitro chemotaxis assay, mutant neutrophils also showed a normal response to fMLP. Upon in vivo induction of inflammation, the increase of peripheral neutrophils of mutant mice were found to be comparable to wild type mice. To test migration, penetration and adhesion, a peritoneal inflammation model was obtained by injection with sodium periodate. We observed similar neutrophil accumulation between the mutant and wild type mice. Our results indicate that Sbds is dispensable for mature neutrophil and chemotaxis function, and that deficiency in patients is likely due to early hematopoietic abnormalities.

2876

**Mutant Alpha-1 Antitrypsin Induces Expression of Unfolded Protein Response, Apoptosis and Pro-Inflammatory Genes**

V. S. Mishra,[1] C. Lui,[2] J. Stocks,[1] M. Brantly[1]; [1]Medicine, University of Florida, Gainesville, FL, [2]Pathology, University of Florida, Gainesville, FL

Alpha-1 antitrypsin (AAT) is a 52 KD bean-shaped glycoprotein that is synthesized by the liver and secreted in abundance into the circulation. AAT deficiency is one of the most common inherited risk factors for liver disease in adults and children. The most common mutation in the AAT gene associated with AAT deficiency and liver disease is the Z mutation. The Z mutation is a single base pair substitution of A to G that causes a single amino acid (Glu342Lys) change at the base of the reactive site loop. The mutant Z AAT mis-folds and accumulates in the rough ER of the cell as both polymer and monomer. In this context Z AAT is a classic conformational disease. Mis-folded proteins may induced an unfolded protein response (UPR). We hypothesize that Z AAT also induces a UPR that in turn activates down stream genes associate with inflammation and cell death. To evaluate this hypothesis, we used a cell line derived from the liver of PI*Z individual and AAT-specific siRNA to evaluate UPR & AAT gene expression by quantitative PCR. Positive and negative controls demonstrated the there were not off target effects of AAT siRNA transfection. siRNA knock down of AAT gene expression caused significant reductions in the expression of UPR related genes including ATF6 ($p=0.0001$) and Perk ($p=0.002$) as well as, down stream genes involved in protein folding such as BiP ($p=0.008$) & GP96 ($p=0.02$), innate immunity such as TLR4 ($p=0.03$), NFkB ($p=0.02$) and IRAK $p=0.01$) and apoptosis, CHOP ($p=0.01$). These results establish an important relationship between mis-folding of Z AAT, the UPR, pro-inflammatory responses and cell death.

2877

**Effects of BLX-1060, an Orally Active, Amino-Acid Based Small Molecule, in Rodent Models of Inflammatory Bowel Disease**

A. P. Sen, M. Anumula, H. Vargas, A. Nag, D. Dey, P. Nag, B. Nag; Bexel Pharmaceuticals, Union City, CA

BLX-1060 is a water-soluble, amino-acid conjugated small molecule with anti-inflammatory properties. It does not show any cytotoxicity in different cell types upto 100 uM concentrations. Here we report the effects of BLX-1060 on rodent models of inflammatory bowel disease (IBD) and IL-12, a biomarker for IBD. At 3-100 uM concentrations, BLX-1060 in a dose-dependent manner inhibited LPS-induced IL-12 increase in human peripheral blood mononuclear (hPBMC) cells and in mouse peritoneal macrophages. In an *in vivo* efficacy study mice were fed with dextran sodium sulfate (4% w/v) in drinking water to induce IBD. Disease activity index (DAI), a measure for the severity of IBD, was measured. DAI consists of body weight changes, stool consistency and occult blood. BLX-1060 was administered at 1, 10 and 100 mg/kg/day, PO, for 21 days. BLX-1060 dose-dependently decreased the DAI. Histological evaluation of the colons showed a decrease in the severity of colitis by BLX-1060 compared with the vehicle-treated group. In another *in vivo* efficacy study rats were treated with 30 mg of trinitrobenzene sulfonic acid (TNBS) rectally to induce colitis. BLX-1060 was administered at 100 mg/kg/day, PO for 15 days. BLX-1060 prevented TNBS-induced decrease in body weights. Upon termination the colons were subjected to histopathological evaluation. BLX-1060 was found to decrease the severity of inflammation in the colons. Taken together, these studies conclude that BLX-1060 is a potential new drug for the treatment of inflammatory bowel disease.

2878

***hprt* Locus Permissivity for *in vivo* Inducible Over- and Down-expression through Targeted Transgenesis**

F. Jaisser,[1] C. Fages,[2] R. Willmotte,[2] G. Palais,[1] K. Grisoni,[2] A. Peterson[3]; [1]INSERM, Paris, France, [2]Nucleis, Lyon, France, [3]McGill University, Montreal, PQ, Canada

Random transgenesis has many limitations like positional effects (ectopic expression and variability of transgene expression level). One alternative approach is targeted transgenesis at the permissive *hprt* locus. We are using a powerful technology (Speedy Mouse® Technology) for generating "high throughput" *in vivo* models. This strategy is based on ES cells called BPES cells with high germline transmission potency and selectable targeted transgenesis. First, we have optimized different strategies for conditional transgene expression, *ex vivo* and *in vivo* in ES-derived transgenic models. Conditional and inducible gene expression is achieved with the tetracycline system. Recombined BPES with a bidirectional GR-tetO-LacZ construct (allowing tet dependent expression of the glucocorticoid receptor (GR) and LacZ) have been obtained and stably transfected with a CMV-rTAS2-M2 construct. This led to high, inducible LacZ expression, only in the presence of the Doxycycline, indicating the absence of leakness and efficiency of inducibility. F1 mice were obtained by breeding the MHCtetOFF mouse strain and the mouse chimeras derived from the GR-tetO-LacZ BPES cells. Cardiac LacZ expression is currently compared to those obtained after random integration of the same construct. Second, we developed strategies for conditional and inducible *in vivo* RNAi expression after shRNA targeted transgenesis.. In vivo expression of a CD8α shRNA construct targeted into the *hprt* locus of BPES cells led to a specific 82 % inhibition of CD8α expression in both thymus and spleen in F0 and F1 generations. This is similar to what previously obtained by classical random transgenesis with CD8α shRNA lentivirus. In conclusion, single copy integration of either tet inducible or shRNA constructs through targeted transgenesis in the BPES cells appears to be as efficient as random transgenesis but more poweful in term of time and predictability.

2879

**Steady Shear Flow Suppresses Cytokines-Induced Responses in Endothelial Cells**

L. D. Wang; Institute of Biomed. Sciences, Academia Sinica, Taipei, Taiwan Republic of China

Endothelial cells (ECs) are constantly exposed to blood flow-induced shear stress (SS). Laminar shear stress protects ECs from atherogenesis, whereas disturbed flow occurred near bifurcation predisposes ECs toward inflammation. We have shown that SS suppresses serum- and IL-6-induced Stat3 activity. IFNγ-induced chemokines'expression for T cells attachment was shown to be associated with atherogenesis. In this study, the effect of shear stress (SS) on IFNγ-induced responses in ECs was examined by utilizing a well-defined flow chamber system. ECs exposed to IFNγ triggered JAK/STAT1 activation with the phosphorylation of Tyr701 and Ser727 in STAT1. SS alone had no effect on STAT1 activation in ECs at basal condition. When SS was applied to IFNγ-treated ECs, it significantly attenuated IFNγ-induced Tyr701 phosphorylation with a shear force- and time- dependent manner whiles Ser727 phosphorylation was unaffected. Consistently, IFNγ-induced STAT1-DNA binding ability was abrogated by SS. ECs after IFNγ treatment increased the expression of three STAT1-mediated CXC chemokines for T cells attachment, i.e., IFN-inducible protein-10 (IP-10), monokine induced by IFNγ (Mig) and IFN-inducible T-cell a-chemoattractant (I-TAC). SS to IFNγ-treated ECs

reduced the expression of these chemokines. Furthermore, the inhibitory effect of SS on the IFNγ-induced responses was not observed in those ECs subjected to disturbed flow. Our results provide a new insight for the athero-resistant nature in the straight segments of arterial tree where cytokine-induced responses including T cells recruitment are suppressed.

