Intraflagellar transport (IFT) is a bi-directional microtubule-based transport system essential for the assembly and maintenance of eukaryotic cilia/flagella. In *Chlamydomonas*, the IFT system consists of two motor complexes, kinesin-2 and cytoplasmic dynein 1b (cDynein1b), and an IFT particle containing ca. 17 different polypeptides in two complexes, A and B. Kinesin-2 contains two motor subunits, FLA10 and FLA8, and one non-motor subunit, KAP. cDynein1b contains heavy chain (HC) and light intermediate chain (LIC) subunits, and possibly additional as yet unidentified subunits. Although analysis of mutants with defects in various components of the IFT system have provided significant insights into the molecular mechanisms of IFT, several questions remain unsolved. In the current model for IFT, kinesin-2 carries cDynein1b, IFT particles and axonemal precursors from the basal body to the flagellar tip, and cDynein1b transports kinesin-2, IFT particles and axonemal turnover products back to the cell body. The mechanisms by which cargo unloading/loading, and IFT motor exchange occur at the flagellar tip are unknown. We have used a variety of *Chlamydomonas* mutants with defects in kinesin-2 (KAP, FLA10), cDynein1b (LIC), or IFT complex B (IFT172) and RNAi to begin to dissect the molecular mechanisms of IFT. We find that kinesin-2 can associate with cDynein1b HC independently of LIC and IFT complex A and B, and show that binding of cDynein1b to kinesin-2 requires KAP. Furthermore, we show by transmission EM that the tip turn-around point for IFT particles is localized distal to the +end of the B outer doublet microtubules on which IFT occurs. Based on these and previous findings we propose a new model for IFT in which tip-turnaround involves 1) dissociation of complex A and B, 2) binding of A to cDynein1b LIC, 3) re-association of B with A prior to retrograde IFT.

**Role of IFT46 Protein in Intraflagellar Transport (IFT)**

Y. Hou,[1] H. Qin,[2] W. L. Dentler,[3] G. J. Pazour,[4] J. L. Rosenbaum,[2] G. B. Witman[1]; [1]Cell Biology, UMASS Medical School, Worcester, MA, [2]Department of Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT, [3]Division of Biological Sciences, University of Kansas, Lawrence, KS, [4]Program in Molecular Medicine, UMASS Medical School, Worcester, MA

IFT, the bi-directional movement of particles along the length of eukaryotic cilia and flagella, is required for ciliary and flagellar assembly and maintenance. The IFT machinery includes IFT-particle proteins and anterograde and retrograde motors. Biochemical analysis of *Chlamydomonas* IFT particles showed that they contain ~16 proteins, arranged into complexes A and B. We have cloned IFT46, a putative complex B protein. Quantitative RT-PCR shows that IFT46 expression is induced upon deflagellation. Immunofluorescence microscopy (IFM) shows that IFT46 has a cellular localization typical for IFT-particle proteins. We identified a *Chlamydomonas* null mutant for IFT46. Western blotting indicates that this mutant has elevated levels of complex A proteins and reduced levels of complex B proteins, with the exception of IFT172, which is near wild-type level. Whereas other published IFT-particle protein mutants are aflagellate, *ift46* has short, stumpy flagella. IMF indicates that the flagella contain some IFT-particle proteins, but IFT particles are not detected by EM. EM also reveals that the axonemes lack outer arms and have defects in central pair assembly. This is in contrast to mutants in the retrograde IFT motor, DHC1b, which have short, stumpy flagella that accumulate IFT particles and can form a normal axonemal structure. The defects are rescued by the wild-type IFT46 gene, confirming that they are due to lack of IFT46. Thus, IFT46 is important for the stability of complex B and for transporting cargo, including the outer arms, into flagella. We also found that IFT46 is phosphorylated and identified 3 phosphorylation sites by MS analysis. Two constructs that encode modified IFT46 genes were transformed into

the null mutant. The transformants express modified IFT46 that mimics either the phosphorylated or non-phosphorylated form. Further characterization of these transformants is underway to determine the function of IFT46 phosphorylation.

**Bardet-Biedl Syndrome 3 is a Centrosomal Small GTP-Binding Protein Associated with Intraflagellar Transport**

M. A. Esmail, M. Kang, M. R. Leroux; Molecular Biology and Biochemistry, Simon Fraser University, Burnaby, BC, Canada

Bardet-Biedl syndrome (BBS) is a pleiotropic disorder linked to eight genes and typified by abdominal obesity, retinal degeneration, polycystic kidneys, polydactyly, anosmia and cognitive impairment. Recent work with *M. musculus* and *C. elegans* mutants has pointed to a defect in cilia as the underlying cause of BBS. Current evidence suggests a transport or trafficking function for BBS proteins. We have recently shown that mammalian BBS4 likely functions in the retrograde transport of pericentriolar material 1 protein, which is required for anchoring microtubules at the centrosome. We have also demonstrated that *C. elegans* BBS7 and BBS8 participate in intraflagellar transport (IFT), a process required to build functional sensory cilia. Using a bioinformatic approach in conjunction with DNA sequence analysis, we discovered that *ARL6* is the gene responsible for the last uncloned *BBS* gene, *BBS3*. *ARL6/BBS3* encodes an ADP-ribosylation factor-like protein, belonging to the Arf/Arl family of small GTP-binding proteins. Immunocytochemistry reveals that ARL6/BBS3 localizes to the centrosome in IMCD-3 cells, a ciliated mouse kidney cell line. This localization occurs independently of microtubules as neither nocodazole nor over expression of p50 dynamitin affect the centrosomal signal. In *C. elegans*, ARL6/BBS3 is found at the base of cilia and undergoes IFT. 3D modeling of ARL6 indicates that all the substitution mutations identified in human patients map to the GTP-binding pocket of ARL6, and GTP-binding assays confirm that each of the protein mutants have disrupted nucleotide binding. Although Arf/Arl proteins had previously been implicated in intracellular transport, our findings show that at least one member is associated with IFT and is one of several genes causing BBS, a disorder that affects a large number of vital systems in humans.

1019

**LF4p, a Regulator of Flagellar Length in Chlamydomonas, is a Cargo for Transport by IFT**

N. F. Wilson, P. A. Lefebvre; Plant Biology, University of Minnesota, St. Paul,, MN

Chlamydomonas actively maintains its two flagella at an equal and appropriate length. Genetic studies have identified four genes (*LF1, LF2, LF3*, and *LF4*) that when mutated generate cells with abnormally long flagella. *LF4* was recently shown to encode a MAP kinase with a unique C-terminal domain. Both the kinase activity and the C-terminal domain of LF4p are required for rescue of the long-flagella phenotype. In cell bodies LF4p migrates as a doublet at 72/73 kDa, whereas LF4p in flagella migrates as a single band at 65 kDA. The shift of LF4p from a single band in flagella to a doublet in cell bodies was confirmed by 2D SDS-PAGE. Both cell body forms of LF4p are phosphorylated on the TEY motif suggesting that in cell bodies LF4p is an active kinase. The flagellar form of LF4p is maintained in a largely inactive state by the activity of one or more phosphatases. Analysis of *lf4* flagella revealed an increase in the level of FLA10p. Consistent with an interaction between LF4p and FLA10p, LF4p was lost from *fla10* flagella at the restrictive temperature. Sucrose gradient fractionation of flagella revealed that LF4p co-fractionated with IFT particle proteins at 16S. LF4p, however, did not co-fractionate with either complex A or complex B proteins under high salt conditions. Interestingly, the inclusion of phosphatase inhibitors during high salt extraction of flagella prevented the dissocation of complex A and complex B suggesting they interact via one or more phosphorylated proteins. Moreover, in the presence of phosphatase inhibitors, FLA10p co-fractionated with IFT particles at 16S suggesting that this interaction is also dependent on phosphorylation. Experiments are currently underway to identify the phosphatase(s) that regulates the kinase activity of LF4p in flagella.

**Architectural Analysis of the *Chlamydomonas* Intraflagellar Transport Complex B**

B. F. Lucker,[1] R. H. Behal,[1] H. Qin,[2] J. L. Rosenbaum,[2] D. G. Cole[1]; [1]Microbiology, Molecular Biology and Biochemistry, University of Idaho, Moscow, ID, [2]Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT

Intraflagellar transport (IFT) is a strongly conserved process required for the assembly and function of eukaryotic cilia and flagella. During IFT, large protein particles carry axonemal precursors to the distal tip of the organelles while axonemal turnover products are ferried back to the cell body (Qin *et al.*, 2004). Excluding motor complexes, IFT particles consist of multiple copies of two separate complexes, A (at least 6 subunits) and B (at least 13 subunits). Here we report on our ongoing characterization of the *Chlamydomonas* complex B architecture. We have found that several B subunits dissociate from the complex in moderate ionic strength (~300 mM NaCl) revealing a salt-stable core that contains IFT88, IFT81, IFT74, IFT72, IFT52, IFT46 and IFT27. Using yeast-based two-hybrid analysis, we have identified a 200 amino acid coiled-coil region of IFT74/72 that interacts with the coiled-coil subunit, IFT81. Similar analysis reveals that IFT81 has the ability to homodimerize. Using a combination of biochemical and yeast-based three-hybrid analyses we have found IFT81, IFT74, and IFT72 appear to form a higher order oligomer within the complex B core at a ratio of 2:1:1, respectively. Currently we are using additional approaches, including chemical cross-linking, to further characterize these and other complex B interactions. Supported by GM61920 (DGC), P20RR016454 (DGC) and GM14642 (JLR).

1021

**Proteomic Investigation of the Eukaryotic Flagellum Using the Model Organism *Trypanosoma brucei***

R. Broadhead,[1] H. Dawe,[2] S. Hart,[3] N. Portman,[2] M. Ginger,[2] S. Gaskell,[3] P. McKean,[1] K. Gull[2]; [1]Department of Biological Sciences, Lancaster University, Lancaster, United Kingdom, [2]Sir William Dunn School of Pathology, University of Oxford, Oxford, United Kingdom, [3]Michael Barber Centre for Mass Spectrometry, University of Manchester, Manchester, United Kingdom

We have used the newly completed *T. brucei* genome project along with mass spectrometric techniques to investigate the proteomic constituents of a eukaryotic flagellum. Salt-extracted axonemes were isolated from *T. brucei* strain 427 and subjected to one-dimensional or two-dimensional SDS-PAGE. Bands, spots and regions were excised, trypsin-digested, and analysed by LC-MS/MS. Mascot was used to search the *T. brucei* genome for the most likely peptide matches. 522 proteins were identified. 128 were discarded following verification of mass spectra by manual sequencing, leaving 394 proteins. We used the presence of ribosomal proteins in this dataset as a marker for contamination by highly basic proteins aberrantly binding to tubulin following disruption of cell membranes. Discarding proteins with a predicted pI of greater than 10.1 left a final dataset of 341 proteins that we confidently predict to be genuine components of the salt-extracted flagellum. These data were further interrogated by

comparative genomics using an informative set of model organisms. Proteins were separated by their phylogenetic distribution into trypanosomatid-specific, flagellate-specific, and those with a distribution not wholly restricted to flagellates. Approximately 50% of the dataset fell into the first group and, as the roles of cilia and flagella vary widely both between and within organisms, these probably represent organism-specific structures and functions. Two-thirds of the remaining proteins were flagellate-specific, representing conserved components of the axoneme. The remaining proteins include tubulins and calcium-binding proteins that have cellular roles in addition to their function in flagella. Finally, we have compared our dataset to other bioinformatic and proteomic studies and generated a list of 134 proteins that have appeared in multiple studies. We propose that this cohort of proteins forms a core axoneme conserved across eukarya.

1022

**Insights into Flagellar Function and Disease from RNAi Validation of a Flagellar Proteome**

H. Dawe,[1] H. Farr,[1] N. Portman,[1] P. McKean,[2] K. Gull[1]; [1]Sir William Dunn School of Pathology, University of Oxford, Oxford, United Kingdom, [2]Department of Biological Sciences, Lancaster University, Lancaster, United Kingdom

We have recently completed a proteomic and comparative bioinformatic analysis of the *Trypanosoma brucei* flagellum. In order to validate our proteome biologically, a set of proteins from our final dataset was selected for investigation by RNAi. This set covers each of the major groups identified in our bioinformatic screen (trypanosomatid-specific; flagellate-specific; and those with a distribution not wholly restricted to flagellates). Protein expression was knocked down by inducible RNAi and the mutant cell lines were scored for aberrant flagellar, growth and cell morphogenesis phenotypes. Induction of RNAi did not prevent flagellum assembly for any of the proteins examined; however we found motility phenotypes consistent with a defect in the flagellum. Two proteins did not produce a phenotype on RNAi induction, and proved to be members of a gene family in *T. brucei*. We therefore performed simultaneous ablation of both proteins and observed a slow growth phenotype and paralysis of the flagellum, indicating gene redundancy. We analysed our proteomic dataset for the presence of *T. brucei* orthologues of known and putative ciliary disease genes. We identified the orthologues of 11 genes known to cause diseases with a clinical spectrum suggestive of ciliary dysfunction. Four of these represent novel axonemal components that we identify in this work. In addition over 45 proteins in our set have orthologues that map to genetic loci linked to diseases that have pathologies consistent with ciliary defects, and represent a valuable resource for the identification of novel ciliary disease genes.

1023

**IC97, A Novel Dynein Intermediate Chain From Flagellar Inner Arm Dynein I1, Interacts with Tubulin In Situ**

M. Wirschell,[1] T. W. Hendrickson,[2] L. Fox,[1] N. A. Haas,[3] C. D. Silflow,[3] G. B. Witman,[4] W. S. Sale[1]; [1]Cell Biology, Emory University School of Medicine, Atlanta, GA, [2]Department of Biology, Morehouse College, Atlanta, GA, [3]Department of Plant Biology, University of Minnesota, St. Paul, MN, [4]Department of Cell Biology, University of Massachusetts, Worcester, MA

Our goal is to determine the molecular basis of assembly and regulation of flagellar dyneins, particularly *Chlamydomonas* inner arm dynein I1. Here we focus on a previously uncharacterized I1 intermediate chain (IC), IC97. Sequences of peptides from band-purified IC97 were determined by MS/MS and used to clone the IC97 gene, which maps to linkage group XV. IC97 is a novel IC without notable structural domains such as WD-repeats. BLAST reveals IC97 shares homology to an axonemal protein in *Ciona* and with Las1 proteins - encoded by part of the multigenic pulmonary adenoma susceptibility 1 (Pas1) locus implicated in lung tumorigenesis in mice. An IC97 antibody detects a ~90-kDa protein in purified I1 fractions and isolated axonemes; this protein is missing in I1-defective mutants (see also Bower *et al*., these proceedings). Previous data determined an axonemal protein, postulated to be IC97, interacts with IC138 and IC140 (Hendrickson *et al*., 2004 and Yang *et al.* 1998). To test this, EDC crosslinking was used to identify IC97-interacting proteins. No bands corresponding to the IC138 and IC140 crosslinked products were detected. Rather, a ~140-kDa crosslinked product was identified, indicating IC97 interacts with a ~50-kDa axonemal protein. The crosslinked product was immuno-precipitated and components identified by MS/MS. In addition to IC97, the only other significant peptides obtained corresponded to α- and β-tubulin. The interaction of IC97 and α-tubulin was confirmed in EDC-crosslinked axonemes from an HA-tagged α1-tubulin strain. These results demonstrate that IC97 interacts with tubulin components *in situ*, and suggests that IC97 is located at the base of I1, providing additional evidence for the localization of ICs at the doublet microtubule "cargo" binding site.

1024

**The Flagellar A-Kinase Anchoring Protein, RSP3, is a Dimer**

M. Wirschell,[1] F. Zhao,[1] D. Diener,[2] A. R. Gaillard,[3] C. Yang,[4] P. Yang,[4] J. Rosenbaum,[2] W. S. Sale[1]; [1]Cell Biology, Emory University School of Medicine, Atlanta, GA, [2]Department of Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT, [3]Deparment of Biology, Sam Houston State University, Huntsville, TX, [4]Department of Biology, Marquette University, Milwaukee, WI

Experimental evidence in *Chlamydomonas* has demonstrated that the radial spokes are required for regulation of dynein-driven microtubule sliding and control of ciliary/flagellar bend symmetry. In particular, radial spoke protein 3, RSP3, is an A-kinase anchoring protein thought to anchor PKA and locally regulate dynein. To further explore the role of RSP3, we used EDC crosslinking to identify RSP3 interacting proteins. EDC crosslinking in isolated axonemes results in 150-kDa RSP3 product. Several independent experiments demonstrate that the 150-kDa crosslinked product is a dimer of RSP3. First, the extracted crosslinked product co-sedimented with isolated 20S radial spokes and was also formed in the isolated 20S radial spokes and 12S radial spoke precursor. Therefore, the crosslinked product was strictly formed within individual radial spokes, between radial spoke proteins. Second, given the size of the crosslinked product, RSP3 interacts with a second RSP3 or another similar sized radial spoke protein. To distinguish between these possibilities, two approaches were taken; crosslinking of mutant axonemes missing specific spoke proteins, and 2D gel analysis of the crosslinked product's pI. The 150-kDa RSP3 crosslinked product was successfully formed in mutant axonemes lacking the spoke head, RSP2 or RSP23. 2-D gels demonstrate the pI of the crosslinked product is the same as un-crosslinked RSP3. Third, the 150-kDa crosslinked product was formed using purified, bacterially expressed RSP3. Fourth, native gel electrophoresis demonstrated the purified recombinant RSP3 migrated as two distinct species; a faster migrating form that co-migrated with denatured, monomeric RSP3, and a slower migrating form-indicative of an RSP3 dimer. These data support a model in which each radial spoke is founded on an RSP3 homodimer, and indicate that each radial spoke can localize two PKAs in position to control dynein activity and axonemal bending.

**Stepwise Ciliary Growth on Sea Urchin Embryos Supported by Kinesin-2**

R. L. Morris, D. Erkoboni, J. Nordberg, C. N. English, F. J. Dufort, A. Manning; Biology, Wheaton College, Norton, MA

The ciliary lifecycle in sea urchin embryos involves the assembly, maintenance, retraction and disassembly of the axoneme at least once each mitotic cell cycle. Previous evidence suggests that cilia on sea urchin embryos first form an assembly intermediate, or procilium, that requires the activity of kinesin-2 to mature into a full-length beating organelle. To test this hypothesis, we employed quantitative light microscopy and GFP-tagged kinesin-2 subunits to investigate patterns of cilia growth in sea urchin embryos and the roles of kinesin-2 in the ciliary lifecycle. Although ciliary elongation was steady when cilia growth was monitored as a population, pauses in cilia growth during ciliogenesis were detected in both *L. pictus* and *L. variegatus* embryos when the growth of individual cilia was monitored. Pauses in growth occurred consistently in the range of lengths predicted for procilia. Final lengths of *L. variegatus* cilia fell into three discrete modes of 2 μm, 11 μm, and 23 μm suggesting that stepwise ciliary maturation may occur over successive cell divisions. Interestingly, sister cells (twin daughters of the same mother cell mitosis) on *L. variegatus* embryos were observed repeatedly and synchronously growing and retracting cilia in the 11 μm length mode without undergoing mitosis. Ciliary retractions were typically continuous and linear and showed that retraction acts to pull the axoneme down and out of its plasma membrane sheath possibly using motors at the ciliary base. Roles of kinesin-II in the stepwise assembly and maturation of cilia was investigated using the GFP-tagged non-motor KAP subunit of kinesin-2. Observations of KAP-GFP redistributing between basal bodies, axonemes, and nuclei support the hypothesis that kinesin-2 in sea urchin embryos plays roles in ciliary assembly and maintenance through intra-flagellar transport (IFT) and may play a signaling role in the nucleus.

1026

**A Molecular Dissection of Ciliogenesis**

E. S. Kannegaard, W. F. Marshall; Biochemistry, University of California San Francisco, San Francisco, CA

Cilia are known to be crucial for many developmental and physiological processes, yet the establishment and maintenance of cilia are not well understood. In particular, apart from intraflagellar transport proteins, molecular players in the process of ciliogenesis are largely unknown. Two recent studies utilizing the unicellular green alga *Chlamydomonas reinhardtii*, which has two flagella that are homologous to human cilia, have determined the proteome of the flagellum and identified genes that are upregulated upon deflagellation. By analyzing these datasets we have identified a set of genes that are upregulated during flagellar regeneration for which the gene products are not components of the flagellum itself, suggesting that there is a class of proteins whose function is to act as cofactors in flagellar assembly. Potential roles for these proteins include chaperones, signaling intermediates, and targeting proteins. We propose to investigate the functions of ciliogenesis cofactor proteins utilizing knockdown and knockout strategies in *Chlamydomonas* and ciliated mammalian tissue culture cells.

1027

**Identification and Characterization of a Guanine Nucleotide Exchange Factor in *Tetrahymena thermophila***

A. J. Bell, C. Guerra, A. Awan, P. Satir; Department of Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

In 1999, a guanine nucleotide exchange factor (GEF) was identified in *Paramecium* from a screen for ciliary proteins and was named PSec7 (Nair et al, FASEB J.) Use of the *Paramecium* PSec7 antibody in *Tetrahymena thermophila* recognized a putative GEF protein, Gef1p, which localizes to the cilia in immunofluorescence, immunoEM and western blot experiments. Gef1p coimmunoprecipitates with and is probably transported by the *Tetrahymena* intraciliary transport kinesin motor protein, Kin5. PCR methods and database analysis were used to identify *GEF*1. A protein 2053 amino acids in length, containing Sec7 motifs, truncated IQ motifs and PH domains, homologous to similar domains in Psec7, was cloned. Upregulation of the product of this gene was observed via RT-PCR following deciliation and subsequent regrowth of cilia in *Tetrahymena* cells. In order to confirm previous experimental results for Gef1p, a second antibody is being made against the cloned protein. In addition, a knockdown of the cloned protein will be performed by utilizing RNAi. A proposed model for the role of GEFs in the cilium will be presented based on these data.

1028

**A Lis1-like Protein is Associated with Axonemal Outer Arm Dynein in *Chlamydomonas***

L. B. Pedersen,[1] J. L. Rosenbaum,[2] S. M. King[3]; [1]Molecular Biology and Physiology, University of Copenhagen, Copenhagen, Denmark, [2]MCDB Department, Yale University, New Haven, CT, [3]Department of Molecular, Microbial, and Structural Biology, University of Connecticut Health Center, Farmington, CT

Lissencephaly is a severe developmental brain disorder characterized by a smooth cerebral surface, thickened cortex, and misplaced neurons. Type I lissencephaly is caused by mutations in the *LIS1* gene, which encodes a WD-repeat protein previously implicated in cytoplasmic dynein regulation, nuclear migration, and mitosis (Morris et al., 1998, Trends Cell Biol., 8:467-470). Several proteins involved in nuclear migration in *Aspergillus* bind directly to Lis1, including the nuclear movement protein NudC (Morris et al., 1998, Curr. Biol., 8:603-606). Mammalian NudC is highly expressed in ciliated epithelia, and localizes to motile cilia in various tissues, including brain (Gocke et al., 2000, Histochem. Cell Biol., 114:293-301). Moreover, a NudC ortholog is upregulated upon deflagellation in *Chlamydomonas* (Stolc et al., 2005, PNAS, 102:3703-3707). We cloned a gene encoding a Lis1-like protein (CrLis1) from *Chlamydomonas*. CrLis1 contains 347 residues with a mass of 37.2 kDa and contains seven WD-repeat domains, similar to Lis1 proteins from other organisms. Immunoblotting using an antibody raised against CrLis1 revealed that this protein is present in flagella and is mostly solubilized following detergent treatment. Furthermore, CrLis1 is depleted from flagella of mutants with defects in outer arm dynein assembly (*oda1*, *oda3*, *oda6*), but is present in strains missing other axonemal structures including inner arms (*ida1*, *ida4*), radial spokes (*pf14*) and the central pair microtubule complex (*pf18*). GST pull-down experiments indicate that CrLis1 physically interacts with outer arm dynein components from *Chlamydomonas* flagella. Furthermore, CrLis1 binds directly to rat NudC indicating that it is a functional ortholog of the mammalian Lis1 protein. These results suggest that CrLis1 and NudC are present in cilia/flagella and may play a role in regulating outer arm dynein activity.

1029

**Analysis of a Rab-like Protein Involved in Lifespan Regulation in *C elegans* Cilia**

J. C. Schafer,[1] B. DuBose,[1] C. J. Haycraft,[1] P. Swoboda,[2] B. K. Yoder[1]; [1]Cell Biology, University of Alabama at Birmingham, Birmingham, AL, [2]Department of Biosciences, Karolinska Institute, Section of Natural Sciences, Södertörn Univerity College, Huddinge, Sweden

Cilia are important structures that function in a variety of ways including sensory perception, cell and fluid motility, and embryonic patterning. Intraflagellar Transport (IFT) is a mechanism by which proteins necessary for cilia formation and maintenance are assembled into large rafts at the base of the cilia and are carried along the cilium axoneme in anterograde and retrograde directions by motor proteins. Several IFT genes in *C. elegans* are regulated by the transcription factor DAF-19 which binds to a sequence known as an X-box in the promoters of these genes. Based on this fact, we have identified a novel cilia protein, T28F3.6, that shares significant homology with members of the Rab family of proteins involved in protein trafficking. T28F3.6 is homologous to the RabL5 protein that is conserved among ciliated eukaryotes including human, mouse, and *Drosophila*. We have found that T28F3.6::GFP localizes to cilia in *C. elegans* and moves along the cilium axoneme similar to other IFT proteins. Furthermore, mutation of a single amino acid believed to be involved in GTP binding causes delocalization of the protein throughout the ciliated sensory neurons. Also, analysis of T28F3.6::GFP in several known cilia mutants shows that T28F3.6::GFP remains localized to cilia despite loss of other IFT proteins. Characterization of two mutants in the T28F3.6 gene in *C. elegans* has shown an extended lifespan phenotype. Interestingly, these mutants show no defects in cilia morphology and also do not exhibit other cilia mutant phenotypes such as osmotic avoidance or chemotaxis defects indicating that T28F3.6 is not a typical IFT protein involved in ciliogenesis. Therefore, we are continuing our research into the role of T28F3.6 in the *C. elegans* lifespan pathway as a way to discern its role in the cilia.

1030

**The *C elegans* Homologs of Nephrocystin-1 and Nephrocystin-4 are Cilia Transition Zone Proteins Involved in Chemosensory Perception**

M. E. Winkelbauer,[1] J. C. Schafer,[1] C. J. Haycraft,[1] P. Swoboda,[2] B. K. Yoder[1]; [1]Department of Cell Biology, University of Alabama at Birmingham, Birmingham, AL, [2]Department of Biosciences, Section of Natural Sciences, Karolinska Institute, Sodertorn University College, Huddinge, Sweden

Nephronophthisis (NPH) is a cystic kidney disorder that causes end-stage renal failure in children. Five nephrocystin (nephrocystin-1 to nephrocystin-5) genes whose function is disrupted in NPH patients have been identified and data indicate they form a complex at cell junctions and focal adhesions. More recently, the nephrocystin proteins have also been localized to cilia, as have multiple other cystic kidney disease related proteins. Significant insights into this cilia and cystic kidney disease connection have come from analyses in simpler eukaryotic organisms such as *C. elegans*. In this regard, we became interested in the *C. elegans* homologs of nephrocystin-1 (*nph-1*) and nephrocystin-4 (*nph-4*) due to an in silico based screen to identify genes coordinately regulated by the ciliogenic transcription factor DAF-19. Here we show that expression of *nph-1* and *nph-4* is DAF-19 dependent, that their expression is restricted to ciliated sensory neurons, and that both NPH-1 and NPH-4 concentrate at the transition zones at the base of the cilia, but are not found in the cilia axoneme. In addition, NPH-4 is required for the localization of NPH-1 to this domain. Interestingly, *nph-1* or *nph-4* mutants have no obvious cilia assembly defects; however, they do have abnormalities in cilia mediated sensory functions as evidenced by abnormal chemotaxis and lifespan regulation. Our data suggest that rather than having a ciliogenic role, the NPH proteins play an important function as part of the sensory or signaling machinery of this organelle. These findings suggest that the defects in human NPH patients may not be the result of aberrant ciliogenesis but abnormal cilia-sensory functions.

1031

**Epitope Tagging of Novel, Conserved Flagellar Proteins in *Chlamydomonas reinhardtii***

K. F. Lechtreck, G. B. Witman; Depratment of Cell Biology, University of Massachusetts Medical School, Worcester, MA

Proteomic analysis of flagella isolated from *Chlamydomonas reinhardtii* has identified more than 600 proteins by two or more peptides (Pazour et al. 2005, JCB 170:103). This data set includes known proteins that were not previously reported to be flagellar constituents, and numerous previously uncharacterized proteins, of which ~90 are highly conserved in vertebrates. We are using epitope tagging to test whether the latter are genuine flagellar proteins, and to determine their locations within the flagellum. To date, 16 genes have been cloned by PCR and ligated into a vector that fuses three consecutive HA tags to the C-terminus of the gene products. Eight of these (C_20334, C_30068, C_320063, C_380055, C_410061, C_450085, C_630058, C_650031), with predicted products in a size range from 36 to 90 kDa, were transformed into Chlamydomonas and stably expressed as revealed by western blotting using anti-HA. Indirect immunofluorescence of methanol-fixed cells confirmed a flagellar localization for all eight; five fusion proteins showed additional localization at the basal bodies or in the cytoplasm. Within the flagellum, distinctly different distributions of the fusion proteins were observed, including preferential labeling of the subdistal part, exclusion from the distal part, and a proximo-distal decrease in signal strength. Six of the eight proteins could be detected after detergent extraction and aldehyde fixation, suggesting a firm association with the axoneme. The results show that HA-tagging is a suitable method for rapid validation of putative flagellar proteins. HA-tagging also should facilitate identification of those components that interact with the tagged proteins.

1032

**Proteins of the Radial Spoke, a Mechanochemical Signal Transducer in 9+2 Cilia and Flagella**

P. Yang,[1] D. R. Diener,[2] C. Yang,[1] T. Kohno,[3] G. J. Pazour,[4] J. M. Dienes,[1] N. Agrin,[5] S. M. King,[6] W. S. Sale,[7] R. Kamiya,[3] J. L. Rosenbaum,[2] G. B. Witman[5]; [1]Biology, Marquette Universty, Milwaukee, WI, [2]MCDB, Yale Universty, New Haven, CT, [3]Biological Sciences, Universty of Tokyo, Tokyo, Japan, [4]Program in Molecular Medicine, University of Massachusetts, Worcester, MA, [5]Cell Biology, University of Massachusetts, Worcester, MA, [6]MMSB, University of Connecticut Health Center, Farmington, CT, [7]Cell Biology, Emory Universty, Atlanta, GA

The radial spoke is a ubiquitous component of “9+2” cilia and flagella and plays an essential role in the control of dynein arm activity by relaying signals from the central pair of microtubules to the arms. The *Chlamydomonas reinhardtii* radial spoke contains at least 23 proteins, only 8 of which have been characterized at the molecular level. Here we report the use of mass spectrometry to identify 10 additional radial spoke proteins. Many of the newly identified proteins in the spoke stalk contain domains associated with signal transduction, including calcium-, calmodulin-, nucleotide- and AKAP-binding domains. This suggests that the stalk is both a scaffold for signaling molecules and itself a transducer of signals. Moreover, in addition to the recently described HSP40 family member, a second stalk protein is predicted to be a molecular chaperone, implying

that there is a sophisticated mechanism for the assembly of this large complex. Among the 18 spoke proteins identified to date, 13 have apparent homologues in humans, indicating that the protein composition of the radial spoke has been conserved throughout evolution. The identification of human genes predicted to encode radial spoke proteins provides new candidates for causing primary ciliary dyskinesia, a severe inherited disease involving missing or defective axonemal structures, including the radial spokes.