**Effects of Hyaluronan on Inflammation-Induced Angiogenesis**

M. Onodera,[1,2] T. Muneta,[3] K. Miyazaki,[4] H. Yoshimasu,[1] I. Morita[2]; [1]Community Oral Health Care Science, Tokyo Medical and Dental University, Tokyo, Japan, [2]Cellular Physiological Chemistry, Tokyo Medical and Dental University, Tokyo, Japan, [3]Orthopedic Surgery, Tokyo Medical and Dental University, Tokyo, Japan, [4]Seikagaku Corporation, Tokyo, Japan

Hyaluronan (HA), a core component of extracellular matrix, plays multifaceted roles in patho-physiological conditions. Among a lot of functions, we focused on effects of HA on inflammation-induced angiogenesis. First, we examined the direct effect of different molecular size of HA on angiogenic activity in bovine endothelial cells (EC) in vitro. The angiogenic activity was assessed by tube forming activity of EC in type I collagen gel. EC cultured between collagen were morphologically changed and formed tube-like structure. HA (MW<200K) had no effect on angiogenic activity, but HA (950K) used clinically inhibited it in a dose dependent manner. The inhibitory effect of HA (950K) was also observed in angiogenic activity induced by VEGF, and the inhibition was partly abolished by an addition of neutralizing antibody against CD44, one of the HA receptors. Next, we examined the effect of HA on inflammation-induced angiogenesis. The angiogenesis in rheumatoid arthritis (RA) has a crucial role in the progression of the disease. Synovial cells were isolated from RA and osteoarthritis (OA) patients and cultured successively. The production of prostaglandin E2, one of the angiogenic factors, induced by IL-1 was dramatically inhibited by HA (950K) via inhibition of COX-2 expression in synovial cells. In synovial fluids, HA is decomposed to lower molecule HA by hyaluronidase. Therefore, finally we identified hyaluronidase in the synovial fluid. As a result, hyaluronidase in the synovial fluid was identified as hyaluronidase-1, and the activity in RA-synovial fluid was higher than that in OA-synovial fluid. (Conclusion) High molecule HA inhibited angiogenesis directly and indirectly in inflamed tissues such as RA, and endogenous hyaluronidase-1 may regulate the anti-angiogenic activity of HA.

**Human Endothelial Cells Secrete ST2, an Interleukin-1 Receptor Family Member, in Response to Inflammatory/Growth Stimuli**

K. A. Kassik, E. O. Weinberg; Medicine/Cardiovascular, Boston University Medical Center, Boston, MA

ST2 is an interleukin-1 (IL-1) receptor family member encoding a membrane-anchored receptor and a soluble secreted receptor that directs T cell function and negatively modulates interleukin-1 receptor signaling in T cells and macrophages. We have previously shown that serum levels of soluble ST2 predict mortality in cardiovascular diseases in humans. We tested whether human endothelial cells can secrete soluble ST2 and studied signaling pathways involved in ST2 induction in cultured human fibroblasts and endothelial cells. Methods: Fibroblasts were treated with phorbol ester (PMA, 0.2 microM) with and without the ER/Golgi vesicular traffic inhibitors, brefeldin (5 microg/mL) or monensin (200 nM). Endothelial cells were treated with PMA, IL-1 beta (5 ng/mL), VEGF (100 ng/mL) or TNF-alpha (100 ng/mL). Culture media was collected and assayed for ST2 (pg/mL) by ELISA (N=3-6/group). Results: Fibroblasts secrete ST2 in response to PMA (4.2 fold, 0.053+0.005) vs. control (0.012+0.002, $p<0.01$). Brefeldin prevented PMA-induced ST2 secretion (1.2 fold vs. control, NS). Monensin paradoxically enhanced PMA-induced ST2 secretion (8.7 fold, 0.10+0.006, $p<0.001$). In endothelial cells, ST2 secretion was induced by PMA (2.7 fold, 0.36+0.003), interleukin-1beta (3.2 fold, 0.427+0.005), VEGF (1.5 fold, 0.201+0.006) vs. control (0.133+0.006, all $p<0.01$). TNF-alpha did not induce secretion of ST2. In endothelial cells, ST2 secretion was completely blocked by ERK inhibition (U0126, 10 uM or PD098059, 10 uM), 50% blocked with JNK inhibition (SP600125, 50 uM), and marginally blocked (8%) with p38 inhibition (SB203580, 15uM). Conclusions: Induced secretion of ST2 involves ER/Golgi trafficking (blocked by brefeldin). Off-target effects of monensin (Na ionophore) may be the mechanism for enhanced ST2 secretion. Endothelial cells secrete ST2 in response to growth/inflammatory stimuli through ERK and JNK activation and are a potential source of elevated serum ST2 levels in patients with cardiovascular diseases.

**Studies on *O*-GlcNAc Modification of NF-κB p65 Subunit**

W. Yang, S. Park, D. Kim, H. Kim, J. Cho; Biology, Yonsei University, Seoul, Republic of Korea

NF-κB is a transcription factor and is important for expressing variable proteins related to inflammatory and immune responses. It is composed of a heterodimer of p65 and p50 subunits and is located in the cytoplasm by I-κB. When the nuclear localization signal is transduced, I-κB is degraded by ubiquitn-dependent manner and NF-κB is transported to nucleus. Functions of NF-κB is regulated by variable posttranslational modification like phosphylation, acetylation and ubiquitination. Also, NF-κB p65 is modified by *O*-GlcNAc but, the exact function of *O*-GlcNAc on NF-κB p65 has not been studied well. *O*-GlcNAc is dynamically modified in a β-linkage to serine or threonine residues of nuclear and cytoplasmic proteins by two enzymes, *O*-GlcNAc transferase (OGT) and *O*-GlcNAcase. In this report, roles and sites of *O*-GlcNAc modification on NF-κB p65 using human lung carcinoma cell, A549 has been investigated. We demonstrate that show that the treatment of STZ (streptozotocin), an *O*-GlcNAcase inhibitor, increases *O*-GlcNAc modification and the activity of NF-κB p65 without the degradation of I-κB and inhibits the binding of NF-κB p65 with I-κB. Also, we identified Thr 352 as a target for *O*-GlcNAc modification and transcriptional activation in response to STZ by mutational analysis. Moreover, *O*-GlcNAc modification and the transcriptional activity of NF-κB p65 were increased in STZ-induced diabetic mice. Our finding suggests that *O*-GlcNAc modification on Thr 352 of NF-κB p65 subunit increases the transcriptional activity and the increment of O-GlcNAc on NF-κB p65 subunit may be a reason for diabetic-associated NF-κB p65 subunit activation in diabetic mice. Therefore, our data may contribute to understanding of diabetes and its complications-associated NF-κB p65 activation.

**Myocardial Ischemia-Reperfusion Injury Results in Less Cardiac Tissue Damage and No Serum IL-6 Concentrations in W/W$^v$ Mast Cell Deficient Mice as Compared to their Normal +/+ Littermates**

K. Farwell,[1] K. Bhattacharya,[2] M. Huang,[1] J. Cao,[1] D. Kempuraj,[1] J. Donelan,[1] T. Theoharides[3]; [1]Pharmacology and Experimental Therapeutics, Tufts University School of Medicine, Boston, MA, [2]Department of Cardiac Surgery, University of Glasgow, Glasgow, United Kingdom,

[3]Pharmacology and Experimental Therapeutics, Biochemistry, and Internal Medicine, Tufts University School of Medicine, Boston, MA

Myocardial ischemia reperfusion (IR) injury complicates all forms of coronary artery revascularization. Cardiac mast cells have been implicated in IR; however, their involvement has never been quantified. We have shown that cardiovascular disease is associated with cardiac release of IL-6 and acute stress increases mast cell-dependent serum IL-6 levels in mice. In this study, we compared cardiac tissue susceptibility and serum IL-6 changes between the mast cell deficient ($W/W^v$) mice and their normal littermates (+/+). Twelve male $W/W^v$ mice and their +/+ littermates were anaesthetized with 2.5% isofluorane. The left coronary artery was ligated for 30 minutes. After 6 hours of reperfusion, the animals were sacrificed. The muscle viability was assessed on fresh whole-mount slices by the nitroblue tetrazolium histochemical assay and serum IL-6 concentrations measured with ELISA. Cardiac muscle viability was significantly higher in $W/W^v$ than the +/+ mice. Baseline serum IL-6 levels were higher in the +/+ controls (range=300-700 pg/ml, n=6) than $W/W^v$ mice (range=70-250 pg/ml, n=6) before IR and this level increased significantly after reperfusion only in the +/+ mice (range=500-800 pg/ml, n=6, $p<0.05$), while it remained the same in the $W/W^v$ mice (range=70-280 pg/ml, n=6). These results show that the absence of mast cells reduces the myocardial damage associated with IR injury. Furthermore, there is an attenuation is the inflammatory response, as measured by serum IL-6 levels, following this local insult. This finding entertains the prospect of developing prophylactic therapy - targeting selective inhibition of cardiac mast cell activation, in clinical situations involving medical or surgical myocardial revascularization (Supported by Theta Biomedical Consulting and Development Co., Inc., Brookline, MA; KF was a Tufts University Shader Family Summer Research Fellow).