1033

**The Parkin Co-Regulated Gene Product, PACRG, is an Evolutionarily Conserved Axonemal Protein that Functions in Outer Doublet Microtubule Morphogenesis**

H. Dawe, H. K. Farr, N. Portman, M. Shaw, K. Gull; Sir William Dunn School of Pathology, University of Oxford, Oxford, United Kingdom

Eukaryotic cilia and flagella are highly conserved structures composed of a canonical 9+2 microtubule axoneme. Comparative genomics of flagellated and non-flagellated eukaryotes provides one way to identify new putative flagellar proteins. We analysed candidates emerging from such a screen by comparison with published human proteomic data and interrogated their putative flagellar function by RNA interference (RNAi) using the genetically tractable protozoan parasite *Trypanosoma brucei*. One such candidate was identified as the Parkin co-regulated gene product, PACRG. Male mice deficient in PACRG are sterile, but its function remains unclear. Bioinformatics revealed that *T. brucei* possesses two homologues of *PACRG*. We performed RNAi knockdown experiments of the two genes independently and together. Inducible RNAi knockdown of either protein individually had no effect on cell morphogenesis, growth or motility. However, simultaneous ablation of both proteins produced slow growth and paralysis of the flagellum with consequent effects on organelle segregation, suggesting functional redundancy. Transmission electron microscopy revealed structural defects in the axoneme, with microtubule doublets missing from the canonical 9+2 axoneme. The occurrence of missing doublets increased toward the distal end of the flagellum and sequential loss of doublets was observed along individual axonemes. Using videomicroscopy, we observed cells where the distal region of the flagellum was paralysed, although a beat was still observed in the proximal region of the flagellum. GFP fusion proteins of both PACRG homologues localised along the full length of the axoneme, but not to the basal body. Our results provide the first evidence for PACRG function within the axoneme, where we suggest that PACRG acts to maintain functional stability of the axonemal outer doublets of both motile and sensory cilia and flagella.

1034

**Characterization of the $SSTR_3$ Ciliary Targeting Signal**

Y. Vucica, G. Pazour; Molecular Medicine, University of Massachusetts Medical School, Worcester, MA

The ciliary membrane is continuous with the apical plasma membrane but it contains a unique set of membrane proteins. Very little is known about ciliary targeting but a mechanism must exist that recognizes motifs in ciliary membrane proteins to target them for insertion into this membrane subdomain. To address this question, we have characterized the ciliary targeting motif in the $SSTR_3$ isoform of the somatostatin receptor. The $SSTR_3$ somatostatin receptor specifically localizes to primary cilia (Handel *et al*., Neurosci. 89:909-26). GFP-tagged $SSTR_3$ is highly localized to the ciliary membrane in cultured kidney cells, while the highly similar $SSTR_5$ isoform is not. Domain swapping experiments with $SSTR_5$ have identified the 19 amino acid extracellular loop between transmembrane helices 4 and 5 as the minimal sequence required for ciliary localization. This sequence is conserved in vertebrate $SSTR_3$ isoforms but not in other ciliary targeted membrane proteins. Thus, ciliary membrane targeting does not appear to be directed by common motifs as is observed for targeting to other organelles and to the basal-lateral surface of cells. Ciliary targeting appears more similar to apical membrane targeting where no common motif has been identified. In apical targeting, interaction with lipid rafts (driven by multiple mechanisms) appears to be the key step. Since the cilium projects from the apical surface of cells we are testing the idea that ciliary targeting is a specialized form of apical targeting. To do this, we are determining how the depletion of cholesterol, which disrupts lipid rafts, and how palmitoylation inhibitors, which can disrupt interaction of proteins with lipid rafts, affects the targeting of $SSTR_3$ to the cilium. Both perturbants affect ciliary targeting indicating that lipid raft association is likely to be a key event in ciliary targeting.

1035

**A Novel *Chlamydomonas* Mutant Having Flagellar Axonemes with Irregular Numbers of Outer Doublet Microtubules**

Y. Nakazawa, R. Kamiya, M. Hirono; Department of Biological Sciences, University of Tokyo, Tokyo, Japan

Almost all eukaryotic flagella and cilia have the same basic structure consisting of nine outer doublet microtubules and two central microtubules. How this structure is formed has been a long-standing question. We isolated a new *Chlamydomonas* mutant that has a defect in the basal body and assembles flagella with irregular numbers of doublet microtubules. This mutant, named *vdn1* for variable doublet number, grew slowly and displayed variable cell size. Approximately 89% of the cells were aflagellate, 9% uniflagellate, and 2% biflagellate. Electron microscopy revealed that, in most cells, basal bodies were split in pieces consisting of one to five triplets. However, all the axonemes possessed by this mutant consisted of doublet microtubules arranged in circles. Strikingly, the number of the doublets was variable between eight and eleven. Of the total of ~10,000 axonemal cross sections observed, 5% had eight doublets, 90% nine, 5% ten, and 2-3% eleven. All the eight-doublet axonemes contained no central pair microtubules. This is probably because an axoneme with such a small diameter with internally projecting radial spokes does not have space to accommodate central microtubules. In fact, the double mutant of *vdn1* with *pf14*, a mutant that lacks the radial spokes, displayed eight-doublet axonemes containing the central microtubules. In the axoneme with 10 or 11 doublets, the distance between the outer doublets and the central pair was not constant, resulting in a distorted arrangement of the doublets. In *vdn1 pf14*, however, no distortion was observed. From these observations, we concluded that the outer doublet microtubules in the axoneme have self-organizing properties to form a cylindrical structure, and that the radial spokes contribute to the assembly of the axonemal structure with a proper diameter.

1036

**HSP40 Is Required for the Final Assembly of Radial Spoke Complex in Flagella**

C. Yang,[1] D. R. Diener,[2] J. L. Rosenbaum,[2] H. A. Owen,[3] P. Yang[1]; [1]Department of Biological Sciences, Marquette University, Milwaukee, WI, [2]Department of Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT, [3]Department of Biological Sciences, University of Wisconsin-Milwaukee, Milwaukee, WI

Chaperone machinery has been implicated in the assembly of axonemes that occurs primarily at the tip of flagella. Recently, we have discovered

that a radial spoke protein, RSP16 in *Chlamydomonas* flagella is an HSP40. Interestingly, RSP16 is not a component of the 12S spoke precursor complex that is assembled in cell body and delivered to the flagellar tip by anterograde intraflagellar transport. Rather, in flagella RSP16 joins the precursors and becomes a constitutive component of the 20S stable spoke complexes. We postulate that RSP16 functions as a co-chaperone for converting precursors into mature spokes. To test this, we co-transformed wild type cells with one plasmid containing an RSP16-hairpin and the other conferring paromomycin-resistance. Among ~ 200 paromomycin-resistant transformants, four cells have flagella that jerk actively. Western analysis showed that RSP16 is not detected in their axonemes and cell body extract, while the other proteins in spokes, dyneins and central pair appear normal and the extracted radial spokes still sediment as 20S particles. Interestingly, negative stain electron microscopy reveals that the spokehead appears less compact. Consistently, chemical cross-linking of spokehead proteins is less efficient in RSP16-less spokes whereas the basal end of the spoke is not affected. Together, the results suggest that spoke HSP40 is specifically involved in the final folding of the head end of radial spokes; the improperly folded spokes in the absence of spoke co-chaperone results in defective interactions between spokes and central pair and, therefore, jerky flagellar beating.

## Cell Motility II (1037-1065)

1037

### Large-scale Spatial Coordination of Actin Meshwork Flow in Rapidly Moving Cells

C. A. Wilson,[1] P. T. Yam,[1] L. Ji,[2] G. Danuser,[2] J. A. Theriot[1]; [1]Biochemistry, Stanford University, Stanford, CA, [2]Cell Biology, The Scripps Research Institute, La Jolla, CA

The persistent movement of crawling cells depends on the proper spatial coordination of actin polymerization, actin depolymerization and myosin contraction, with actin polymerization biased toward the cell's leading edge and myosin contraction strongest at the rear. In the case of a motile cell, the entire cell coordinate system moves relative to the frame of reference in which the cell was observed. We use a rapid, non-iterative image cross-correlation approach to track cell rotation and translation, which is then used to define the relationship between cell and lab reference frames. This enables us to apply high-resolution tracking techniques including fluorescent speckle microscopy to measurements of the actin meshwork in rapidly moving cells such as fish keratocytes. We are characterizing, in both lab and cell reference frames, the coordination of F-actin flow dynamics across regions of cells undergoing different movement behaviors such as transient and sustained turns, and in the presence of drugs such as the myosin-II inhibitor blebbistatin. We find that cichlid keratocytes treated with blebbistatin do not lose polarity; however they do exhibit an accumulation of actin filaments at the rear and a slight decrease in speed. Blebbistatin also eliminates the inward (perpendicular to cell movement) flow of F-actin in the keratocyte rear and drastically reduces traction forces on deformable gelatin substrates. Thus, cell polarity and directional movement can be sustained solely by the actin polymerization-depolymerization cycle in keratocytes, with myosin playing a secondary role in generation of inward traction at the cell rear. Cell turning, however, appears to be strongly correlated with an imbalance in the relative rates of inward F-actin flow on the right and left sides at the rear of the cell, suggesting a strong role for myosin contraction in determining directional persistence.

### Actin Rockets Guide Membrane Protrusion and Position Primed Integrins to Direct Pathfinding

C. G. Galbraith,[1] K. M. Yamada,[1] J. A. Galbraith[2]; [1]NIDCR, NIH, Bethesda, MD, [2]NINDS, NIH, Bethesda, MD

Migrating cells constantly probe their surrounding extracellular matrix in search of permissive adhesion sites where integrin adhesion receptors can connect the matrix to the force-generating actin cytoskeleton. The probing is not uniform along the advancing cell margin; adjacent regions of the leading edge are simultaneously advancing and retracting. However, the mechanism connecting the localized control of membrane protrusion with the function of probing for matrix ligand is unknown. Here we show that actin polymerizing as rockets along the leading edge guides local membrane protrusion and positions high affinity fibronectin receptors at discrete locations along the leading edge. The actin rockets move transversely along the leading edge, independent of retrograde actin network flow. The rockets are part of preferential actin polymerization in the direction of membrane protrusion, and their trajectories shape membrane protrusion in both fibroblast lamellae and neuronal growth cones. The transversely polymerizing actin also clusters beta1 integrins and drives synchronous integrin sideways movement, positioning conformationally activated but unligated beta1 integrins along the cell perimeter. The localization of activated beta1 integrins along the edge of fibroblast lamellae and at the tips of growth cone filopodia is dependent upon the availability of free actin ends. Our experiments establish that rapid transverse actin movement steers local changes in cell protrusions and positions primed integrin adhesion receptors at the leading edge, providing a mechanism for quickly sampling the permissiveness of the surrounding matrix to guide the cell toward new adhesion sites and preferred directions of migration.

1039

### Plasma Membrane Organization is Essential for Balancing Competing Pseudopod- and Uropod- Promoting Signals During Neutrophil Polarization and Migration

S. F. Bodin, M. D. Welch; Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

Exposure of neutrophils to chemoattractant induces cell polarization and migration. These behaviors require the asymmetric activation of distinct signaling pathways and cytoskeletal elements in the protruding pseudopod at the front of cells, and the retracting uropod at the rear. An important outstanding question is, how does the organization of the plasma membrane participate in establishing and maintaining asymmetry during polarization and migration? To answer this question, we investigated the function of cholesterol, a lipid that is known to influence the organizational properties of the membrane. Using controlled cholesterol depletion to alter membrane composition, we found that a cholesterol-dependent membrane organization played an essential role in cell polarization and migration by enabling uropod function and suppressing ectopic pseudopod formation. At the molecular level, cholesterol-dependent membrane organization was required for the activation of RhoA, a major determinant of uropod activity. Moreover, it was essential for restraining to a single membrane area the accumulation of D3-phosphoinositide lipids, which serve as critical cues for pseudopod formation. At a mechanistic level, cholesterol was directly required to suppress the activation of $G_i$, and in turn to suppress inappropriate PI3-kinase activation while permitting the activation of RhoA. Our findings suggest a model in which a cholesterol-dependent membrane organization plays an essential role in the establishment of cellular asymmetry by balancing the activation and

segregating the localization of competing pseudopod- and uropod-inducing signaling pathways during neutrophil polarization and migration.

1040

**A Specific Role of Integrin Mac-1 in Inflammatory Macrophage Migration**

C. Cao, Y. Li, L. Zhang; Physiology, University of Maryland School of Medicine, Baltimore, MD

A Specific Role of Integrin Mac-1 in Inflammatory Macrophage Migration In response to acute inflammation, monocytes/macrophages accumulate at the site of injury, where they participate in various biological processes. The number of inflammatory monocytes/macrophages within the injury site increases during the early phase of inflammation and then returns to basal level when inflammation is resolved. However, the mechanism underlying the disappearance of these inflammatory monocytes/macrophages is not fully understood. In this study we examined the accelerated migration of inflammatory macrophages from the inflamed peritoneum to the draining lymph nodes, using a thioglycollate (TG)-induced peritonitis model for in vivo and a Boyden-chamber type transwell plate for in vitro migration assays. We found that unlike neutrophils the inflammatory macrophages did not undergo apoptosis within the site of inflammation. Instead, they migrated across the peritoneal mesothelium into the lymphatics at the end of acute inflammation, and from there they further moved to the lymph nodes and to the blood circulation. Most importantly, we found that genetic inactivation of Mac-1 in mice abolished this accelerated macrophage efflux from the inflammatory site to the lymphatics, but not the accumulation of blood monocytes into the inflamed peritoneum. In summary, our study demonstrates that Mac-1 is involved specifically in the efflux of activated inflammatory macrophages to the lymphatics, suggesting that Mac-1 may play an important role in the removal of local inflammatory macrophages and in their subsequent migration to the lymph nodes, a process that is critical to the development of the adaptive immunity

**mDia1 Regulates Cell Adhesion and Microtubule Stabilization During the Migration of Chick Embryo Cardiac Fibroblasts**

L. H. Tahtamouni,[1,2] L. P. Cramer,[3] J. R. Bamburg[1]; [1]Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO, [2]Biology, The Hashemite University, Amman, Jordan, [3]MRC-Laboratory for Molecular Cell Biology and Department of Biology, University College London, London, United Kingdom

Establishing polarized migration involves spatial and temporal reorganization of actin and microtubules. mDia1, a member of the formin protein family, coordinates both actin and microtubule cytoskeletons through its FH1-FH2 unit. We examined effects of both constitutively active (CA) and dominant negative (DN)-mDia1 on polarized migration of chick embryo cardiac fibroblasts (CCFs). Twenty-four hours prior to plating, cardiac explants in suspension were infected with recombinant AdTrack adenovirus to express the protein of interest. Polarized cells comprised 52% of uninfected and control infected cells, but only 24.9% of CAmDia- and 4.8% of DNmDia-expressing cells. Directional migration in control CCFs was maintained for a minimum of 15 min at an average rate of 1.14 mm/min, whereas polar and bipolar cells expressing CA-mDia1 migrated at 0.49 μm/min and 0.11 μm/min, respectively. Overexpression of CAmDia1 did not alter the G-actin/F-actin ratio in CCFs, but it increased the size, number, and total area of focal adhesions in CCFs. It also caused a 71% increase in the number of microtubule plus ends/unit area penetrating the lamellipodium, 65% of which were stabilized. Most cells expressing DN-mDia1 failed to migrate out of the explants and DNmDia expression in dissociated cells prevented their attachment. Co-expression of paxillin restored cell adhesion but not polarized migration. Together, our data demonstrate that mDia1 regulates cell adhesion and microtubule dynamics in CCFs. (Supported by NIH grants GM35126 and NS40371 (JRB), a Royal Society Fellowship and Wellcome Trust grant (LC), and a Jordanian government/The Hashemite University fellowship (LT)).

**α4 Integrin Phosphorylation as a Mechanism to Regulate Cell Migration**

L. A. Rivera Rosado, J. T. Yang; Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD

α4β1 integrin confers motility to many cell types *in vivo* and to cells in culture. In the present study we proposed that phosphorylation at the cytoplasmic tail of the α4 integrin subunit (α4 tail) may directly activate an intracellular signaling pathway to regulate cell migration. We and others have shown that, in response to scratch-wounding, the Y991A mutation, which reduces paxillin binding to α4, enhances the lamellipodia-promoting activity of α4β1, whereas the S988A mutation, which abolishes $Ser^{988}$ phosphorylation in the α4 tail, impairs this activity. To determine whether α4 phosphorylation regulates paxillin-dissociation, which in turn promotes migration, or directly activates downstream signals, an epistasis test was performed using CHO cells stably expressing α4 carrying both Y991A and S988A mutations. The double mutant (DM) α4 tail was not recognized by the phospho-α4 antibody and did not co-immunoprecipitated paxillin, indicating that both α4 phosphorylation and paxillin binding were disrupted. To determine the effect of α4-DM on the lamellipodia-promoting activity of α4β1, CHOα4-DM cells were tested in the scratch-wound assay. We found that CHOα4-DM resulted in the S988A phenotype, impairing the ability of α4 to promote lamellipodia protrusion, and closed scratch-wounds slower than CHOα4-GFP and CHOα4Y991A-GFP cells. These results indicate that paxillin dissociation from the α4 tail is not sufficient to promote cell migration and that phosphorylation at $Ser^{988}$ is required for the lamellipodia-promoting activity of α4β1 even in the absence of paxillin binding. These data support the hypothesis that α4 phosphorylation plays an active role in activating downstream signaling and promoting lamellipodia protrusion.

1043

**A Wnt-Like Pathway Controlling Polarity during Cell Migration**

K. Schlessinger,[1] J. Cau,[1] E. J. McManus,[2] D. R. Alessi,[2] A. Hall[1]; [1]MRC-LMCB, University College London, London, United Kingdom, [2]MRC Protein Phosphorylation Unit, University of Dundee, Dundee, United Kingdom

Wound-induced directed cell migration leads to reorientation of the Golgi and the MTOC. The signaling events controlling this process require localized activation of Cdc42 and the Par6/PKCζ complex at the leading edge. GSK3β is coordinately phosphorylated on Ser9, leading to APC release from GSK3β and binding to microtubule plus ends, thereby stabilizing microtubules in the direction of migration. GSK3 can be inactivated through Ser phosphorylation, which occurs during insulin signaling, or by protein-protein interaction, which occurs during Wnt signaling and requires Dishevelled (Dvl). To investigate the role of GSK3 phosphorylation in reorientation, GSK3α/β Ser to Ala double knockin fibroblasts (GSK3-KI) were used. Surprisingly, GSK3-KI cells had no defect in Golgi/MTOC reorientation. However, GSK3 inhibitors did block reorientation

in GSK3-KI cells, suggesting that GSK3 is required for reorientation in a phosphorylation-independent manner. To test whether GSK3 inactivation occurs through Dvl interaction, Dvl2 was microinjected into migrating fibroblasts. Reorientation was blocked in cells over-expressing Dvl2, suggesting that Dvl may be involved. When different Dvl mutants were injected, only constructs containing the DIX domain were able to block reorientation, implying that Dvl interaction with Axin or another Dvl molecule are required for reorientation. Coimmunoprecipitation experiments confirmed a complex formation between different Dvl isoforms following wounding, and Dvl depletion using siRNA also led to defects in reorientation. Our data suggest that Dvl is required for Golgi/MTOC reorientation, and therefore GSK3 inactivation through Dvl, rather than phosphorylation, may be the mechanism regulating reorientation during directed cell migration. The similarity to Wnt signaling prompted further investigation into the possible involvement of Wnt ligands and Frizzled receptors in this process.

1044

**PDZ-dependent Binding is Essential for Rho Guanine Exchange Factor Function and Cell Migration**

M. Liu, A. Horowitz; Angiogenesis Research Center, Dartmouth Medical School, Lebanon, NH

We have previously reported that a recently characterized RhoA-specific guanine exchange factor (GEF) was expressed as two splice variants, where the C-terminus of one variant (SYnectin-interacting eXchange factor 1 - Syx1) conformed to the consensus sequence of class 1 PDZ motifs and bound the PDZ adaptor protein synectin, while the other (Syx2) did not, as it was shorter by two C-terminal amino acids (MBC 14:285a, 2003). Overexpression of each splice variant in endothelial cells (EC) produced contrasting effects: EC overexpressing Syx1 migrated significantly faster than EC overexpressing Syx2. Silencing of the expression of endogenous Syx1, which is the predominant Syx isoform in EC, reduced global RhoA activity by ~50%, indicating that Syx1 is a major RhoA agonist in EC. Since Syx1 binds synectin, we examined the dependence of EC migration on the expression level of the latter protein. Silencing endogenous synectin expression in EC that overexpressed Syx1 reduced their migration by 80%. Similar to endogenous Syx, YFP-Syx1 was localized in the perinuclear region and at the plasma membrane (PM), where it collocated with synectin. YFP-Syx2, however, was diffusely distributed in the cytoplasm. In EC from synectin-null cells, endogenous Syx1 assumed a diffuse distribution pattern similar to that of overexpressed YFP-Syx2, indicating that Syx1 targeting is dependent on binding to synectin. Though global RhoA activity levels in EC overexpressing Syx1 or Syx2 were similar, their spatial activity patterns were drastically different. FRET experiments revealed that active RhoA in Syx1-overexpressing EC was located at the PM, but in Syx2-overexpressing EC it was diffusely distributed in the cytoplasm, similar to the localization of Syx2. These results show that the interaction of the C-terminus PDZ-binding motif of Syx1 with synectin is essential for its targeting and its promotion of cell migration.

1045

**PTP-PEST Mediates Cell Spreading and Motility through an Interaction with Paxillin**

J. S. Jamieson,[1] D. A. Tumbarello,[1] M. Hallé,[2] M. C. Brown,[1] M. L. Tremblay,[2] C. E. Turner[1]; [1]Dept. of Cell & Developmental Biology, SUNY Upstate Medical University, Syracuse, NY, [2]McGill Cancer Centre, McGill University, Montreal, PQ, Canada

The tyrosine phosphatase PTP-PEST has been implicated in the regulation of cell spreading and migration through dephosphorylation of focal adhesion proteins and inhibition of Rac GTPase activity (Sastry et al, JCS, 2002, 115:4305-16). Paxillin, a focal adhesion adaptor protein, is also required for cell spreading and motility (Brown and Turner, Physiol Rev, 2004, 84:1315-39). In this study we use paxillin -/- and PTP-PEST -/- fibroblasts to show that the paxillin-PTP-PEST interaction, via the LIM 3 and 4 domains of paxillin and the Pro 2 domain of PTP-PEST, is required for PTP-PEST to inhibit spreading and protrusion. In addition, we show that paxillin is required for stimulation of migration in reconstituted PTP-PEST -/- fibroblasts. Furthermore, using PBD analysis, we demonstrate that paxillin is essential for PTP-PEST to inhibit adhesion-induced Rac1 activity. Mutational analysis of paxillin indicates that PTP-PEST regulation of spreading and protrusion involves an interaction with the LIM domains in the carboxyl-terminus signaling via two regions in the amino-terminus: the LD4 motif and the tyrosine phosphorylation sites 31 and 118. These domains couple paxillin to the regulation of Rac1 activity via interaction with PKL-PIX-PAK and Crk respectively (Brown and Turner, Physiol Rev, 2004, 84:1315-39). Using “substrate trapping” approaches and immunoprecipitation analysis we show PKL to be a potential target of PTP-PEST. Additionally, we show that a PKL-paxillin interaction is required for PTP-PEST to regulate spreading. Together these results provide insight into the role of the paxillin-PTP-PEST interaction in integrin signaling events. Supported by NIH GM47606.

**PKA Regulates Abl Function During Chemotaxis**

P. B. Deming, L. C. Baldor, A. K. Howe; Pharmacology, University of Vermont, Burlington, VT

The cAMP-dependent protein kinase (PKA) plays important roles in cytoskeletal re-organization and cell migration. Spatial regulation of PKA is an critical component of chemotactic cell movement as disruption of either PKA activity or anchoring impairs pseudopod formation. In response to growth factor, PKA phosphorylates the vasodilator stimulated phosphoprotein (VASP) within pseudopodia which disrupts its interaction with the Abl tyrosine kinase. Abl is also an important modulator of cytoskeletal dynamics and is thought to exert a negative effect on cell migration. This suggests that PKA may exert its effects on cell migration, at least in part, through spatial regulation of Abl function. Intriguingly, we have observed that like PKA, Abl protein is also spatially regulated during chemotaxis. While Abl protein was enriched in pseudopods, the kinase activity of Abl - as assessed by phosphorylation of tyrosine 221 of the Crk adaptor protein - was not increased in pseudopodia. Inhibition of PKA activity in pseudopods resulted in an increased phosphorylation of endogenous Crk on Tyr221. Moreover, biochemical fractionation analyses imply that PKA may modulate the subcellular localization of Abl. Given our recent demonstration that PKA activity presides over Rac activation in pseudopods and the central role of Rac in chemotactic cell migration, our current data suggest that PKA may regulate Rac activity via modulating Abl function during chemotactic cell movement.

**Inhibition of Serine/Threonine Kinases Stimulates Proliferation and Migration in Polyamine Depleted Intestinal Epithelial Cells**

H. Guo, M. Patel, R. M. Ray, L. R. Johnson; Department of Physiology, University of Tennessee Health Science Center, Memphis, TN

Previously, we showed that polyamine-depletion inhibits proliferation and migration in intestinal epithelial cells (IEC-6). We also found that polyamine depletion inhibits protein phosphatase 2A (PP2A) activity. From these results, we hypothesized that polyamine-depletion inhibits

proliferation and migration by increasing serine/threonine phosphorylation. Staurosporine (STS) is a potent, cell permeable, and broad-spectrum serine/threonine kinase inhibitor. We determined whether STS-induced inhibition of serine/threonine kinases in polyamine-depleted cells restores proliferation and migration. Cells grown in the presence of DFMO (polyamine depletion) showed a significantly higher proportion of multi-nucleated cells indicating defective cytokinesis. In polyamine depleted cells, p-MLC (phospho myosin light chain) (Thr 18/Ser19) localized with a thick actin cortex. Although, 5 nM STS almost completely restored migration in polyamine depleted cells within 4h, prolonged exposure showed apoptotic effects. However, 1 nM STS restored migration within 7 h without any sign of apoptosis. Polyamine depletion inhibited lamellipodia formation, cytokinesis, and sequestered the p- MLC with the actin cortex. STS caused dissolution of the actin cortex, leading to the formation of lamellipodia in polyamine-depleted cells. STS significantly inhibited phosphorylation and the subsequent localization of MLC at the cell periphery. STS treatment increased Rac1 activity in polyamine-depleted cells. Cells grown in the presence of DFMO plus 0.1nM STS had a significantly higher rate of proliferation compared to cells grown in the presence of DFMO. These observations indicate that balance between serine/threonine kinases and serine/threonine phosphatases play a critical role in the regulation of proliferation and migration, and that it is altered in polyamine depleted cells.

### Central Role of the Phosphatidylinositol-3-kinase Signalling Pathway in the Regulation of Human Gastric Epithelial Cell Migration

M. Tétreault, P. Chailler, N. Rivard, D. Ménard; Anatomy and Cell Biology, Université de Sherbrooke, Sherbrooke, PQ, Canada

The integrity of the human gastric mucosa is maintained through its highly-dynamic regenerative capacity upon wounding. Our previous studies established that growth factors (GFs : TGFα, HGF) differently regulate the regeneration of human gastric epithelial cells. However, the intracellular signaling pathways that transmit extracellular cues and that regulate basic and stimulated gastric epithelial cell migration are still unclear. **Aim**: To investigate the involvement of PI3K signalling pathway in the regulation of gastric epithelial migration. **Methods**: Confluent HGE-17 cell monolayers were wounded with a razor blade and migration was quantified by counting the number of cells across the wound margin. The effects of a synthetic form of PtdIns(3,4,5)$P_3$ and of pharmacologic inhibitors (LY294002, rapamycin, toxinB) were examinated with and without growth factors. Wounded cultures were lyzed at different time intervals and the activation profiles of Akt and p70S6K were analyzed. The biological consequences of wild-type Akt (wt-Akt) and myristylated Akt (myr-Akt) overexpression in HGE-17 cells were studied. **Results:** LY294002 (PI3K inhibitor) strongly decreased basal and GFs-induced cell migration (40-70%) and this inhibition was already significant after only 60 min exposure. In accordance, treatments with PtdIns(3,4,5)$P_3$ greatly accelerated cell migration by 230%. Putative targets such as Akt and p70S6K were all stimulated in a PI3K-depedent manner by wounding and GFs. Specific inhibitors of RhoGTPase and mTOR/p70S6K significantly decreased HGE-17 cell migration by 40% and 25% respectively. Even though wounding induced Akt activation as early as 5 min, overexpression of wt-Akt and myr-Akt did not accelerated migration. **Conclusion :** Activation of PI3K is a central and early event involved in the control of basal and GFs stimulated gastric cell migration but the intracellular targets responsible for the differential actions of GFs are probably downstream in the pathway.

### JSAP1/JIP3 Cooperates with FAK to Regulate C-jun N-terminal Kinase and Cell Migration

T. Takino,[1] H. Miyamori,[1] K. M. Yamada,[2] H. Sato[1]; [1]Molecular Virology and Oncology, Cancer Research Institute, Kanazawa, Japan, [2]CDBRB, NIDCR/NIH, Bethesda, MD

c-Jun N-terminal kinase (JNK)/stress-activated protein kinase-associated protein 1 (JSAP1) (also termed JNK interacting protein 3; JIP3) is a member of a family of scaffold factors for the mitogen-activated protein kinase (MAPK) cascades, and it also forms a complex with focal adhesion kinase (FAK). Here we demonstrate that JSAP1 serves as a cooperative scaffold for activation of JNK and regulation of cell migration in response to fibronectin (FN) stimulation. JSAP1 mediated an association between FAK and JNK, which was induced by either co-expression of Src or attachment of cells to FN. Complex formation of FAK with JSAP1 and p130 Crk-associated substrate ($p130^{Cas}$) resulted in augmentation of FAK activity and phosphorylation of both JSAP1 and $p130^{Cas}$, which required $p130^{Cas}$ hyperphosphorylation and was abolished by inhibition of Src. JNK activation by FN was enhanced by JSAP1, which was suppressed by disrupting the FAK/$p130^{Cas}$ pathway by expression of a dominant-negative form of $p130^{Cas}$ or by inhibiting Src. We also documented the co-localization of JSAP1 with JNK and phosphorylated FAK at the leading edge and stimulation of cell migration by JSAP1 expression, which depended on its JNK binding domain and was suppressed by inhibition of JNK. The level of JSAP1 mRNA correlated with advanced malignancy in brain tumors, unlike other JIPs. We propose that the JSAP1/FAK complex functions cooperatively as a scaffold for the JNK signaling pathway and regulator of cell migration on FN, and we suggest that JSAP1 is also associated with malignancy in brain tumors.