**Corticotropin-Releasing Hormone Induces Vascular Endothelial Growth Factor (VEGF) Release from Human Mast Cells via the cAMP/PKA/p38 MAPK Pathway**

J. Cao,[1] T. C. Theoharides[2]; [1]Departments of Biochemistry and Pharmacology and Experimental Therapeutics, Tufts University School of Medicine, Boston, MA, [2]Departments of Biochemistry, Pharmacology and Experimental Therapeutics, and Internal Medicine, Tufts University School of Medicine, Boston, MA

Mast cells are involved in allergic and anaphylactic reactions, but also in innate immunity and inflammation. Corticotropin-releasing hormone (CRH), the key regulator of the hypothalamic-pituitary-adrenal axis responses to stress, also has proinflammatory peripheral effects, apparently through mast cells. We showed recently that CRH selectively stimulates human leukemic mast cells (HMC-1) and human umbilical cord blood-derived mast cells (hCBMCs) to release newly synthesized VEGF without the release of preformed or other newly synthesized cytokines. This effect was mediated through activation of CRH receptor-1 and adenylate cyclase with increased intracellular cAMP. However, the precise mechanism by which CRH induces VEGF secretion has not yet been defined. In this study, we investigated whether protein kinase A (PKA) and mitogen-activated protein kinase (MAPK) signaling pathways are involved in this process. Using ELISA, we showed that CRH-induced VEGF release was dose-dependently inhibited by the specific PKA inhibitor H89 or the p38 MAPK inhibitor SB203580, but not by the specific inhibitors of MEK (PD98059), the upstream kinase of the extracellular signal-regulated protein kinase (ERK) or the c-Jun N-terminal kinase (JNK) inhibitor SP600125. Furthermore, CRH significantly increased PKA activity, which could be mimicked by the cell-permeable cAMP analogue 8-bromo-cAMP, and was blocked by H89 or the adenylate cyclase inhibitor SQ22536. Using Western blot analysis, we showed that CRH induced rapid phosphorylation of p38 MAPK, which was inhibited by H89 or SB203580. These results indicate that CRH induces VEGF release in human mast cells via the cAMP/PKA/p38 MAPK signaling pathways, thereby providing further insight into the molecular mechanism of how CRH affects the release of a key proinflammatory mediator. .

**Surface-cleaning Effects of Macrophages on Titanium Particles**

Z. Xing,[1] L. Pillati,[1] C. Alley,[2] K. A. Hasty,[1] R. A. Smith[1]; [1]Orthopaedic Surgery, University of Tennessee-Campbell Clinic, Memphis, TN, [2]Smith & Nephew, Inc., Memphis, TN

Titanium wear debris can stimulate the secretion of macrophages and result in bone resorption around orthopaedic implants. Titanium particles are non-degradable in human body and their long-term effects in vivo are yet to be studied. Titanium particles (Johnson Matthey, 1-3μm) washed with 70% ethanol were labeled as “As received particles”. The particles that were further incubated in 0.78μg/ml Lipopolyssacharide for 24 hours were labeled as “LPS-bound particles”. Some particles were added into Macrophage (IC-21, ATCC) culturing flask. After 24 hours, the flask was flushed by PBS to remove the free particles. The macrophages with phagocytosed titanium particles were incubated for 48 more hours until lysed by distilled water. After lysis, the titanium particles released by the macrophages were collected and washed with water and labeled as “cell treated particles”. The particles were suspended in RPMI-1640 medium and the concentrations were determined by scanning electronic microscope. Different types of titanium particles were added in macrophage culturing plate with a particle to cell ratio of 300 to 1. The media were harvested after 18 hours and the levels of TNF-α in the media were measured by ELISA. As received particles stimulated TNF-α secretion to a level of 37.46±6.49pg/ml, while LPS-bound particles resulted in a TNF-α level of 284.66±32.25pg/ml in the medium ($p<0.01$). However, after treated by macrophages, the particles lost their stimulatory effects on TNF-α secretion (10.23±5.11pg/ml; and 15.11±8.28pg/ml for as received/cell treated and LPS-bound/cell treated particles, respectively), although they were still extensively phagocytosed by the macrophages. This indicates that the titanium particles phagocytosed by the macrophages undergo processing that alters their surface features. After death of the macrophages, the released particles can still be phagocytosed by other macrophages, however they will no longer activate the secretion of the macrophages.

**Fluoride Regulates the Transcriptional Expression of MMP20 *in vitro***

Y. Zhang; Orofacial science, University of California, San Francisco, San Francisco, CA

Objective: Excessive fluoride intake during tooth enamel formation can result in enamel fluorosis, characterized by a delayed removal of amelogenin proteins as the enamel matures. In this study, we used ameloblast-lineage cells to investigate the effect of fluoride on the synthesis and secretion of matrix metalloproteinase 20 (MMP20), a proteinse involved in amelogenin hydroysis. Methods: Cultured ameloblast-lineage cells, isolated from human fetal tooth organs, were exposed to 10 μM fluoride and analyzed for synthesis of MMP20 by immunobloting and real-time PCR. Fluoride-specific effect on cell signaling pathways was investigated via gene array, enzyme activity blocking and Western Blot. Results:

Immunoblotting showed that 10uM NaF down-regulated the synthesis of MMP20 by 21.17%, but did not alter the amount of amelogenin and TIMP2 synthesized by the cells. Real-time PCR showed that 10uM NaF down-regulated MMP20 mRNA expression to 28.27% of the levels found in the non-treated cells. A human MAP kinase pathway gene array indicated that fluoride-mediated down-regulation of MMP20 transcription is related to the JNK/c-Jun MAP kinase signaling pathway. Meanwhile, Western blot analysis showed that fluoride suppressed the phosphorylation of JNK and c-Jun. Moreover, the JNK specific inhibitor SP600125 down-regulated the expression of MMP20, incidentally with the decline of phosphorylated JNK and c-Jun. DNA affinity precipitation assay showed that c-Jun bound to an AP-1 site on the MMP promoter. Conclusions: Those results suggest that the fluoride-mediated alternation of MMP20 synthesis is primarily regulated at the transcriptional level. A fluoride related reduction of MMP20 expression by ameloblasts through JNK/c-Jun signal pathway, may result in a disturbance of the balance between MMP20 and its protein substrates contributing to the mechanisms of enamel fluorosis.

**Pathogenesis of Light Chain (AL) Amyloidogenesis**

S. Davern, C. Murphy, S. Bohne, J. Wall, A. Solomon; Human Immunology & Cancer Program, University of Tennessee Medical Center, Knoxville, TN

The mechanism(s) responsible for the pathologic deposition of monoclonal light chains (i.e., Bence Jones protein [BJP]) as fibrils in the organs or tissue of patients with primary (AL) amyloidosis is presently unknown. As part of an effort to elucidate the pathogenesis of this disorder we have utilized an *in vitro* experimental culture system in which BJPs obtained from individuals with and without amyloidosis were incubated for 1-3h with human or murine fibroblasts and the extent of interaction determined quantitatively using a highly sensitive fluoroimmunoassay and qualitatively by fluorescence microscopy. These studies revealed that amyloidogenic BJPs bound preferentially; notably, this reactivity markedly increased when these molecules were rendered less stable through chemical modifications. Based on these findings, we posit that *in vivo* exposure of amyloid-associated BJPs to local cellular-derived factors results in destablilizing tertiary structural alterations and ultimately their deposition as amyloid fibrils.

2888

**Cell Culture Model of Hemifacial Hyperplasia and PTEN/mTOR Regulation**

S. L. Yen,[1] Y. Kiyomi,[1] C. Eng,[2] C. Cheung,[1] S. Kuznetsov,[3] P. Robey[3]; [1]Center for Craniofacial Molecular Biology, University of Southern California, Los Angeles,, CA, [2]Human Clinical Genetics Program, Ohio State University, Columbus, OH, [3]National Institute of Dental and Craniofacial Research, Bethesda, MD

The mechanisms involved in asymmetric facial overgrowth syndromes such as hemifacial hyperplasia(HFH) are not well understood. The PURPOSE of this study was to develop a model for comparing the difference between cells from normal and overgrowing bone. METHODS: Primary cultures of marrow stromal osteoblasts were developed from bone biopsies of normal and overgrowing bone. These cell cultures were seeded at the same concentrations and measured for cell size and number by flow cytometry. Affymetrix U95 microarrays were used to compare molecular phenotypes. The PTEN gene and promoter were sequenced; PTEN gene expression was examined by real-time PCR and Western blot analysis. Rapamycin(50 ng) was cultured with overgrown cell cultures for 72 hrs. RESULTS: Cell cultures from the overgrown side showed a 2-fold increase in cell size and cell number. A germline missense mutation was detected in the PTEN promoter which correlated with a 40% suppression of PTEN transcripts and protein. Akt-PKB phosphorylation increased in overgrown cells. Rapamycin treatment rescued the overgrown cell phenotype. CONCLUSION: The cell culture model suggests PTEN/mTOR regulation of bone cell growth in human patients with HFH

2889

**DALIS are Stress-Induced Protein Storage Compartments for Substrates of the Proteasome and Autophagy**

J. Szeto,[1] N. A. Kaniuk,[1] V. Canadien,[1] R. Nisman,[1] N. Mizushima,[2] T. Yoshimori,[3] D. P. Bazett-Jones,[1] J. H. Brumell[1]; [1]Cell Biology, Hospital for Sick Children, Toronto, ON, Canada, [2]Bioregulation and Metabolism, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan, [3]Cell Genetics, National Institute of Genetics, Mishima-Shizuoka, Japan

Dendritic cell aggresome-like induced structures (DALIS) are protein aggregates containing polyubiquitinated proteins. Originally identified in maturing dendritic cells, DALIS act as storage compartments for Defective Ribosomal Products (DRiPs) prior to their degradation by the proteasome. The purpose of this study was to investigate whether DALIS are able to form in other cell types. Here we demonstrate that DALIS can be observed in a variety of cell lines such as macrophages, fibroblasts, and epithelial cells in response to stress, including oxidative stress, transfection and starvation. In most cases, protein synthesis was essential for DALIS formation, indicating that DRiPs incorporation is required. Using immunofluorescence and electron spectroscopic imaging, we show that DALIS are protein-rich structures and are distinct from cytoplasmic stress granules, which can also form in response to a number of cellular stresses. Autophagy, which mediates the degradation of organelles, bacteria, and long-lived proteins, was found to regulate the DALIS phenotype. By using a chemical inhibitor of autophagy and an autophagy-deficient fibroblast cell line, we show that autophagy disruption enhanced DALIS formation under a variety of stress conditions. However, during starvation, DALIS formation in autophagy-deficient cells was only partially inhibited by protein synthesis inhibitors, indicating that both long-lived proteins and DRiPs can be targeted to DALIS. Our findings show DALIS formation can occur under a variety of stress conditions. Significantly, the DALIS phenotype is not exclusive to immune cells and can form in other cell types. Furthermore, we demonstrate that DALIS formation is negatively regulated by autophagy in response to stress, starvation, and infection. These studies indicate that in addition to DRiPs, long-lived proteins in the cytosol may also be incorporated into DALIS.