### The Role of Caveolae Endocytosis in Caveolin-1 Polarization in Migrating Endothelial Cells

V. Santilman,[1] J. Baran,[1] M. A. McNiven,[2] M. Parat[1]; [1]Center for Anesthesiology Research, Cleveland Clinic Foundation, Cleveland, OH, [2]Department of Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN

Endothelial cell migration is a critical event in angiogenesis. Caveolae as well as their major protein caveolin-1 are polarized in migrating cells and the polarization of caveolin-1 varies with the migration mode (planar migration versus transmigration). Tyr-14 residue of the protein is necessary for this polarization. The phosphorylation of Tyr-14 of caveolin-1 is thought to be involved in a number of processes such as caveolin-1 -protein and -lipid binding and caveolae endocytosis. In this work, we wanted to test the requirement of caveolae endocytosis for caveolin-1 polarization in migrating endothelial cells. For this purpose, we inhibited the internalization of caveolae using a dominant negative mutant of dynamin-2 (K44A mutant). This mutant lacks normal GTPase activity and its expression inhibits GTP-induced fission, budding and internalization of caveolae. We verified its efficiency to inhibit caveolae endocytosis in bovine aortic endothelial cells (BAEC) by looking at bovine serum albumin and cholera toxin internalization. We examined the localization of caveolin-1 in dynamin-transfected cells migrating in two or three dimensions. For the transmigration assay, BAEC were placed in the top well of a Boyden Chamber and allowed to migrate across the pores of a collagen-coated polycarbonate filter. The localization of caveolin-1 was detected by immunofluorescence in transfected cells identified by the expression of WT or mutant dynamin-2-GFP. The K44A dynamin-2 mutant effectively inhibited caveolae endocytosis in BAEC. Our data indicate that the inhibition of caveolae internalization does not decrease the rate of planar migration or transmigration but, on the contrary, increases the rate of transmigration.

Moreover, the expression of the mutant dynamin-2 does not disturb the localization of caveolin-1 in either migration mode. Our results indicate that caveolae endocytosis is not critical for the polarization of caveolin-1 in migrating endothelial cells.

**Collective Migration of Epithelial Cells**

R. Farooqui, G. Fenteany; Chemistry, University of Illinois at Chicago, Chicago, IL

The mechanism by which epithelial, endothelial and other strongly cell-cell adhesive cells migrate collectively as continuous sheets is not clear, even though this process is critical for embryonic development and tissue repair in virtually all multicellular animals. We used wound closure in Madin-Darby canine kidney (MDCK) epithelial cell monolayers as a model to study migration of cells both at and behind the wound edge. We report here for the first time that cells behind the margin of wounded MDCK cell monolayers, even hundreds of microns from the edge, extend "cryptic" lamellipodia against the substratum beneath cells in front of them toward the wound, as determined by confocal, two-photon and transmission electron microscopy. These so-called submarginal cells nevertheless strictly maintain their more apical cell-cell contacts as they migrate as part of a coherent cell sheet, hiding their basal protrusions from conventional microscopy. The submarginal protrusions display the hallmarks of traditional lamellipodia based on morphology and dynamics. The rate of migration is inversely proportional to distance from the margin, and cells move coordinately yet still partly autonomously toward the wound area. We also clarify the ancillary role played by non-protrusive contractile actin bundles that assemble in a Rho GTPase-dependent manner at the margin after wounding. In addition, some cell proliferation occurs at a delay after wounding but does not contribute to closure, instead apparently serving to replace damaged cells so that intact spread cells can revert to their normal cuboidal morphology and the original cell density of the unbroken sheet can be restored. Cells behind the margin therefore actively crawl, instead of just moving passively as cells at the margin pull on them.

**Coupling Actin Cytoskeleton Dynamics to Substrate Adhesion in Migrating Epithelial Cells**

S. L. Gupton, C. M. Waterman-Storer; Cell Biology, Scripps Research Institute, La Jolla, CA

Cell migration is mediated by the formation of ECM ligand - receptor complexes in the cell front and their weakening and disassembly in the cell rear. The receptors assemble with structural and signaling proteins to form focal adhesions, complexes that link the intracellular actin cytoskeleton to the ECM, allowing myosin-driven tension in the cytoskeleton to produce traction against the ECM and drive cell movement. Cells show biphasic migration velocity in response to increasing adhesion strength, indicating an optimal adhesion strength exists for migration. In this study we sought to determine if adhesion-dependent changes in migration velocity are mediated by distinct dynamic states of focal adhesions and the actin cytoskeleton. We show changes in the lamellipodium module do not correlate with cell migration, but rather do changes in the lamella contractile module of the cell. We find evidence for a "clutch" linking lamella actin retrograde flow to the substrate, and suggest tuning this clutch modulates actin flow and migration. We characterize an optimal actin phenotype for migration, which includes rapid actin convergence coupled to rapid actin depolymerization in the convergence zone, which is likely driven by increased bound and active myosin. We show rapid renewal of focal adhesions components coupled to intermediate focal adhesion lifetime and turnover rates correlate with fast cell migration. These studies indicate that simple models for modulation of cell biphasic migration velocity are mediated by a complex spatio-temporal feedback between adhesion sites and myosin activity driving the organization of an actin cytoskeleton optimized for directed cell migration.

**The Shwachman-Diamond Syndrome Gene Encodes an RNA-Binding Protein That Localizes to the Pseudopod of Dictyostelium Amoebae During Chemotaxis**

D. Wessels,[1,2] T. Srikantha,[1] S. Yi,[1] S. Kuhl,[1] L. Aravind,[3] D. R. Soll[1]; [1]Dept. Biological Sciences, University of Iowa, Iowa City, IA, [2]Dept. Biological Sciences, W.M.Keck Dynamic Image Analysis Facility, Iowa City, IA, [3]NIH, Computational Biology Branch NCBI, Bethesda, MD

The Shwachman-Diamond Syndrome (SDS) is an autosomal disorder with multisystem defects. The gene *SBDS*, which contains mutations in a majority of SDS patients, encodes a protein with a deduced function in RNA metabolism. Recently it was demonstrated by computer-assisted methods that the single behavioral defect of polymorphonuclear leukocytes (PMNs) of SDS patients is the incapacity to orient correctly in a spatial gradient of chemoattractant. Although the deduced function of the *SBDS* gene product is in RNA metabolism, the very specific behavioral defect exhibited by PMNs of SDS patients suggested that it played a role in chemotactic orientation. Given that several proteins involved in chemotactic orientation localize to the pseudopod of cells during chemotaxis, we tested whether the *SBDS* gene product did the same. We identified the homolog of *SBDS* in the social amoeba *Dictyostelium discoideum*, a model for PMN chemotaxis, produced an *SBDS*-GFP chimeric in-frame fusion gene, and generated transformants either with multiple ectopic insertions of the fusion gene or multiple copies of a non-integrated plasmid carrying the fusion gene. The *SBDS*-GFP protein was dispersed equally through the cytoplasm and pseudopods of cells migrating in buffer, but exhibited differential localization in the pseudopods of cells undergoing chemotaxis in a spatial gradient of chemoattractant in both types of transformants, suggesting that the SBDS protein may play a role in chemotactic orientation. Pseudopod localization was demonstrated to be a result simply of chemotactic receptor occupancy, not a result of chemotaxis per se. To our knowledge, SBDS represents the first protein involved in RNA metabolism that localizes to pseudopods in response to a chemoattractant.

**Two Putative WAVE Associated RacGAP (WRP) Proteins Are Important in All Aspects of *Dictyostelium discoideum* Motility**

R. J. W. Heath, R. H. Insall; School of Biosciences, The University of Birmingham, Birmingham,, United Kingdom

Cellular movement and shape change is dependent upon cycles of actin polymerization and depolymerization. The Arp2/3 complex is a principal component of this process, nucleating actin filaments at the side of existing filaments. WRP (Soderling *et al*, 2002) has recently been identified in mammalian tissues as a binding partner of SCAR/WAVE1 and is a proposed signal termination factor for Rac but has no affect on Rho or CDC42. Here we identify two putative *D. discoideum* WRP proteins. We have disrupted both WRP1 and WRP2 genes by homologous recombination and made a WRP1$^-$/2$^-$ double knockout. We find a strong cytoskeletal phenotype in WRP1$^-$ cells and a relatively subtle chemotaxis defect in WRP2$^-$ cells. WRP1$^-$/2$^-$ double mutant cells have a seriously aberrant cytoskeleton and drastically impaired motility. In addition WRP1$^-$ slugs have a subtle

phototaxis phenotype while WRP2$^-$ slugs are totally defective in phototaxis and WRP1$^-$/2$^-$ slugs fail to migrate at all. The development of all WRP$^-$ cell lines is also affected. WRP2$^-$ cells develop slightly earlier than wild type cells, WRP1$^-$ fruiting bodies have short, thin stalks and the WRP1$^-$/2$^-$ double mutant line fails to form differentiated fruiting bodies. WRP is clearly important in linking external signals to the cytoskeleton; however, we find little evidence for a genetic interaction with SCAR.

**Distinct Mechanisms Regulate Hemocyte Chemotaxis During Wound Healing and Development in Drosophila**

W. Wood, C. Faria, A. Jacinto; Instituto de Medicina Molecular, Lisbon, Portugal

*Drosophila* hemocytes are highly motile macrophage-like cells that undergo a stereotypic pattern of migration to populate the whole embryo by late embryogenesis. Our results demonstrate that the migratory patterns of hemocytes at the embryonic ventral midline are orchestrated by chemotactic signals from Pvf signals. Also, these directed migrations seem to be independent of Phosphoinositide 3-Kinase (PI3K) signalling as shown by the overall distribution of hemocytes expressing a PI3K Dominant Negative form and by a detailed quantification of both cell directionality and velocity. In contrast we show, using both laser ablation and a novel wounding assay that allows localised treatment with inhibitory drugs, that PI3K is essential for hemocyte chemotaxis towards wounds and that Pvf signalling is not required for this rapid chemotactic response. Our results imply that at least two separate mechanisms operate in *Drosophila* embryos to direct hemocyte migration, and whilst PI3K is crucial for hemocytes to sense a chemotactic gradient from a wound it is not required to sense the signals that coordinate their developmental migrations along the ventral midline during embryogenesis.

**Glutamate in Neutrophil Activation: A New Role in Wound Healing Process**

R. Gupta,[1,2] D. Chattopadhyay[1,2]; [1]Department of Biochemistry, University of Calcutta, Calcutta, India, [2]Department of Biochemistry, Dr. B. C. Guha Center for Genetic Engineering and Biotechnology, Calcutta, India

Human placental extract has been found to be efficacious against wound healing for a long time. When a wound is inflicted, neutrophils migrate to the wound site within minutes of injury; to clear up the infection by engulfing the bacteria and also as the source of pro-inflammatory cytokines, which activate the surrounding fibroblasts and keratinocytes. HPLC analysis of the hot aqueuos human placental extract revealed Glutamate to be the predominant free amino acid. We investigated the role of glutamate as a chemoattractant with particular attention to its ability to activate neutrophil responses. Boyden chamber assay and FACS (F-actin quantification with phalloidin) analysis revealed the induction of chemotaxis and actin polymerization respectively optimally at a concentration of 8 µM of glutamate. A time-lapse videomicroscopy showed the polarization of neutrophils with the addition of glutamate in a span of 500 seconds. Immunofluorescence with phalloidin staining revealed the polarization of actin cytoskeleton with glutamate addition. The glutamate induced chemotaxis and the related events were found to be PI3K dependent phenomena as phospho-TLC showed the induction of PIP3 and the PI3K inhibitors wortmannin, LY29004 abrogated the glutamate effect. The translocation of GFP fluorescence to plasma membrane by a global glutamate stimulation following a PH-Akt-GFP construct electroporation reconfirmed the PI3K dependent pathway. Rac2 activation was also observed with 8µM glutamate. Incubation of neutrophils with glutamate (8 µM-32 µM) triggered oxidative burst after plating on fibrinogen. At the receptor level, the glutamate effect was actually a pertussis toxin insensitive effect, with a non-involvement of the characteristic chemoattractant G-protein-coupled receptors. Blocking antibodies to integrin beta 2 totally abrogated the glutamate signaling. Taken together, these results suggest a role for the glutamate as a chemoattractant, which is able to induce neutrophil activation.

1057

**Formin-binding Protein 2 (FNBP2) as a Candidate Regulator of Neuronal Migration in the Cortex**

S. Guerrier, F. Polleux; Department of Pharmacology, University of North Carolina-Chapel Hill, Chapel Hill, NC

The proper formation of functional neuronal circuits within the central nervous system is critically dependent upon the coordinated migration of two types of neurons, glutamatergic pyramidal neurons (excitatory), and GABAergic interneurons (inhibitory). Defects in the migration of these neurons play a role in several neuropathologies including schizophrenia and epilepsy. Formin Binding Protein 2 (FNBP2) was recently identified as a transcriptional target of Neurogenin 2, a basic-helix-loop-helix transcription factor that we have shown to regulate the migration properties of glutamatergic neurons in the developing cortex. FNBP2 is a member of the Slit/Robo GTPase activating protein family and was initially identified through its interaction with the Robo receptor. In situ hybridization indicates that FNBP2 is expressed in the ventricular zone in the developing cortex, where glutamatergic neurons initiate radial migration. Protein motif analysis indicates that FNBP2 is composed of 3 domains, an Fes/Cip4 homology (FCH) domain, rho GTPase activating (GAP) domain and a Src homology 3 (SH3) domain. These domains have been previously characterized as regulators of the cytoskeleton and protein-protein interactions, however the role of these domains in mediating the function of FNBP2 has not been determined. In this study, we aimed to determine the role of FNBP2 in the migration of cortical glutamatergic neurons. Our preliminary results demonstrate that overexpression of FNBP2 causes significant cytoskeletal rearrangement in cos7 cells. Furthermore, overexpression of FNBP2 in cortical neurons using electroporation-mediated gene transfer impairs their migration in a slice culture assay. These results suggest that FNBP2 might regulate cortical migration by controlling cytoskeletal dynamics. Current investigation involving structure-function analysis as well as in vivo loss-of-function analysis will allow us to determine the mechanism underlying FNBP2 regulation of cytoskeletal dynamics during neuronal migration

**Disruption of Centrosome Positioning Ahead of Nucleus Impairs Leading Process Outgrowth and Nuclear Translocation during Neuronal Migration**

H. R. Higginbotham,[1] T. Tanaka,[2] B. C. Brinkman,[2] J. G. Gleeson[2]; [1]Biomedical Sciences, University of California, San Diego, La Jolla, CA, [2]Dept. of Neuroscience, University of California, San Diego, La Jolla, CA

In comparison with other migratory cells, neurons exhibit a unique, highly polarized morphology and a distinctive pattern of movement. The leading process extends forward in the direction of migration and subsequently the nucleus translocates into the leading process, but the events

controlling these phases are not known. In olfactory bulb neuronal precursors we find that nuclear translocation occurs in two distinct stages: first, the centrosome moves into the leading process, which coincides with process extension, then the nucleus follows, moving abruptly towards the centrosome. Application of the chemorepellent Slit, which reverses cell polarity, first leads to establishment of a new process, then reorientation of the centrosome followed by nuclear translocation in the reverse direction. Inhibition of either GSK-3b or PKC-zeta, critical cell polarity factors, resulted in impaired process outgrowth and centrosome reorientation, with resultant failure in nuclear translocation in the reverse direction. Our findings suggest that positioning of the centrosome ahead of the nucleus is an important step in directed neuronal migration and repolarization in response to guidance cues.

**Role of Glycogen Synthase Kinase - 3 in Sperm Function Examined with Lithium Chloride**

P. Puri,[1] S. P. R. Shenoy,[2] D. W. Kline,[1] S. Vijayaraghavan[1]; [1]Department of Biological Sciences, Kent State University, Kent, OH, [2]Department of Molecular Cardiology,, Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, OH

Testicular spermatozoa are immotile and cannot bind to the egg. Sperm undergo maturation during their passage through the epididymis attaining motility and fertility potential. Biochemical mechanisms underlying sperm maturation are not completely understood. We suggested that signaling mechanisms involving serine threonine phosphatases and glycogen synthase kinase-3 may be involved in motility initiation. Both α and β isoforms of GSK-3 are serine phosphorylated in sperm. The upstream regulators of GSK-3, PI-3 kinase and Akt are also present in spermatozoa. We have examined the role of GSK-3 in sperm motility using the GSK-3 inhibitor, lithium chloride (LiCl). Motility was measured using computer assisted semen analysis. Lithium chloride dramatically decreased all motility parameters of bovine caudal epididymal spermatozoa in a concentration dependent manner. Maximum inhibitory effect was observed at 20 mM LiCl. Remarkably, motility inhibition by LiCl could be completely reversed by cAMP agonists, 2-chloroadenosine, and the protein phosphatase inhibitor calyculin A. Pretreatment of spermatozoa with these compounds also prevented the inhibitory effect of LiCl. The compound wortmanin had no effect on motility by itself or in combination with LiCl suggesting that PI-3 kinase pathway may not have a direct role on motility. Paradoxically, yet another inhibitor of PI-3 kinase, LY294002, reversed the inhibitory effect of LiCl on motility. We attribute this effect of LY294002 to an elevation of sperm cAMP levels rather than an inhibition of PI-3 kinase. Studies are underway to determine whether motility inhibition through inhibition of GSK-3 by lithium chloride involves changes in the activity of glycolytic enzyme and changes in serine phosphatase activities. Our data argue for an important role for GSK-3 in sperm function. (Supported by NIH HD38520)

**Signaling through Ephrin-B3 Regulates Migration and Invasion of Glioma Cells**

M. Nakada, K. L. Drake, J. A. Niska, M. E. Berens; Neurogenomics, Translational Genomics Research Institute, Phoenix, AZ

Eph receptor tyrosine kinases and their ligands, ephrins, mediate neurodevelopmental processes such as boundary formation, axon guidance, vasculogenesis, and cell migration. To date, Eph receptor involvement in glioblastoma invasion has been demonstrated. Eph ligands, termed ephrins, are transmembrane proteins that bind to Eph receptors; binding leads to phosphorylation of an ephrin kinase domain, which prompts successive phosphorylation of many cytoplasmic substrate proteins. Here we determined the expression profiles of the ephrin-B family members in four glioma cell lines under migrating and non-migrating conditions. Ephrin-B3 mRNA was overexpressed in all four during migration (1.3-1.7 fold). Laser capture microdissection of invading glioblastoma cells revealed elevated ephrin-B3 mRNA (1.2-10.0 fold) in 8 out of 8 biopsy specimens. Forced expression of ephrin-B3 in two low expressor glioma cell lines (U87, T98G) stimulated cell migration and invasion concomitant with the tyrosine phosphorylation of ephrin-B3. In high expressor glioma cell lines (U251, SNB19), migration and invasion were accelerated by treatment with EphB2/Fc chimera. U251 and SNB19 cells transfected with ephrin-B3 siRNA showed decreased migration and invasion. Moreover, depletion of endogenous ephrin-B3 expression abrogated the increase of migration and invasion by EphB2/Fc, indicating that increased migration and invasion is dependent on ephrin-B3. Confocal imaging of U251 and SNB19 cells showed ephrin-B3 localized in lamellipodia of motile wild type cells, and revealed a significant morphological change and the absence of ephrin-B3 localization in cells transfected with ephrin-B3 siRNA. In human brain tumor specimens, ephrin-B3 expression and phosphorylation correlated with increasing grade of gliomas. These data suggests that dysregulation of ephrin-B3 expression or function may underlie glioma invasion.

1061

**Lysophosphatidic Acid (LPA) and Sphingosine 1-Phosphate (S1P) Markedly Regulate Tumor Cell Migration and Invasion of Three-Dimensional Collagen Matrices Through Membrane-Type Metalloproteinase 1 (MT1-MMP)**

K. E. Fisher, A. Pop, W. Koh, N. J. Anthis, W. B. Saunders, G. E. Davis; Pathology and Laboratory Medicine, Texas A&M Health Science Center, College Station, TX

Tumor cell navigation through three-dimensional (3D) extracellular matrices (ECMs) occurs via interactions between the cell and its environment. Here we describe new tumor invasion microassay systems that assess the ability of lysophosphatidic acid (LPA) and sphingosine 1-phosphate (S1P) to regulate tumor cell migration and invasion. In migration assays, most tumor cells migrated in response to LPA and were inhibited by S1P while HT1080 cells uniquely migrated in response to both lipids. Likewise, HT1080 cells invaded dramatically in 3D type I collagen invasion assays with either lipid. Treatment with synthetic matrix metalloproteinase (MMP) inhibitors or tissue inhibitors of metalloproteinases (TIMPs)-2, -3, and -4 strongly blocked HT1080 invasion but not migration suggesting a role for membrane-type MMPs (MT-MMPs) in invasion. siRNA targeting MT1-MMP markedly inhibited both S1P- and LPA-induced HT1080 invasion. Transfection of migratory, non-invasive HEK293 cells with MT1-MMP cDNA resulted in LPA-induced invasion of 3D collagen matrices. These data suggest that LPA effectively promotes the migration and invasion of multiple tumor cell types while S1P inhibits these processes in most cases. Thus, LPA markedly stimulates MT1-MMP dependent tumor cell invasion of 3D collagen matrices suggesting a role for coordinated signaling between LPA and/or S1P receptors and MT-MMPs during cellular invasive events.

1062

**SSX-new Molecular Target Regulating Cancer Invasion**

K. Itoh, K. Yoshioka; Biology, Osaka Medical Center for Cancer, Osaka, Japan

The SSX genes were initially identified as fusion partners to the SYT gene in human synovial sarcomas carrying a recurrent t (X; 18)(p11.2; q11.2) chromosomal translocation. Besides adult human testis, SSX genes were expressed at varying frequencies in a number of malignancies thereby categorized as cancer/testis antigens. Using nucleic acid sequence-based amplification, we have reported that the expression level in the malignant tumors (3.8+-1.4 copies/micro g of total RNA in log10 order) was significantly higher than that in the benign tumors (2.4+-0.5, $p<0.0001$). In order to examine the biological function of SSX, we firstly made stable transfectants with wild type SSX using human osteosarcoma cell line, SaOS2, which moderately expressed SSX. The expression of SSX was mainly localized in the nucleus with patched pattern. The SSX transfectants promoted colony formation in soft agar and tumor formation in nude mice, but showed little change in growth rate in culture. The transfectants also increased motility, chemotaxis and invasiveness using scratch wound assay and Boyden chamber assay. Since the C-terminal region of SSX strongly bound to Histone in the nucleus, we next made stable transfectants with C-terminal deletion mutants of SSX1, using human fibrosarcoma cell line, HT1080, which highly expressed endogenous SSX1. The transfectants showed marked stress fibers and focal adhesions, decreased motility, chemotaxis and invasiveness in vitro, and attenuated tumorigenesis in nude mice. Furthermore, the lowering of the endogenous expression of SSX1 in HT1080 cells by the treatment with specific siRNA markedly decreased chemotaxis, but did not affect cell proliferation. Collectively, these data suggested that SSX protein regulated several gene expressions resulting in leading to the tumor invasion, and could be a new molecular target under clinical setting.

**Unraveling h-prune Function Together with Nm23 Family Protein in Breast Cancer induced Cell Motility and Metastases**

M. Zollo,[1] L. Garzia,[1] P. Carotenuto,[1] N. Marino,[1] C. Roma,[1] N. Tata,[1] A. M. Bello,[1] G. Vitale,[1] V. Maffia,[1] A. Amoresano,[2] N. Curtin,[3] A. Galeone[4]; [1]CEINGE, Naples, Italy, [2]Dipartimento di Chimica Organica e Biochimica, University Federico II, Naples, Italy, [3]Tyne Research Group, University of Newcastle, Newcastle, United Kingdom, [4]Dip. di Chimica delle Sostanze Naturali, University Federico II, Naples, Italy

Increase in cellular motility is one of the first events occurring during metastatic processes. We have demonstrated that overexpresssion of h-prune induces cells proliferation and we identified its cAMP phosphodiesterase activity effectively suppressed by dipyridamole, a phosphodiesterase inhibitor. High levels of h-prune protein versus low levels of nm23-H1 was found correlated to advanced breast cancer stage disease, thus being h-prune a new marker for diagnosis. The increase of h-prune phosphodiesterase activity resulted by protein overexpression and protein-protein interaction with nm23-H1 enhances cellular motility in breast cancer cells. Human nm23 genes display a regulative role in cellular proliferation, apoptosis, differentiation and tumor metastasis. Here we identified the molecular mechanism by which h-prune interacts with nm23 and how this complex takes part in the cellular motility network. The nm23 protein region is subjected to serine phosphorylation by Casein KinaseI. We show by spectrometry MALDI analyses, that the phosphorylation is occurring “in vivo” in a region of nm23 where serine residues of the protein are found phosphorylated. We found that IC261, a CKIδ-ε inhibitor, and a new competitive cell penetrating peptide impair nm23 specific region of phosphorylation and therefore the protein complex formation with h-prune. Additionally, we show that, IC261 and the specific peptide are both able to inhibit the h-prune pro-motility function, and the IC261 also cause h-prune relocation below the cytoplasm membrane (co-localizing with F-actin). These findings are presenting new challenges in the use of IC261 or the competitive peptide in the inhibition of cellular motility enhanced by h-prune-nm23 complex in breast cancer. 1064

**Polycystin-1 Induces Cell Migration in MDCK Cells**

M. Boca,[1] D. Deflorio,[1] G. G. Germino,[2] A. Boletta[1]; [1]Functional Genomics, Dulbecco Telethon Institute (DTI)- DIBIT-HSR, Milano, Italy, [2]Division of Nephrology, Johns Hopkins University School of Medicine, Baltimore, MD

Autosomal Dominant Polycystic Kidney Disease, one of the most common inherited disorders, is characterized by cyst formation in the kidney. Mutations of PKD1 are responsible for ~85% of all cases. Polycystin-1 (PC-1), its gene product, is a large (520kDa) non-tyrosine kinase receptor involved in cell-cell/matrix interactions as well as in mechanosensation on the primary cilium. We have shown that PC-1 expression in renal epithelial cell (MDCK, Madin Darby Canine Kidney), determines reduced growth rates, resistance to apoptosis and spontaneus tubologenesis in 3D collagen gels. We now find that PC-1 expressing cells have a scattered phenotype as compared to controls that grow in clusters. Staining with rodamine-labelled phalloidin revealed profound cytoskeletal re-arrangements in these cells as compared to controls, suggestive of an acquired migratory phenotype. We therefore perfomed time-lapse videomicroscopy of wound healing assays to assess the migratory properties of PC-1 expressing cells. Interestingly, the control cells move forward as a compact unit, the edge remaining attached to adjacent cells. In contrast, PC-1 expressing cells start pulling away from the edge as individual cells and acquire a polarized migratory phenotype. In addition, the rate of migration in these cells is considerably higher (14.62 ± 2.38 μm/h in PC-1 expressing cells vs 9.25 ± 2.71 μm/h in controls). Concomitantly, E-cadherin and β-catenin are quickly internalized. In search for the molecules that could mediate cell migration and tubulogenesis in our model system we have found that Phosphatidylinositol-3-kinase (PI3k) as well as Glycogen Synthase Kinase 3β (GSK3β) seem to be implicated, although in different aspects of the phenotypes. Furthermore, we find activation of the small GTPase cdc42 during wound healing assays in PC-1 positive cells, but not in the controls. We are currently investigating the role played by these different molecules in Polycystin-1 mediated cell migration.

1065

***Helicobacter pylori* CagA Induces AGS Cell Elongation Independent of Cdc42 and Rac1**

K. M. Bourzac, K. J. Guillemin; Institute of Molecular Biology, University of Oregon, Eugene, OR

*Helicobacter pylori* is the causative agent of gastric diseases including duodenal ulcers and gastric cancer. A more severe disease outcome is associated with strains harboring the *cag* pathogenicity island whose genes include components of a Type IV secretion system and its secreted substrate, CagA. Once delivered into host cells, CagA is tyrosine phosphorylated by Src-family kinases and then binds to and activates SHP-2 phosphatase and other components of the c-Met receptor tyrosine kinase pathway. This inappropriate signaling is thought to lead to cancer

development. The gastric adenocarcinoma cell line AGS respond to CagA-induced signaling by undergoing pronounced cellular elongation in tissue culture. While recent studies have identified key steps in early CagA signaling events, little is known about downstream molecules important for initiation of cell shape changes. The Rho GTPases Cdc42 and Rac1 are key mediators of actin dynamics, and there has been speculation that they could play an important role in the CagA phenotype. To test this hypothesis, AGS cells were transiently transfected with dominant negative alleles of Cdc42 or Rac1 and then challenged with *H. pylori* infection. We found that neither of these constructs blocked AGS cell elongation. Cdc42 effector protein 2 (CEP2), a downstream effector of Cdc42 that is upregulated in AGS cells during infection, was also found to play no role in the elongation phenotype. Further, we were unable to detect activation of Cdc42 or Rac1 during an infection time course using GST-CRIB affinity pulldown experiments. We also found that the localization of the cellular population of Cdc42 and Rac1 is not changed during infection. Therefore, we conclude that CagA-induced cell elongation is independent of Cdc42 and Rac1.

## Cytoskeletal Organization I (1066-1089)

1066

### CD28 Initiates Polarization of the Microtubule Organization Center and Cytolytic Granules to the Synapse by Inducing Phosphorylation of ERK2

X. Chen, D. Allan, K. Krzewski, J. L. Strominger; Molecular and Cellular Biology, Harvard University, Cambridge, MA

Activation of natural killer (NK) cell cytotoxicity requires adhesion and formation of a conjugate with a susceptible target cell, localized actin polymerization, and polarization of cytolytic granules for targeted release. Previously PI3K-mediated ERK activation was shown to be required for cytolytic granule translocation, and thus necessary for NK cell cytotoxicity (*Djeu Y.J. et al. Clinic cancer research, V8:636,2002*). Here, the mechanism of the phenomenon has been examined in detail. The PI3K/ERK pathway is shown to modulate microtubule rearrangement. Specifically, activated ERK2 (but not ERK1) participates in NK cell cytotoxicity by contributing to the polarization of the microtubule organization center (MTOC) to the NK cell immune synapse (NKIS). ERK is observed to directly interact with microtubule filaments. Actin polymerization in the NKIS and NK cell/target cell conjugate formation is not affected by blocking ERK activation. Using the YTS NK cell line model, CD28 signaling plays an essential and sufficient role in stimulating NK cell cytotoxicity, while LFA-1 signaling is normally required but not sufficient. Interestingly, CD28 signals MTOC polarization through sustained ERK2 phosphorylation. On the contrary, LFA-1 ligation transduces a transient ERK2 activation and fails to polarize the MTOC. Rather, LFA-1 signals initiate actin polymerization and conjugate formation, while CD28 does not. Thus, in YTS cells, these two receptors appear to play distinct functional roles, each essential for formation of the NK immune synapse, regulating different cytoskeletal processes, and differing in their pattern of ERK2 activation.