**Inhibition of Retinal Photoreceptor Cell Apoptosis by αA Crystallin**

G. Wu, S. Saraswathy, N. A. Rao; Ophthalmology, Doheny Eye Institute, Los Angeles, CA

Previously in the early phase of experimentally-induced intraocular inflammation, commonly referred as experimental autoimmune uveitis (EAU), we found the nitration of cytochrome c (cyto c) and upregulation of αA crystallin in the retina. Nitrated cyto c is known to cause apoptosis, but this cell damage was not observed. In this study, we determine if αA crystallin prevents the induction of an apoptotic cascade initiated by nitrated cyto

c. S-antigen was used to induce EAU in Lewis rats. In this induction, the peak of disease is normally seen at day 14 postimmunization (pi). In retinas of day 5 pi, cyto c was nitrated by mitochondrial peroxynitrite and released into the cytosol. In Western blot, nitrated cyto c was co-immunoprecipitated with anti-αA crystallin, indicating a binding of αA crystallin to the nitrated cyto c. Further, an *in vitro* cell-free system was used to duplicate the features of *in vivo* apoptotic program. In this system, the addition of nitrated cyto c/dATP triggered the cleavage of procaspase-3, initially into an intermediate subunit p24, and then to the final executioner subunits p20/p17. In this assay, the addition of αA crystallin led to a dose-dependent accumulation of p24 subunit and eliminated the subsequent formation of the executioner p20/p17 subunits as revealed by the Western blot. When nitrated cyto c is released in day 5 pi, with apoptotic protease activating factor-1 and ATP, it activates procaspase-9. The active caspase-9 then initiates the activation of procaspase-3. In this mitochondrial pathway of apoptosis, our results indicated that αA crystallin binds to 1) the upstream apoptogenic molecule, nitrated cyto c and; 2) the proteolytically-cleaved intermediate caspase-3 subunit p24, thereby effectively curtailing the subsequent generation of active caspase-3 in the early phase of intraocular inflammation. Supported by NIH EY015714

**Expression and Secretion of a Recombinant Protein Norrin in Yeast Cells**

B. S. Shastry,[1] R. Blackburn,[2] B. Kana,[2] N. Motwani[2]; [1]Biological Sciences, Oakland University, Rochester, MI, [2]ApoLife, Detroit, MI

The ocular manifestations of disorders such as familial exudative vitreoretinopathy, Norrie disease (ND), retinopathy of prematurity and Coats' disease are very similar and involve abnormal vascularization of the peripheral retina and retinal detachment. Previous studies have shown that all of these disorders are associated with mutations in the ND gene. In spite of this, little is known about norrin, its molecular mechanisms of action and its functional relationships with the detachment of the retina or the abnormal retinal vasculature. To obtain a large quantity of norrin for structural and functional studies, a cDNA fragment of approximately 450 bp was isolated by amplification of a plasmid containing norrin cDNA with a pair of primers. The primers contained an overlapping region of yeast secretory signal, XhoI and NotI restriction sites and a 6 x His - tag that was incorporated into the reverse primer. The amplified cDNA fragment was cloned into two yeast expression vectors containing either galactose or ethanol inducible hybrid promoters and transferred into yeast cells. A total of 12 clones were analyzed in four different shake flask fermentation for the presence of recombinant norrin using 4-20% Tris-Glycine gels under reducing conditions and GelCode Blue staining technique. Of the 12 clones analyzed, 5 clones were found to express a protein of approximate molecular weight 15kDa that was not detected in the control plasmid fermentation sample. This protein was secreted into the fermentation medium and not present in the cell extract of the fermentation sample. When attempts have been made to purify the protein using the Novagen His-Band system, no significant amount of purified protein was obtained.

2892

**Decreased Reproduction Capacity in Male Connective Tissue Growth Factor (CTGF/CCN2) Transgenic Mice**

Z. Zhou,[1] J. T. Hoskins,[1] S. Chakraborty,[1] D. R. Brigstock,[2] P. A. Harding[1]; [1]Zoology, Miami University, Oxford, OH, [2]Center for Cell and Vascular Biology, Columbus Children's Research Institute, Columbus, OH

Connective tissue growth factor (CTGF/CCN2) is a member of the CCN family. CCN family members are cysteine-rich proteins that are implicated in biological properties such as cellular proliferation, adhesion, extracellular matrix production, migration, and pathologies including tumor formation and fibrosis. An in vivo approach was taken to assess the biological significance of CTGF/CCN2 using transgenic mice. Transgenic mice were generated using the pIRES-EGFP expression vector using a bicistronic mRNA containing both human CTGF cDNA and enhanced green fluorescent protein (EGFP) coding sequences under the regulation of the cytomegalovirus immediate-early (CMV-IE) promoter. We observed a reduced reproductive ability for male CTGF transgenic mice. In order to begin to examine this phenomenon, male CTGF (n=6) and non-transgenic male littermates (n=6) were each placed with three wild-type female mice and plugs were examined every morning until bred. The ratio of plug to litter was 1:1 for wild-type males, whereas male CTGF mice exhibited a 4:1 ratio. Secondly, epididymal sperm was collected and examined for motility and number. No differences in sperm motility (~50% after 1 hr) or sperm number ($7.5 \times 10^5$ and $8.8 \times 10^5$ sperm/ml) between CTGF and non-transgenic littermates, respectively, were observed. However, upon histological examination of testes from 7-week CTGF and non-transgenic littermates using Masson-Trichrome, collagen was present within the interstitium of testes from CTGF transgenic mice. No collagen was present in the interstitium of male non-transgenic mice. Furthermore, electron microscopy (EM) of testes of 7-week CTGF transgenic mice presented occluded seminiferous tubules and an altered interstitium, as compared to non-transgenic littermates (n=4). In conclusion, we have generated a CTGF transgenic mouse model in which male CTGF mice have demonstrated a decreased reproductive ability that may be due to the formation of testicular fibrosis.

**Investigation of Advanced Glycation End Products - Anterior Cruciate Ligament Transection Model in Rat**

S. Lee,[1,2,3] S. Choi,[4] G. Song,[4] C. Uhm[1,2,3]; [1]Department of Anatomy, Korea University College of Medicine, Seoul, Republic of Korea, [2]Brain Korea 21 Biomedical Sciences, Seoul, Republic of Korea, [3]Korea Lung Tissue Bank, Seoul, Republic of Korea, [4]Department of Rheumatology, Korea University College of Medicine, Seoul, Republic of Korea

Osteoarthritis (OA) is one of the most frequent diseases in human musculoskeletal system, and the incidence of OA is increased with age. Most characteristic change in OA is the structural change of collagen and loss of proteoglycan present between collagens. Advanced glycation end products (AGEs) are formed by the nonenzymatic glycation and increased in amount by aging and hyperglycemia. AGEs are usually accumulated in the long-lived protein such as collagen in the articular cartilage. Accumulated AGEs make articular cartilage more stiff and fragile. This study was designed to compare the structure of normal articular cartilage in the knee joint to that of OA induced by ACLT after AGEs induction by streptozotocin. Eighteen male Wistar rats (200g ~ 250g) were divided into 4 groups based on the treatment; AGE induction/ACLT, sodium citrate buffer treatment/ACLT, AGE induction/no ACLT and control (No AGE induction, no ACLT) group. AGE was induced by injecting 65 mg/kg of streptozotocin (Sigma) intraperitoneally. After 4 weeks of streptozotocin injection, ACLT was performed in ACLT groups. Weigh bearing tests were performed at 1, 2, 4, 7, 14, 21 and 28 days after ACLT in all 4 experimental groups. Rats were sacrificed, knee joints were dissected. AGEs and type II collagens in knee joint cartilages were visualized by immunochistochemistry and quantified by ELISA. Weigh bearing tests results were dramatically decreased after ACLT. Immunohistochemical staining for AGEs and type II collagen showed an increased labeling in AGE

induction/ACLT group. Measurement of AGEs and type II collagen in articular cartilages revealed the highest level of both in AGE induction/ACLT group. These results suggest the AGEs are associated with the developing OA. Continued research of AGE induction/ACLT would provide a basis for understanding of the pathogenesis of OA.

**c-Jun N-terminal Kinase Programs Gene Expression Pattern toward Tissue Destruction in Abdominal Aortic Aneurysm**

H. Aoki,[1] K. Yoshimura,[1] Y. Ikeda,[1] K. Fujii,[1] A. Furutani,[2] Y. Hoshii,[3] N. Tanaka,[4] T. Ishihara,[3] K. Esato,[2] K. Hamano,[2] M. Matsuzaki[1]; [1]Molecular Cardiovascular Biology, Yamaguchi University School of Medicine, Ube, Japan, [2]First Department of Surgery, Yamaguchi University School of Medicine, Ube, Japan, [3]First Department of Pathology, Yamaguchi University School of Medicine, Ube, Japan, [4]Department of Radiology, Yamaguchi University School of Medicine, Ube, Japan

Abdominal aortic aneurysm (AAA) is a common disease among elderly people that is characterized by chronic inflammation of aortic walls with destructive remodeling of extracellular matrix (ECM). Because many patients are already at high risk of rupture at the point of initial diagnosis, a non-surgical therapy is much awaited to achieve the reduction of AAA diameter, a major predictor of its rupture. Here, we report that c-Jun N-terminal kinase (JNK) is the major determinant of the disease progression of AAA, which programs coordinated gene expression pattern toward the tissue destruction. JNK enhances the expression of matrix metalloproteinases, MMP-9 and MMP-2, in macrophages and vascular smooth muscle cells that mediate the tissue destruction in AAA. In addition, JNK suppresses biosynthetic enzymes for ECM in vascular smooth muscle cells. In vivo inhibition of JNK activity resulted in effective prevention of AAA development in the disease models in mice. In contrast, n vivo gene transfer of lysyl oxidase, an ECM biosynthetic enzyme, ameliorated the development of experimental AAA. Strikingly, pharmacological inhibition of JNK caused significant reduction of established AAA diameter with normalized tissue architecture. Taken together, our findings demonstrate that JNK represents a promising therapeutic target by which inhibition we can achieve regression of AAA.

**Effects of Catechin Derivatives upon STAT1 Activity and Their Role on Inteferon-gamma-induced Intestinal $Na^+$-$K^+$-ATPase**

B. Igreja, P. Soares-da-Silva; Inst. Pharmacol. Ther., Faculty of Medicine, Porto, Portugal

This study evaluated the effects of a series of catechin analogues on interferon-γ (IFN-γ) induced STAT1 activation and tested effectiveness of active compounds in preventing IFN-γ-induced decreases in $Na^+$-$K^+$-ATPase activity. Treatment with IFN-γ markedly increased total and phospho-STAT1 in human intestinal epithelial Caco-2 cells. The abundance of total STAT1 and phospho-STAT1 was not affected by treatment of cells with (-)-catechin (C), (-)-catechin-3-gallate (CG), (-)-gallocatechin (GC), (-)-gallocatechin-3-gallate (GCG), (-)-epicatechin (EC), (-)-epicatechin-3-gallate (ECG), (-)-epigallocatechin (EGC), (-)-epigallocatechin-3-gallate (EGCG) or EGC plus gallic acid (all at 20 μM) for 48 h. The IFN-γ-induced increase in phospho-STAT1 was completely prevented by pre-treatment of Caco-2 cells with EGCG (20 μM), whereas C, CG, GC, GCG, EC, ECG, EGC, and EGC plus gallic acid failed to prevent the IFN-γ-induced increase in phospho-STAT1. The increase in short circuit current ($I_{sc}$) by amphotericin B, a measure of $Na^+$-$K^+$-ATPase activity, was markedly attenuated in IFN-γ-treated cells. This effect of IFN-γ was completely prevented in cells that were treated for 48 h with EGCG, but not with EGC. Treatment of mice with IFN-γ resulted in a marked decrease in $Na^+$-$K^+$-ATPase activity in the proximal colonic mucosa, this being prevented by treatment with EGCG, but not by EGC. In conclusion, ECGC, which was unique among a series of catechin derivatives in effectively inhibit STAT1 phosphorylation and prevent IFN-γ-induced decreases in $Na^+$-$K^+$-ATPase activity, may be useful in a clinical setting in that IFN-γ-induced inhibition of intestinal $Na^+$-$K^+$-ATPase activity proceeds in parallel alterations in water and electrolyte handling at the intestinal level.

2896

**Experimental Ulcerative Colitis: Chemical and Bacterial Induction**

A. R. Jurjus,[1] I. Abdallah,[2] K. Barada,[1] R. Tohmé,[1] M. H. Mostapha,[3] S. M. Kamal,[3] J. Freud[4]; [1]Human Morphology, American University of Beirut, Beirut, Lebanon, [2]Human Morphology, American University of Beirut & Beirut Arab University, Beirut, Lebanon, [3]Beirut Arab University, Beirut, Lebanon, [4]INSERM, Strasbourg, France

Over the past 2 decades, more than 20 experimental models for ulcerative colitis have been developed supporting the concept that genetic, environmental and immunologic influences may all contribute to the disease process. The aim of this work is to develop and characterize an experimental model of chronic ulcerative colitis induced by chemical and bacterial factors. The experiment consisted of 132 adult Sprague-Dawley rats divided into 4 groups (G). G1 (Sham) consisted of 28 animals injected weekly with the vehicle 1% methylcellulose (MC) intrarectaly (IR). G2 consisted of 38 animals injected IR weekly with 100 μl iodoacetamide (IA) in 1% MC. On the otherhand, G3 consisted of 38 animals injected IR with IA and enteropathogenic E. coli independently every week. The last group G4 consisted of 28 animals injected IR only with enteropathogenic E. coli on a weekly basis. The experiment was stopped after a hundred days. Symptoms and signs like weight loss, diarrhea and bloody stools were recorded. In addition, the animals from each group were sacrificed on a weekly basis whereby gross abdominal inspection was performed for signs of inflammation (redness, vasodilatation…) as well as adhesions, necrosis and megacolon. Histological studies were done on biopsies from descending colon, jejunum and ileum. Preliminary results depicted the persistence of inflammation in the group G2 and to a higher degree in G3. However, weight loss was mostly in G3 in addition to persistent diarrhea with or without blood in the stools in this group compared to others. Furthermore, adhesions, redness and vasodilatation in addition to marked necrosis in the descending colon were also depicted in group G2, and, in particular, in group G3. Further characterization of the model is being carried out at the molecular, immunological and physiological levels. (Grant from The Lebanese CNRS).

**Biogenesis of Lysosome-Related Organelles Complexes (BLOCs) in Human Genetic Disease**

A. Helip-Wooley,[1] W. Westbroek,[1] H. Dorward,[1] R. Boissy,[2] M. Huizing,[1] W. A. Gahl[1]; [1]NHGRI, NIH, Bethesda, MD, [2]Department of Dermatology, University of Cincinnati College of Medicine, Cincinnati, OH

Hermansky-Pudlak syndrome (HPS) is a disorder of impaired lysosome-related organelle (LRO) biogenesis. Defects in melanosomes in melanocytes and dense bodies in platelets are hallmarks of the disease and manifest clinically with oculocutaneous albinism and a bleeding

diathesis. There are seven subtypes of human HPS described. HPS-3, HPS-5 and HPS-6 generally have mild hypopigmentation with little or no bleeding, while HPS-1 and HPS-4 have severe albinism, bleeding and early death from pulmonary fibrosis. The correlation between disease subtype and severity is becoming more apparent as we learn how HPS proteins interact and function in Biogenesis of Lysosome-Related Organelles Complexes (BLOCs). HPS3, HPS5 and HPS6 proteins are found in BLOC-2. EM of melanocytes from patients with these subtypes reveals fewer mature melanosomes and an abundance of small tyrosinase (tyr)-positive vesicles mislocalized throughout the cell. We have found that HPS3 has a functional clathrin-binding domain and that HPS3 co-localizes with clathrin on small vesicles. We hypothesize that BLOC-2 binds these tyrosinase-positive vesicles and delivers them to early stage melanosomes. HPS1 and HPS4 are members of BLOC-3. The small mis-localized vesicles seen in BLOC-2 deficient cells are absent from BLOC-3 deficient melanocytes, but large, tyrosinase-containing multilamellar compartments are present. Additionally, some melanosomal and lysosomal proteins accumulate in the trans-Golgi region. It appears that BLOC-3 deficient cells fail to form the small vesicles that serve as transport intermediates for some melanosomal proteins. In contrast, BLOC-2 deficient cells form these vesicles, but they do not properly traffic to and/or fuse with maturing melanosomes. Thus, BLOC-3 acts at an earlier stage of LRO biogenesis, so HPS-1 and HPS-4 result in clinically more severe disease than BLOC-2 defects (HPS-3, -5 and -6). HPS illustrates a new paradigm of using cell biology to understand human genetic disease.