### The Regulation of Immune Cell Function by the Rho GTPase Rif

S. L. Passey, S. Pellegrin, H. Mellor; Biochemistry, Univerisity of Bristol, Bristol, United Kingdom

Rho family GTPases are critical regulators of the actin cytoskeleton, and play important roles in regulating cell shape and motility. We have shown that the novel Rho GTPase family member Rif (Rho In Filopodia) induces the formation of long actin-based structures called filopodia when expressed in a number of mammalian cell types. We find that it functions independently of the classical filopodia-inducing Rho GTPase Cdc42 as well as the downstream signalling components of this pathway WASP and Arp2/3, instead Rif induces filopodia formation the actin-nucleating formin mDia2. Thus Rif represents an alternative route to filopodia formation which allows the cell to generate subtly different filopodia-like protrusions to perform different roles. We are particularly interested in the physiological role for Rif and Rif-induced filopodia in mammalian cells. Microarray data and western blotting have revealed that Rif is highly expressed in a subset of immune cells, suggesting that it may play an important role in immune function. Overexpression of Rif and constitutively active Rif mutants in these cells results in dramatic actin rearrangement. We are currently investigating the regulation of the actin cytoskeleton by Rif in immune cells and hypothesise that Rif plays an important role in regulating the essential changes in morphology that underpin immune cell function and the generation of an efficient immune response.

1068

### The Rho Family GTPase Rif Induces Filopodia through mDia2

S. Pellegrin, H. Mellor; Biochemistry, University of Bristol, Bristol, United Kingdom

The Rho GTPases RhoA, Rac1 and Cdc42 are well-characterised regulators of the actin cytoskeleton but little is known about the other 19 mammalian Rho GTPases. We have isolated a novel Rho-family GTPase, Rif (Rho in filopodia), which is present in chordates including ascidians. When transiently expressed in mammalian cells, Rif is localised at the plasma membrane and induces the formation of long, thin, actin-rich projections called filopodia. The Rho GTPase Cdc42 is a key mediator of filopodia formation. Cdc42 may generate filopodia by regulating CRIB motif-containing effectors including WASP proteins, IRSp53 and mDia2. We have shown that Rif induces filopodia independently from Cdc42 and does not bind CRIB motifs. Rif interacts with the formin mDia2 and mDia2 is required for Rif-induced filopodia formation. The CRIB motif of mDia2 is not required for its interaction with Rif and the filopodia generated by Cdc42 are morphologically different to those induced by Rif. Thus Rif and Cdc42 represent two distinct routes to the induction of filopodia, producing structures with both shared and unique properties.

### Chemical Genetic Analysis of the Orb6 Kinase Pathway in *S pombe*

S. M. Nicholls,[1] D. Wiley,[1] M. Tress,[1] K. Shah,[2] F. Verde[1]; [1]Pharmacology, University of Miami, Miami, FL, [2]Chemistry, Purdue University, West Lafayette, IN

We have previously identified Orb6, a serine/threonine kinase in *Schizosaccharomyces pombe*, which functions in the control of cell morphology. Orb6 is conserved in higher eukaryotic organisms, and is related to mammalian NDR1 and NDR2 kinases, which have a role in tumorigenesis and in the control of cell proliferation. To explore the physiological role of Orb6 kinase activity, we have employed a chemical genetic approach involving site-directed mutagenesis of the kinase active site, which creates a new pocket where specific compounds bind to inhibit kinase activity

(Alaimo *et al*., 2001). Therefore, we have chemically inhibited the function of the Orb6 kinase *in vivo* by altering the ATP binding site so that it can accept the kinase inhibitor 1-NA-PP1 (1-naphthylmethyl-pyrazolo pyrimidine-1). We found that when the Orb6 kinase mutant (*orb6-as2*) cells are exposed to the inhibitor, the actin cytoskeleton is rapidly altered. Actin cables quickly disappear and actin patches become uniformly distributed throughout the cell cortex. Furthermore, we found Orb6 kinase inhibition does not affect actin ring assembly during mitosis in synchronized cells, however it prevents post-telophase actin reorganisation and cell separation. These studies suggest that Orb6 kinase activity controls actin cable and actin patches dynamics, and promotes actin reorganization after mitosis. To identify potential effectors of the Orb6 pathway, we have employed a number of techniques, including Mass Spectometry analysis of the Orb6-associated protein complex and 2-hybrid and genetic screens. Several proteins that are potential effectors of the Orb6 pathway have been identified.

### Two Distinct Modes of Epithelial Repair

M. Tamada,[1] T. Perez,[2] W. J. Nelson,[2] M. P. Sheetz[1]; [1]Biological Sciences, Columbia University, New York, NY, [2]Molecular and Cellular Physiology, Stanford University School of Medicine, Stanford, CA

Morphogenesis involves the bending and folding of epithelial sheets to mold the form of the embryo. Non-muscle myosin II is known to generate forces needed for tissue remodeling during a variety of developmental processes in many organisms. However, the regulatory mechanisms for its polarized assembly and activation are poorly understood. We laser-ablated cells in a confluent monolayer of MDCKII cells expressing EGFP-tagged myosin regulatory light chain (MLC) and found that MLC accumulated at the apical and basal tips of the lateral membranes of cells exposed to the ablated cells. We identified two types of separately regulated cell movements during extrusion of ablated cells: 1) the extension of a thin basal cell membrane accompanied by a basal accumulation of MLC, and 2) the shortening of the lateral cell membrane exposed to the ablated cells accompanied by an apical accumulation of MLC, which formed a ring-like structure where ZO-1 was located. Rho-kinase was also recruited to the same site with apical MLC and was found to be required for MLC accumulation and the proper changes in cell shape. These results from living cells show how cells re-organize in response to morphological changes, and suggest that the tight junction includes the machinery to stimulate the formation of myosin fibers required for changes in epithelial cell shape.

### Fibroblasts Lacking Zyxin Exhibit Increased Motility and Deficits in Actin Stress Fiber Remodeling

L. M. Hoffman, C. C. Jensen, M. Yoshigi, M. C. Beckerle; Huntsman Cancer Institute, University of Utah, Salt Lake City, UT

Integrin receptors and associated proteins link the extracellular matrix to the intracellular actin cytoskeleton at specialized structures called focal adhesions. To determine the cellular function of the focal adhesion protein zyxin, we isolated and characterized fibroblasts from zyxin-null mice. Compared to wild-type fibroblasts, zyxin-null fibroblasts were more migratory in monolayer wound assays. Transwell invasion assays through Matrigel also showed enhanced migration of zyxin-null fibroblasts, a characteristic that was abrogated by the reintroduction of GFP-zyxin into the zyxin-null fibroblasts. Molecular differences between wild-type and zyxin-null cells were explored by using anti-phosphotyrosine antibodies on immunoblots. A tyrosine-phosphorylated protein which was different between wild-type and zyxin-null fibroblasts was determined to be the actomyosin regulator caldesmon. To challenge the actin cytoskeleton, fibroblasts were treated with jasplakinolide, a membrane permeable agent which induces actin assembly and stress fiber reinforcement. Wild-type cells developed thick stress fibers in response to jasplakinolide, but cells lacking zyxin were deficient in this response. Reintroduction of GFP-zyxin restored the ability of the cells to reinforce their cytoskeletons, demonstrating that the defect was directly related to zyxin function. In wild-type cells exposed to jasplakinolide, zyxin dramatically mobilized from focal adhesions to actin filaments. The actin assembly regulator VASP also redistributed to actin stress fibers in response to jasplakinolide and this response required zyxin. Zyxin may contribute to stress fiber reinforcement by localizing Ena/VASP proteins and perhaps influencing their activity. We hypothesize that zyxin, in cooperation with Ena/VASP proteins and caldesmon, influences cell motility and the actin cytoskeleton.

1072

### Brush Border Structure Defects in I-Plastin Deficient Mice

E. M. S. Grimm-Günter,[1] S. Ramos,[1] N. Smyth,[1] C. Revenu,[2] I. Hurbain,[2] G. Raposo,[2] S. Robine,[2] F. Rivero[1]; [1]Center for Biochemistry, Medical Faculty, University of Cologne, Cologne, Germany, [2]UMR 144, Institut Curie, Paris, France

Plastin (or fimbrin) belongs to a subclass of cytoskeletal proteins known as actin-bundling proteins. They consist of two actin-binding domains in tandem preceded by two calcium-binding EF-hands. Plastins are conserved from lower eukaryotes to humans. In mammals three different isoforms are expressed in a cell-type specific manner. I-plastin is specifically expressed in the small intestine, colon and kidney, whereas the isoforms L- and T-plastin are expressed in leukocytes and in all other tissues, respectively. Generally plastins are located in focal adhesions, ruffling membranes, lammellipodia and filopodia. I-plastin localizes in specialized surface structures with highly ordered microfilament bundles such as microvilli and stereocilia. We have generated knockout mice lacking I-plastin. We verified the recombination event by Southern, Northern and Western analyses. I-plastin deficient mice showed no overt phenotype at the whole animal level: growth rate, reproductive rate and litter size were normal. Antibodies specific for the plastin isoforms T- and L-plastin were used to demonstrate that lacking of I-plastin is not compensated by another plastin isoform. Transmission electron microscopy studies revealed morphological differences between wildtype and I-plastin deficient mice in the microvilli of the small intestine. Brush border preparations of knockout mice are sensitive and seem to degrade easily. In immunofluorescence studies of intestinal mucosa cryosections decreased actin staining of the apical membrane was observed. Another abundant actin cross-linker of the brush border, villin, was found to be absent from the apical membrane. I-plastin seems to be an important regulator of the morphological structure and stability of microvilli. Further studies will allow investigating the contribution of this protein to the organization of the intestinal brush border barrier and its role during infectious processes.

### Intracellular Response to Shear Flow is Mediated by Rho-kinase

J. S. Lee,[1] P. Panorchan,[1] Y. Tseng,[2] D. Wirtz[1]; [1]Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD, [2]Chemical Engineering, University of Florida, Gainsville, FL

Cells *in vivo* are often subjected to mechanical shear stresses which have been shown to play important roles in various physiological and pathological processes. However, remarkably little is known about whether and how the cytoskeleton of an adherent cell adapts its mechanical properties in response to fluid shear stresses. Here, by modifying the method of intracellular microrheology (ICM), we monitor the micromechanical response of the cytoskeleton of single cells exposed to flow. ICM reveals that the formation of contractile actin stress fibers and focal adhesions induced by shear in serum-starved Swiss 3T3 fibroblasts mediates a remarkable 25-fold and 4-fold increase in cytoplasmic elasticity and viscosity, respectively. In contrast, our previous study shows that the cytoskeleton of the same cells treated with LPA undergoes only highly transient stiffening of much lower amplitude, despite the formation of long-lived stress fibers and focal adhesions. Pretreatment with either an actomyosin interaction inhibitor or Y-27632, a specific Rho-kinase inhibitor, prevents the formation of stress fibers and eliminates shear-induced cell stiffening. Together these results reveal that adherent cells subjected to fluid shear stress strengthen their cytoskeleton and that biochemical and biophysical stimuli may elicit the formation of seemingly similar cytoskeleton organizations, but qualitatively different micromechanical responses. This study also identifies Rho-kinase as a key factor in the mechano-transduction pathway that controls the cytoskeleton mechanical response of cells to shear.

**Analysis the Mechanism during Otic Placode Invagination**

X. Sai, R. Ladher; Sensory Development, RIKEN CDB, Kobe, Japan

Morphological development of the inner ear begins with formation of the otic placode. Our scanning electron microscope show that the otic placode of stage HH9 (7 somites stage) chick embryo can be observed as a thickened otic primordia on the surface ectoderm. This thickening region invaginates gradually, eventually sealing itself up to form an otocyst at HH17 (64 hours). The mechanisms of this complicated cellular rearragement remain unknown. Using light microscopy, we observed the cells of the otic placode. Cells appear to change shape as the otic placode invaginates, from columnar to a more wedge-shaped appearance. We were interested in further characterizing these cells and used transmission electron microscopy to investigate the intracellular structures. TEM results show unique cytoskeletal structure. Firstly, in a few cells nuclei were displaced basally and in these cells microtubules were located apical to the nucleus. Secondly, F-actin fibers located at the apex of the cells seemed to function to contract the apical membrane of the cells. Thirdly, intermediate filaments were observed around the nuclei of several cells located centrally within the otic placode. Treatment of the otic placode with notacozone and cytochacin D inhibited the closure of the otocyst. We are currently determining the nature of the extrinsic signals and the mechanism of nuclear migration and establishing causal relationships between cellular changes and morphological tissue rearrangement. Our studies imply that microtubules and intermediate filaments play a role in directing basal localization of the nuclei of several cells and that F-actin is important for the purse-string constriction of the peripheral cells. These and other, as yet uncharacterized cellular properties drive the sheet of otic placode cells to invaginate, change morphology into a hollow sphere and become internalized into the head mesenchyme of the embryo.

1075

**Role of PTP-PEST in the Regulation of Phosphorylation of WASP and Resulting Osteoclast Bone Resorption**

M. Chellaiah,[1] D. Kuppuswamy,[2] C. Willey[2]; [1]Department of BMS, University of Maryland, Baltimore, MD, [2]Gazes Cardiac Research Institute, Medical University of S.Carolina, Cardiology Division, Charleston, SC

We have previously shown that osteopontin (OPN)/αvβ3-mediated signaling facilitates WASP to interact with Arp2/3 complex and thereby enable the latter to promote actin nucleation, polymerization and ring formation in osteoclasts. Actin ring formation is a prerequisite for efficient bone resorption in osteoclasts. Despite success in identifying the role of kinases such as, Src, PYK2 and FAK in actin ring formation, the potential target protein of these kinase(s) is poorly understood. WASP phosphorylation was shown to be mediated by several kinases by studies in different cell systems. Phosphorylation state of WASP and WASP interacting protein(s) was determined in osteoclasts treated with OPN or expressing either constitutively active (CA-Src) or kinase negative- Src (KN-Src) by adenoviral- mediated delivery. *In vitro* kinase assay analysis demonstrated an increase in phosphorylation of Src, PYK2, WASP, and three other proteins with MW of 100-110kDa, 120-130kDa, 35-40kDa in OPN-treated and in osteoclasts expressing CA-Src but not in KN-Src. Protein with MW of p100-110 was confirmed as PTP-PEST by Western analysis. Confocal studies revealed that WASP and PTP-PEST form a complex and are colocalized in OPN-treated osteoclasts. Measurement of WASP-associated PTP-PEST phosphatase activity exhibited decreased activity levels both in OPN-treated and CA-Src expressing osteoclasts. Furthermore, OPN stimulation resulted in serine phosphorylation of WASP-associated PTP-PEST. Such increased serine phosphorylation of PTP-PEST was accompanied by an increased tyrosine phosphorylation of WASP and other associated signaling proteins. Experiments with PTP-PEST inhibitor and SiRNA to PTP-PEST further confirmed the involvement of PTP-PEST in the WASP-Arp2/3 complex, actin ring, and bone resorption. Our observations suggest that WASP, which is identified in the actin ring of osteoclasts, associates with Src, PYK2, and PTP-PEST. PTP-PEST and tyrosine kinase(s) coordinate the formation of WASP-Arp2/3 complex and the actin ring

1076

**Coronin 2A Expression Regulates Slingshot-1L Activity**

T. W. Marshall, J. E. Bear; Cell and Developmental Biology, University of North Carolina, Chapel Hill, NC

Coronins are a conserved family of actin cytoskeleton regulators found in all eukaryotes. Coronin 2A and 2B represent a subclass of Coronins (type II) that are found only in vertebrates. These genes are expressed in a restricted manner across tissues. Coronin 2A is highly expressed in the testis, ovaries, and uterus and moderately expressed in the brain and kidneys, while Coronin 2B is highly expressed in the brain with moderate expression in the kidneys. Overexpression of Coronin 2A in Rat2 fibroblasts induces the formation of Cofilin-Actin rods and reorganizes F-actin stress fibers. The stress fibers appear to be pushed to the periphery of the cell and become thicker. This stress fiber phenotype is similar to the phenotype observed when Cofilin activity is inhibited by either overexpressing Lim Kinase or phosphatase-dead Slingshot 1-L (SSH1L). Coronin 2A and SSH1L reciprocally coimmunoprecipitate suggesting that these proteins are in a complex together in cells. By immunofluorescence, the two proteins also strongly colocalize along stress fibers. Slingshot also localizes to the leading edge of the lamellapodia, but Coronin 2A does not. Coronin 2A overexpression increases P-Cofilin levels indicating that Coronin 2A may be affecting Slingshot phosphatase activity. The interaction between Coronin 2A and Slingshot is dependent upon the coiled-coil domain of Coronin 2A. Upon expression of a coiled-coil deletion mutant of

Coronin 2A, SSH1L becomes more enriched at the leading edge, leading to the hypothesis that Coronin 2A may be sequestering Slingshot away from the leading edge. The interaction between Coronin 2A and Slingshot may play a key role in regulating Cofilin activity. Currently, we are determining the in vivo function of type II Coronins and the importance of Coronin 2A on regulating the phosphorylation status of Cofilin.