### Comparative Proteome Bioinformatics: Identification of Phosphotyrosine Signaling Proteins in the Unicellular Protozoan Ciliate *Tetrahymena*

S. Gammeltoft,[1] S. T. Christensen,[2] M. Joachimiak,[3] E. Hill,[3] C. Guerra,[4] P. Satir[4]; [1]Department of Clinical Biochemistry, Glostrup Hospital, Glostrup, Denmark, [2]Department of Biochemistry, August Krogh Institute, Copenhagen, Denmark, [3]Computational Genomics Group, Department of Plant and Microbial Biology, University of California Berkeley, Berkeley, CA, [4]Department of Anatomy and Structural Biology, Albert Einstein College of Medicine of Yeshiva University, Bronx, NY

Protein tyrosine phosphorylation is characteristic of metazoans and a key element in intracellular signal transduction pathways of multicellular organisms. We used bioinformatics to identify protein tyrosine kinases (PTK) and phosphotyrosine signaling domains in the unicellular protozoan *Tetrahymena thermophila*. Hidden Markov models (HMM) searches of the *Tetrahymena* genome and available EST data were performed using http://hmmer.wustl.edu/ with HMM models for PTK and signaling domains. Eight proteins were found with catalytic domains similar to PTK and three have a predicted tyrosine phosphorylation site in the activation loop. We identified several tyrosine phosphorylation motifs for docking of SH2 domains found in metazoan adaptor proteins like Grb2, SH-PTP2, PLCγ, and Src. Based on the structural alignment of the catalytic domain, a large phylogeny tree was reconstructed showing that the *Tetrahymena* kinases are distinct from both canonical tyrosine and serine/threonine kinases. Structural modeling of the catalytic domain showed residues with identity to tyrosine as well as serine/threonine kinases. Finally, HMM searches gave a number of hits with similarity to protein domains involved in metazoan phosphotyrosine signaling including eight protein tyrosine phosphatases, one phosphoinositide 3'-kinase, one SH2, four SH3, seven calponin homology, and 24 pleckstrin homology domains. In conclusion, we have identified protein kinases in *Tetrahymena* that share features of tyrosine and serine/threonine kinases. The presence of proteins in metazoan phosphotyrosine signaling suggests that these *Tetrahymena* protein kinases may phosphorylate tyrosine. We propose that *Tetrahymena* PTK-like kinases are members of an ancient clade of protein kinases that may be classified as kinases with dual specificity possibly predating the serine/threonine and tyrosine kinase divergence.

2899

### Novel Methodology for Identification of Sumoylated Protein by Electrospray-quadrupole-time of Flight (ESI-q-TOF) Tandem Mass Spectrometry

J. Lee,[1] J. Jeong,[2] J. Seo,[2] S. Koh,[2] K. Lee[2]; [1]Ewha Womans University, Seoul, Republic of Korea, [2]Center for Cell Signaling Research, Division of Molecular Life Sciences and College of Pharmacy, Ewha Womans University, Seoul, Republic of Korea

Covalent attachment of small ubiquitin-like modifier (SUMO) represents the important post-translational modification that is involved in various biological processes including cell survival, apoptosis, and signaling processes. However, the regulatory mechanism of sumoylation is poorly understood because it is difficult to identify the sumoylation substrates *in vivo*. Here, we have developed the novel way to determine the sumoylation sites in protein substrates by using the SUMO mutant in amino acid residue 95. This mutant makes it possible to detect the sumoylation sites by nanoLC-ESI-q-TOF tandem mass spectrometry. Distinct type of peptides, sumoylation residue (GG) on lysine residue of substrate, is generated by trypsinolysis of sumoylated protein. This methodology is a novel way to determine the sumoylation site of protein, which will very useful to understand the biological functions of SUMO.

2900

### Protein Expression Profiling Using Gene Ontologies of Human Mesenchymal Stem Cells During Osteogenic Differentiation Induced by Ascorbic Acid-2-Phosphate, β-Glycerophosphate, and Dexamethasone

R. M. Salasznyk,[1] R. F. Klees,[1] A. M. Westcott,[2] S. Vandenberg,[3] K. Bennett,[2] G. E. Plopper[1]; [1]Biology, Rensselaer Polytechnic Institute, Troy, NY, [2]Mathematical Sciences, Rensselaer Polytechnic Institute, Troy, NY, [3]Computer Science, Siena College, Loudonville, NY

We applied 2D gel electrophoresis and 2D liquid chromatography tandem mass spectrometry (2D LC-MS/MS) to identify proteins that are expressed in human mesenchymal stem cells (hMSC) undergoing in vitro osteogenic differentiation induced by the osteogenic stimulants (OS) ascorbic acid-2-phosphate, β-glycerophosphate, and dexamethazone. To assess the effectiveness of OS in inducing osteogenic differentiation, and identify specific changes in protein expression which accompanied OS treatment, Progenesis workstation software and the Database for Annotation, Visualization and Integrated Discovery (DAVID) were used classify these proteins and compare them with those found in undifferentiated hMSC and fully differentiated human osteoblasts (hOST). Of the 534 spots identified in OS-treated hMSC 2D gels, 272 (64%) and 443 (78%) spots matched those found in hMSC and hOST gels, respectively. Of the 909 different proteins identified by 2D LC-MS/MS in all these cell populations, 144 (16%) were found only in hMSC; 154 (17%) were found only in OS-treated hMSC; and 121 (13%) were unique only to

hOST. Differential expression of some of the identified proteins was further confirmed by Western blot analyses. Significant differences in calcium-mediated signaling molecules and extracellular matrix components were found during osteogenic commitment and differentiation in OS-treated cells. Gene ontology analysis with DAVID revealed that these functionally related proteins may serve as novel biomarkers for identifying hMSC commitment along osteogenic fates and demonstrate that protein expression profiling is a valuable tool in elucidating the osteogenic differentiation of hMSC.

**Dynamic Regulation of T Cell Receptor Signaling Pathway Activation in Response to Altered Peptide Ligands**

L. Wille,[1] M. Kemp,[2] C. Stokes,[3] L. Nicholson,[4] D. Lauffenburger[2]; [1]Biology, Massachusetts Institute of Technology, Cambridge, MA, [2]Division of Biologicial Engineering, Department of Biology, Massachusetts Institute of Technology, Cambridge, MA, [3]Entelos, Inc., Foster City, CA, [4]School of Medical Sciences, University of Bristol, Bristol, United Kingdom

T lymphocyte response to antigen is determined, at least in part, by the affinity of the T cell receptor (TCR) for the antigen ligand. We propose that qualitatively and quantitativly different signals are triggered by low and high affinity TCR ligands, for these signals induce distinct cell fates including the production of IL-2 and other cytokines. The capacity of T cells to recognize a set of altered peptide ligands (APLs) -- ligands with amino-acid substitutions within an antigenic peptide -- provides an opportunity for examining how subtle ligand changes can lead to different cellular responses. Our hypothesis is that multiple signaling pathways dynamically encode information in a combinatorial network state which can translate small changes in TCR ligation events into predictable differences in cellular outcomes. To test this hypothesis we are defining a quantitative, multidimensional map of TCR avidity, signaling events, and cytokine production/apoptosis. A mouse T cell hybridoma line 1B6 is activated with three APLs to define changes in signaling pathways' activation that lead to quantitative differences in activation-induced cell death and cytokine production. Cellular outputs as measured via ELISA and FACS demonstrate large changes in IL-2 and apoptosis between the different APLs. Intracellular signaling events for the same APL conditions are measured using semi-quantitative phosphoprotein western blots and high-throughput kinase activity assays. Our studies focus on the signaling dynamics of Erk, p38, Akt, JNK, MK2, NFAT, and IKK. Partial least squares regression is applied to extract statistical relationships between TCR ligation, signaling events, and cytokine production/apoptosis. To date, our methodology has provided unique signatures in the ERK, JNK, Akt, and p38/MK2 pathways associated with weak and strong APL avidity. Our statistical model can successfully account for IL-2 production associated with these activation patterns.

**Modeling Molecular Interactions to Understand Spatial Crowding Effects in Heterodimer Formation**

K. M. Puskar,[1] A. Parisi-Amon,[2] S. Ta'asan,[3] R. Schwartz,[4] P. R. LeDuc[1]; [1]Mechanical Engineering, Carnegie Mellon University, Pittsburgh, PA, [2]Biomedical Engineering, Duke University, Durham, NC, [3]Mathematical Science, Carnegie Mellon University, Pittsburgh, PA, [4]Biological and Computer Science, Carnegie Mellon University, Pittsburgh, PA

Molecular crowding occurs in cells when the density of interacting molecules is sufficient to create deviations from traditional models of chemistry in diffusive systems. Including crowding in models is essential to accurately capture the kinetics of macromolecular complex formation within the cell. These formations are prevalent throughout biology, such as in protein-protein interactions and DNA hybridization. In order to model binding in a crowded environment, we use a lattice based Monte Carlo simulation with both inert, and interacting molecules that bind to form heterodimers. Inert molecules, which occupy space but are not actively involved in the reaction process, might move throughout the solute along with the reactant species by passive diffusion or might be anchored at fixed positions within the solute. While the inert molecules might be expected to exert similar excluded volume effects on reactant molecules under either assumption, they could produce differential effects on reaction progress through their different influences on reactant molecular diffusion. We examine the relative contributions of the two models to crowding effects by examining the effect of moving inert particles versus stationery inert particles on the reaction rates of heterodimer formation. The simulation results from these relatively simple interactions proved to be complex and distinct for the moving versus stationary inert particles. Stationary inert particles exhibited a bimodal response while moving inert particles had little effect on the simulated dimerization reactions. These results may have applications in fields such as cell biology, chemistry, and computational biology.

2903

**Using Classifier Learners to Distinguish between +/- Ras Cell Images**

A. N. Reed,[1] S. Chen,[2] G. Gordon,[2] R. Murphy[2]; [1]University of California, Irvine, Irvine, CA, [2]Carnegie Mellon University, Pittsburgh, PA

H-Ras is a cancer promoting gene that is present in 30% of cancers and has been known to distort the morphology of cells. This has proven to be a challenge for automated analysis of protein location since previous methods are influenced by cell morphology. The difference in morphology must be eliminated for proper unbiased analysis. In order to accomplish this, we extract texture features from a small region in the cytoplasm and use a logistic regression classifier to distinguish between Ras +/- images. NIH 3T3 cells, which were previously CD-tagged with GFP for a specific protein, were transfected with the Ras oncogene. The pairs of Ras +/- were compared to determine if there exist statistically significant differences. Of the eleven proteins analyzed, one demonstrated such a difference: Serum deprivation response protein. Visual inspection confirms that there is a difference between the textures of the Rse +/- images. Biological explanations through literature surveys are needed to support this experimental result. Sophisticated features and classification methods are also explored for investigating other significant differences between the pairs of images for future work. This research will in turn help biologists to better understand the purpose of the Ras protein.

**Utilizing Biobase's Integrated Proteome, Transfac® and Transpath® Databases to Gain Biological Knowledge from Scientific Information**

K. L. Lennon-Hopkins, R. J. Johnson, F. J. Barkalow; Biobase Corporation, Beverly, MA

Genomics and proteomics, when combined with traditional research approaches, offer new opportunities to identify and characterize biological pathways, as well as comprehend changes in these pathways in disease. A challenge faced by researchers is to make sense of the wealth of scientific information generated by these approaches. The Biobase Knowledge Library (BKL) is an integrated information resource that allows researchers to access biological knowledge quickly and efficiently. The BKL comprises interconnected volumes that include the Proteome

databases, TransFac®, and TransPath® and organize public sequence information with information derived from comprehensive curation of scientific literature. Here, we illustrate the utility of the BKL as a tool for easily navigating the vast body of scientific information and for facilitating understanding that allows for efficient future experimental design. We sought to determine the connection between transcription factors associated with Diabetes and their downstream targets, in order to identify additional proteins that may be involved in Diabetes. Using the BKL Retriever search tool, we identified 322 human proteins associated with Diabetes. Of those, 265 displayed abnormal protein expression and 175 exhibited aberrant mRNA expression. Of the 322 Diabetes-associated proteins, 15 were transcription factors. We viewed relationships among these proteins in the interactive BKL Workspace and linked to a comprehensive HNF4A Proteome report that included Gene Ontology, expression, regulation, and protein modification information and links to cited references. Linking to TransFac and TransPath, we obtained details and interactive graphical displays of upstream regulators and downstream targets of HNF4A. We recognized HNF4A targets already linked to Diabetes, and we identified cytochrome P450 proteins as HNF4A targets that warrant examination for possible Diabetes associations. Complimentary BKL access for academic users is available for Disease Spotlight proteins, Public TransFac and Public TransPath (http://www.biobase.de).

### A General Technique for the Segmentation of Individual Cells in Light Micrographs

Z. S. Pincus,[1,2] J. A. Theriot[2,3]; [1]Program in Biomedical Informatics, Stanford University School of Medicine, Stanford, CA, [2]Department of Biochemistry, Stanford University School of Medicine, Stanford, CA, [3]Department of Microbiology and Immunology, Stanford University School of Medicine, Stanford, CA

Many *ad hoc* methods exist for separating cells from background (and, with less success, from each other) in light micrographs. Here we present a general method for this task which is applicable to all cell types and imaging modalities. By using an explicit, parameterized "shape model" learned from training examples, our tool is free of the implicit assumptions about cell shape and packing which characterize *ad hoc* methods. The only assumption of the shape model is that cell shapes in a given population lie along quantifiable, stereotyped deviations from the population average (e.g. large vs. small, round vs. elongated, etc.). We free our method from assumptions about how pixel intensities relate to the cell-versus-background distinction by converting images into a canonical form. By using simple pixel-wise classification, we can convert many different image types (e.g. phase constrast, DIC, epifluorescence, etc.) into "likelihood maps" which represent the likelihood that a given pixel belongs to a cell or to the background. To find a single cell, we then iteratively fit the shape model's pose and shape parameters to the canonical image, and repeat the process to find all cells. Finally, we refine the initial fit by deforming the shape edges to fit the image within a level-set framework. This method has shown human-competitive results in separating out individual cells from the background and from each other on many different image and cell types, including fixed S2 cell cultures, growing bacterial mats, and membrane-stained *Drosophila* epithelia. Moreover, we have been able to use shape models to numerically parameterize the shapes of segmented crawling fish keratocytes and wild-type vs. mutant *Caulobacter*. This demonstrates the potential for truly general micrograph processing and quantitation methods identifying cells and describing variations in cell shape.

### Protein-Arginyltransferases Are an Evolutionary Conserved Family of Enzymes Related to Bacterial Enzymes of Non-Ribosomal Peptide Synthesis

R. Rai,[1] A. Mushegian,[2] A. Kashina[1]; [1]Animal Biology Dept., University of Pennsylvania, Philadelphia, PA, [2]Stowers Institute for Medical Research and Department of Microbiology, Kansas University Medical Center, Kansas City, KS

Arginyltransferases (Ate1) are evolutionary conserved enzymes that mediate posttranslational N-terminal protein arginylation. Ate1 is nonessential in yeast, but has been recently found to be essential for cardiovascular development and angiogenesis in mammals. Mammalian Ate1 gene encodes four ATE1 forms that are produced by alternative splicing of homologous exons that are adjacent within the Ate1 gene and differ in substrate specificity, tissue expression, and intracellular localization. To study the evolutionary connections of arginyltransferases, we used methods of probabilistic sequence comparison and fold recognition and found that Ate1 is related to the FemABX family of tRNA-peptide transferases, which are involved in peptidoglycan biosynthesis in bacteria. Like FemABX, Ate1 appears to have evolved by duplication of the GNAT-like acetyltransferase fold and to contain a patch of negatively charged amino acids that is conserved only in a subset of GNAT acetyltransferases and may represent an oxoanyon hole directly participating in catalysis. We use site-directed mutagenesis to characterize the residues predicted to be involved in Ate1 catalytic activity, substrate binding, and specificity for different N-terminal residues.

## RNAi Technology (2907-2914)

### Dual Fluorescence Assay for Target Validation of siRNA

S. Kojima, O. Danciu, S. Hammond, E. Brown, A. Mongiu, G. G. Borisy; Cell & Molecular Biology, Northwestern Univ. Med. Sch., Chicago, IL

Small interfering RNA (siRNA) is a crucial method for cell biology. An obstacle towards efficient application is that not all siRNAs are effective in gene silencing. As a result, selection of multiple target sequences and validation of knockdown are essential to identify effective sequences. We have developed a ratiometric assay system to evaluate knockdown effectiveness indirectly using two fluorescent reporters. Target sequences for test were embedded in the 3'UTR of the DsRed2 gene. Small hairpin RNA (shRNA) containing the knockdown sequence was expressed from a plasmid also expressing EGFP (Biotechniques 36:74-79 (2004)). Under optimized cotransfection conditions, the relationship between green and red fluorescence was linear, allowing quantitative fluorescence measurement at the individual cell level. Knockdown was assayed as the ratio of red to green fluorescence in each cell and was tabulated as population means with standard deviations. For a proof of principle, we tested six and nine target sequences of human vimentin and laminA/C, respectively. In both cases, the best target sequences identified by our ratiometric assay corresponded to the best target sequences as assayed by western blotting and immunofluorescence of endogenous protein. We applied our assay to identify effective siRNA target sequences of the mouse Arp3 gene. Transfection of shRNA expression plasmids for the two best targets caused similar morphologic changes to mouse melanoma B16F1 cells. Lamellipodia were greatly attenuated in agreement with the array-treadmilling model where dendritic nucleation from the Arp2/3 complex is a major source of lamellipodia protrusion. The results establish that our validation

assay is useful for identification of efficient siRNA target sequences. Since the image acquisition and analysis procedures are adaptable to image readers in an automated mode, our assay will facilitate high-content, high-throughput screening to identify effective target sequences. Supported by NIH GM64346.

2908

**A Modular, Tunable Mammalian Gene Switch Based on RNAi and Repressor Proteins**

T. L. Deans, C. R. Cantor, J. J. Collins; Biomedical Engineering, Boston University, Boston, MA

A number of technologies have been developed to control gene expression in eukaryotes. Much research has focused on the regulation of transcription using repressor proteins such as TetR and LacI, with only moderate success due to leakiness. More recently, RNA interference (RNAi) has advanced as a regulatory tool based on posttranscriptional gene silencing in which specific mRNAs are degraded. Despite these technologies offering ways to decrease gene function, neither method has proven to be an effective way to silence a gene. Here, we introduce an engineered tunable switch that couples repressor proteins and a novel RNAi target design to effectively turn any gene off. LacI is used for transcriptional repression of gene function and any leakage of the transcript is knocked down by the RNAi component of the switch. Gene expression is turned on by adding IPTG, which prevents LacI from binding in the Lac operator sites thereby allowing transcription of the gene. Additionally, IPTG turns the RNAi component of the switch off, allowing for the transcript to be retained and translated. To demonstrate its efficacy, the switch was used to regulate the expression of EGFP in CHO cells. In the absence of IPTG, these cells exhibit effectively no EGFP expression (>99% repression compared to positive controls). Furthermore, a dose-response increase of EGFP expression occurs with the addition of IPTG. These results indicate that the switch is not only capable of mediating on/off states, but it also allows for tunable expression of the gene. We show that the switch possesses reversible stringent control of gene expression, and that it is endowed with modular capabilities that allow for the regulation of any gene, as well as having the potential to be utilized in a tissue specific manner.

2909

**A Novel High-throughput Method for Electroporation of Adherent Primary Cells**

K. E. Jardemark; Physiology and Pharmacology, Karolinska Institutet, Stockholm, Sweden

To meet the demands of effective transfection methods for primary cells and stem cells, electroporation is developing into a powerful alternative to chemical/viral transfection methods, especially in the rapidly growing field of RNAi. Here we use a novel parallel method for electroporation of small cultures of adherent cells. Electroporation allows for introduction of any polar or charged agent that will not spontaneously pass the cell membrane. Addressing multiple adherent cultures in a parallel fashion not only enables perfect spatial control over affected cell areas, but also saves time, and offers real-time monitoring of treated cells. For example, it facilitates the identification and functional characterization of cytoplamic proteins. The technique is suitable for any type of adherent cells, especially cells considered difficult to transfect (*e.g.* primary cells, stem cells and neuronal cells) with agents of any type desired, such as drugs, oligonucleotides, siRNA, plasmids *etc*. Electroporation is performed by focusing capillary electrodes near the surface of adherent cells. The capillary electrodes are constructed to both deliver the transfection agent and an electric field locally to the cells. We have used the method for transfection of plasmids coding for various receptor/ion channel complexes, and silenced the expression of these complexes by transfection of siRNA. The yield and function of the expressed ion-channels, as well as the silencing efficiency of the siRNAs, were assessed by means of patch clamp and rtPCR detection. Moreover, the expression of GAPDH, as well as GFP, were silenced in primary endothelial cells and in a GFP-transfected endothelial cell line. The viability is generally high, i.e. over 90% and the efficiency for medium-sized molecules (*e.g.* siRNAs) is above 70%.

2910

**DNA Vector-based RNA Interference in *Spodoptera Frugiperda* Cells**

C. Lin; Life Sciences, National Tsing Hua University, Hsinchu, Taiwan Republic of China

Double-stranded RNA-mediated interference (RNAi) is rapidly emerging as a powerful tool used for the silencing of specific gene expression in many organisms. The dsRNA precursors might be processed into short interfering RNA (siRNA), which in turn mediates sequence-specific mRNA degradation. Herein, we describe a DNA vector-based method to achieve stable gene silencing in a *Spodoptera frugiperda* cell line, Sf9. With this approach, we have created a stably transfected Sf9 cell line, Sf9/pIBdsLuc, to express large dsRNA fragment mediating specific silencing of *luc*, the firefly luciferase gene. The *luc* dsRNA was constitutively transcribed from an inverted-repeat DNA sequence under the control of the OpIE2 promoter in Sf9/pIBdsLuc cells. Silencing of *luc* mRNA was observed when Sf9/pIBdsLuc cells were infected by rBacLuc, a recombinant baculovirus encoding *luc* gene. The luciferase activity upon rBacLuc infection, at the multiplicity of infection (MOI) of 1, in Sf9/pIBdsLuc cells was decreased by approximately 85% compared to that in control Sf9 cells. Thus, gene silencing in Sf9 cells could be effectively achieved using DNA vectors similar to the facile design described in this study.

2911

**Selective Purification of Small RNAs from Complex Biological Starting Materials**

C. Ritt, S. Carsten, R. Himmelreich, M. Weber; Chemical and Biological Research, QIAGEN GmbH, Hilden, Germany

In recent years, small RNAs have come more and more into the focus of research as they are ubiquitous, versatile molecules that play an important role in the regulation of gene expression and development in animals and in plants. Of special interest are miRNAs and siRNAs, small nucleic acids with a length of about 22 nucleotides. They are able to silence specific genes at the post-transcriptional level by virtue of their sequence complementarity to target mRNAs. To study the cellular role of these and other small RNAs in further detail, they must be isolated from tissue or cell culture in as pure a form as possible. Besides the removal of cellular components such as proteins, sugars, and lipids, nucleic acids that are longer than the desired RNA length should also be removed. We have developed a new method for the isolation of small RNAs from complex biological starting materials. The purification method is a simple and fast procedure that is based on magnetic particles. The method therefore offers convenient handling and is suitable for automation. Data will be presented that show efficient isolation of miRNAs with different combinations of buffers. Depending on the conditions selected, only nucleic acids in the size range of miRNAs are purified, while larger nucleic acids such as tRNAs are removed during the procedure. Varying the buffer conditions results in an isolation procedure that allows for the co-

purification of miRNAs and larger nucleic acids such as tRNAs or snRNAs. A further example will be shown that allows purification of virtually all size classes of nucleic acids contained in the biological starting material.

2912

**siRNA Libraries as Tools for Target Identification**

R. Jarvis, M. Byrom, D. Ovacharenko, C. D. Buchanan, D. Brown, L. Ford, D. Dorris; Ambion, Austin, TX

Small interfering RNAs (siRNAs) are routinely used to establish and confirm gene function in mammalian cells. We use libraries of siRNAs to identify genes involved in cellular pathways and processes and have measured how siRNA concentration, siRNA pooling, cell type, and time between transfection and analysis influence the final screening data. Our results provide a framework for setting up high throughput functional screens in both immortalized and primary cell lines with siRNA libraries and show the power of using such an approach to correlate genes with cellular functions. Using hundreds of siRNAs targeting different human kinases, we have discovered new roles for several of these kinases in apoptotic pathways.

2913

**Controlling Cell Signaling by Novel Transfection**

T. W. Sproul, A. M. Burt, L. T. Mazzola, R. D. Guettler; Excellin Life Sciences, Inc., Menlo Park, CA

Biological research has a compelling need to control processes within the cell, to turn on and off cellular functions through selective activation or inhibition of signal transduction pathways. The ability to transfer a wide range of exogenous materials into cells is of critical importance. Traditional transfection methods are primarily limited to nucleic acids and variously suffer from low efficiency, cell toxicity, and/or limited intracellular release. Here we demonstrate a novel microelectronic transfection approach that enables controlled delivery of virtually all biological components, including proteins, peptides, nucleic acids and small molecules. For comparison, we present data for siRNA into H460 cells, resulting in 90% apoptosis compared to 20% for lipid-based delivery of the same siRNA (5% observed control). We further demonstrate >95% induction of active fluorescently labeled antibodies and peptides into a variety of cell types. This novel process provides highly efficient induction into both suspension and *in situ* adherent eukaryotic cells with minimal impact to cell health - enabling unprecedented control over a wide range of cellular functions.

Scott[1]; [1]Proteomics R&D, Sigma-Aldrich Biotechnology, St. Louis, MO, [2]Molecular Biology R&D, Sigma-Aldrich Biotechnology, St. Louis, MO

The MISSION™ shRNA Library is a comprehensive collection of 150,000 pre-cloned lentiviral-based shRNA vector constructs targeting 30,000 annonated human (MISSION TRC-Hs 1.0) and mouse genes for RNA interference-mediated silencing. This lentiviral-based system allows for infection and integration into non-dividing and primary cells. RNA-mediated interference (RNAi) offers a mechanism for the study of gene function as well as target validation, but currently available methodologies to interrogate and measure protein levels following gene knockdown are inadequate and imprecise. Indeed, there is a pressing and demonstrable need to functionally validate mRNA knockdown by rapid and accurate quantitative surveillance of affected protein(s). Differential isotopic labeling of tryptic peptides using $^{18}O$ water is a well-established technique for measuring relative amounts of protein in two related but discrete samples. $^{18}O$ labeling is a global strategy in that essentially all peptides in a sample are labeled - so any changes between control and test samples are revealed. Absolute Quantification (AQUA™) represents a complementary quantitative proteomics technique to $^{18}O$ labeling. This method is a targeted strategy that exhibits robust efficacy and is being increasingly utilized for a wide variety of quantitative proteomics studies. Utilizing the MISSION shRNA Library lentiviral-based system, a variety of human kinases have been targeted for gene knockdown. Following gene knockdown, AQUA analysis of the targeted protein product and $^{18}O$ labeling are performed to observe both the target protein and other proteins potentially affected by the knockdown event. In the present work, we demonstrate that the $^{18}O$ labeling and PROTEIN-AQUA strategies can be sequentially coupled to RNAi technology in order to perform true quantitative verification of gene knockdown at the protein level.