1077

**Interaction of Smitin Zq Domain with Alpha-actinin Central Rod Spectrin Repeat-like R2-R3 Loops**

R. J. Chi, S. G. Olenych, T. C. S. Keller; Biological Science, Florida State University, Tallahassee, FL

Alpha-actinin interacts with the myosin-binding protein titin to provide an important structural linkage in the Z-line of striated muscle sarcomeres. A similar interaction may contribute to smooth muscle contractile apparatus organization. We previously discovered a titin-like protein - smitin - in smooth muscle cells and mapped smooth muscle alpha-actinin binding sites for native smitin to the central rod R2-R3 spectrin repeat-like and C-terminal domains, sites that are analogous to those in striated muscle alpha-actinin that bind respectively to titin Zq and Z-repeat domains. Using RT-PCR analysis of RNA from rat aortic smooth muscle A7r5 cells and human carotid artery to investigate whether smitin contains Z-repeat and Zq-like domains, we have found products containing sequences identical to exon sequences of the titin gene that encode Z-repeat and Zq domains. A polyclonal antibody raised against an expressed protein encoded by this sequence stained the contractile apparatus of the A7r5 cells in a punctate pattern similar to that for smitin localization. We used the expressed Z-repeat-Zq peptide to test the hypothesis that loops in the R2 and R3 spectrin repeat-like domains, which are modeled to lie in proximity on the surface of the central rod and are highly conserved between smooth and striated muscle titins, constitute the binding site for the Zq domain. We found that a T425A mutation in the R2 loop and a D586A mutation in the R3 loop both decrease binding to the Zq domain in GST-pulldown and solid phase binding assays. These results suggest that smitin contains Z-repeat and Zq domains encoded by the known titin gene and that conserved surface loops from the R2 and R3 spectrin repeat-like domains form the binding site of smooth and striated muscle alpha-actinins for smitin and titin Zq domains.

1078

**Comparing the Effects of siRNA vs Pharmacological Inhibitor of GTPase Kinases**

H. Darenfed,[1] B. Dayanandan,[1] A. Fournier,[2] C. A. Mandato[1]; [1]Anatomy & Cell Biology, McGill University, Montreal, PQ, Canada, [2]Neurology & Neurosurgery, McGill University, Montreal, PQ, Canada

Rho- family GTPases are key regulatory molecules that link extracellular ligands to the organization of the actin cytoskeleton. They regulate many cellular functions including cytokinesis, cell adhesion, motility, stress fiber formation and neuronal growth cone extensions. The Rho protein acts as a switch by cycling between a GTP bound active form and GDP bound inactive form. Once activated it binds to a wide range of effectors to stimulate downstream signaling pathways. These effectors include the ROCK family members, ROCK1 and ROCK2, which regulate multiple downstream substrates to modulate cellular responses. The compound, Y-27632, has been extensively used as a ROCK2 inhibitor for studying the role of ROCK2 in actin/ myosin organization and cytokinesis. However, the mechanistic relevance of this inhibition has not been explored. This is an important question when considering the mechanism of Y-27632 action on various cellular processes. In this study we investigated the role of ROCK2 in fibroblasts and neuronal primary cultures using small interfering RNAs (siRNA). Knockdown of ROCK2 expression levels mediates alterations in actin organization. On the other hand treatment with Y-27632 induces the formation of thin actin extensions and reduces the expression of stress fibers. These results suggest that Y-27632 compound may affect other kinases regulating actin organization during different cellular activities.

1079

**Regulation of Signaling Pathways by Myelin Inhibitors**

J. M. Robens, E. Manser; Institute for Molecular and Cellular Biology, Singapore, Singapore

Neurons in the CNS have the capacity to regenerate once damaged but are inhibited in part by myelin-derived inhibitors such as Nogo, myelin-associated glycoprotein (MAG), and oligodendrocyte-myelin glycoprotein (OMgp). These inhibitors activate a trimeric receptor complex on neuronal membranes and regulate the activation of small GTPases of the Rho subfamily to remodel the actin cytoskeleton leading to growth cone collapse. The mechanism by which this trimeric complex, composed of the Nogo66-receptor (NgR), p75 neurotrophic receptor (p75NTR)/TROY, and Lingo-1, regulates these GTPases still remains elusive. Since the receptors in this complex do not have intrinsic enzymatic activity, this suggests that the recruitment of proteins to the activated receptor complex is crucial in the regulation of these signaling pathways. We have recently identified potential partners that are recruited to the activated NgR-receptor complex. Our current research is now focused on the mechanism by which these recruited proteins regulate the activation of Rho family members and subsequently the remodeling of the actin cytoskeleton and inhibition of neurite extention. This research will provide useful insights into the regulation of signaling pathways by myelin-derived inhibitors and how they may be manipulated therapeutically to treat neurological disorders.

**Centralspindlin Regulates ECT2 and RhoA Accumulation at the Equatorial Cortex during Cytokinesis**

Y. Nishimura, S. Yonemura; RIKEN, Center for Developmental Biology, Kobe, Japan

During determination of the cell division plane, an actomyosin contractile ring is induced at the equatorial cell cortex by signals from the mitotic apparatus and contracts to cause cleavage furrow progression. Although the small GTPase RhoA is known to regulate the progression probably by controlling actin filament assembly and enhancing actomyosin interaction, involvement of RhoA in division plane determination has been largely unknown. In this study, using a Trichloroacetic Acid (TCA) fixation protocol we recently developed, we show that RhoA accumulates at the equatorial cortex before furrow initiation and continues to concentrate at the cleavage furrow during cytokinesis. These observations suggest that RhoA accumulation at the equatorial cortex is involved in formation of the contractile ring during the early stage of cytokinesis. We also demonstrate that both Rho activity and microtubule organization are required for RhoA localization and proper furrowing. Selective disruption of microtubule organization revealed that both astral and central spindle microtubules could recruit RhoA at the equatorial cortex. To elucidate the molecular mechanism of RhoA localization at the equatorial cortex, we tested several candidate proteins that might connect microtubules and RhoA activity. We find that centralspindlin and ECT2, that have been known to form a complex on the central spindle microtubules, are required

for RhoA localization and furrowing. RNAi experiments indicate that centralspidlin regulates RhoA localization through regulation of ECT2 localization. Positional information for division plane determination from microtubules appears to be transmitted to the cell cortex to organize actin cytoskeleton through a mechanism involving these proteins.

1081

**Timed Study of S-crystallin Translation in Light- and Dark-adapted Octopus Retinas**

T. Taylor, S. Kelly, L. J. Robles; Biology, California State University, Dominguez Hills, Carson, CA

Morphological differences exist between light- and dark-adapted octopus retinas with the rhabdomeric microvillus actin cytoskeleton undergoing dramatic reorganization in conditions of light vs. dark. Recent studies showed that S-crystallin is present in significantly greater amounts in dark-adapted octopus retinas and it binds to F-actin, while in light-adapted retinas, S-crystallin is greatly reduced with no apparent F-actin binding. We are investigating whether the presence of S-crystallin is time sensitive; that is, if translation of S-crystallin varies with increasing time in the light or dark. Octopi were either light- or dark-adapted 3-4 hours after which the eyecups of one octopus were dissected for controls. The remaining octopi were transferred to the opposing lighting condition and sacrificed at 15 minute intervals for a period of two hours. At each time point, the octopus was anesthetized on ice, the eyes dissected, the retinas homogenized in phosphate buffer, and protein isolated. Concentrations of the retinal homogenates were determined and equal amounts of protein from each interval were loaded onto SDS gels. The proteins were separated and translational differences in S-crystallin quantified. Translational differences in actin were also analyzed. Preliminary results indicate initially increased levels of S-crystallin, from 5.36% to 10.4%, in the first 15 to 30 minutes of animals moved to the dark after which the levels decrease slightly and remain constant in the second hour. Preliminary results from animals moved to the light indicate more constant but cyclically fluctuating levels of S-crystallin. Increases in S-crystallin during the first 30 minutes in the dark and cyclical levels in the light suggest that the involvement of S-crystallin in the reorganization of the rhabdomeric actin cytoskeleton may be time sensitive. NIH GM08156/62252

1082

**MLCK/actin Interaction in the Contracting A7r5 Smooth Muscle Cell**

S. E. Thatcher, G. L. Wright; Physiology, Joan C. Edwards School of Medicine, Huntington, WV

Recent biochemical data indicates that MLCK could contribute to actin cytoskeletal structure. Since dynamic remodeling of actin to different contractile agonists has been reported, it was of interest to examine MLCK/actin interaction during contractile reorganization of the cytoskeleton. Fluorescent resonance energy transfer (FRET) was utilized to evaluate MLCK association with α- and β-actin in cells contracted with phorbol 12,13 dibutyrate (PDBu) or by addition of the calcium ionophore A23187. Results showed a significant increase (70%) in MLCK/α-actin interaction with PDBu stimulation. By comparison, the interaction between β-actin and MLCK was unchanged after treatment with PDBu. Addition of the calcium ionophore A23187 resulted in a significant increase in the association of MLCK with α-actin (83%) but not β-actin. These results suggest MLCK recruitment and increased interaction with the α-actin cytoskeleton during PDBu- and A23187-induced contraction. This dynamic interaction could be important in optimizing contractile mechanical advantage and/or contribute to actin/myosin reorganization during contraction.

1083

**A PAK4/alphaPIX Complex Regulates Podosome Size and Number in Macrophages**

S. Linder,[1] A. Gringel,[1] D. Walz,[1] G. Rosenberger,[2] K. Kutsche,[2] A. Minden[3]; [1]LMU, Munich, Germany, [2]UKE, Hamburg, Germany, [3]Columbia University, New York, NY

Podosomes are actin-rich adhesion structures typically found in monocytic cells. Major modes of podosome regulation include RhoGTPase signaling and actin regulatory pathways. However, it is not clearly understood how RhoGTPase-triggered signals induce highly localized changes in podosome formation and dynamics. Here, we show that the RhoGTPase effector PAK4, a member of the p21 associated kinase family, and the PAK interactive exchange factor alphaPIX, are central to localized podosome regulation in primary human macrophages. Importantly, part of the cellular pool of PAK4 was found to be associated with podosomes, while expression of PAK4 deletion/truncation mutants as well as transfection of specific siRNA resulted in reduced numbers of podosomes per cell. Moreover, expression of constitutively active or inactive PAK4 mutants enhanced or reduced, respectively, the size of individual podosomes. Similar to the results gained with PAK4, cellular/overexpressed PIX was shown to be closely associated with podosomes, and expression of alphaPIX mutants strongly influenced the ability of cells to form podosomes. As PAK4 and alphaPIX interact in cell lysates, we propose that a complex of both proteins regulates podosome size and number in these cells.

1084

**Epiplakin Is Dispensable for Skin Barrier Function and for Integrity of Keratin Network Cytoarchitecture in Simple and Stratified Epithelia**

D. Spazierer,[1] P. Fuchs,[1] S. Reipert,[1] M. Schmuth,[2] H. Lassmann,[3] G. Wiche[1]; [1]Molecular Cell Biology, University of Vienna, Vienna, Austria, [2]Department of Dermatology and Venereology, Medical University of Innsbruck, Innsbruck, Austria, [3]Center for Brain Research, Medical University of Vienna, Vienna, Austria

Epiplakin, a giant epithelial protein of >700 kDa, belongs to the plakin family of cytolinker proteins. It represents an atypical family member, however, as it consists entirely of plakin repeat domains but lacks any of the other domains commonly shared by plakins. Hence, its putative function as a cytolinker protein remains to be shown. To investigate epiplakin's biological role we generated epiplakin-deficient mice by gene targeting in embryonic stem cells. Epiplakin-deficient mice were viable and fertile, without developing any discernible phenotype. Ultrastructurally, their epidermis revealed no differences compared to wild-type littermates, and cornified envelopes isolated from skin showed no alterations in shape or stability. Furthermore, neither embryonal formation nor later function of the epithelial barrier were affected. In primary cultures of epiplakin-deficient keratinocytes the organization of actin filaments, microtubules, and keratin networks were found to be normal. Similarly, no alterations in keratin network organization were observed in simple epithelia of small intestine and liver, or in primary hepatocytes. We conclude that, despite epiplakin's abundant and highly specific expression in stratified and simple epithelia, it's absence in mice does not lead to severe skin dysfunctions, nor has it detectable consequences for keratin filament organization and cytoarchitecture of cells.

1085

**The Cytoskeleton-Associated Protein Palladin Interacts with Eps8, a Barbed-End Capping Protein**

S. M. Goicoechea,[1] A. Disanza,[2] G. Scita,[2] C. Otey[1]; [1]Department of Cell and Molecular Physiology, University of North Carolina at Chapel Hill, Chapel Hill, NC, [2]IEO, European Institute of Oncology, IFOM, The FIRC Institute for Molecular Oncology, Milan, Italy

The cytoskeleton-associated protein palladin has been shown to play an important role in organizing the actin cytoskeleton. Palladin may function as a critical cytoskeletal scaffold, as it interacts with diverse actin-regulating proteins: profilin, members of the Ena/Mena/VASP family of proteins, the filament cross-linking protein, alpha-actinin, and LASP-1, an actin-associated LIM and SH3 domain-containing protein. We reasoned that palladin was likely to have additional binding partners, and we employed a yeast two-hybrid approach to identify them. Here, we describe a novel interaction between palladin and Eps8, a receptor tyrosine kinase (RTK) substrate that participates in the activation of the Rac-specific guanine nucleotide-exchange function of Sos1, thereby regulating actin remodeling by RTKs. Eps8 was identified in a yeast two-hybrid screen, using full-length palladin as bait. The interaction was confirmed biochemically, using *in vitro* and *in vivo* assays. Binary assays in yeast and immunoprecipitation assays from lysates of cultured cells showed that the interaction is direct and specific. The interacting domains were mapped to the proline-rich region of palladin and the aa 350-530 region of Eps8. The two proteins co-localize extensively in stress fibers, cell-cell junctions and also in the transient, circular, dorsal ruffles that form in response to growth factor stimulation. Together, these data provide strong evidence for a direct and specific interaction between palladin and Eps8. Our data suggest that these two proteins act together in stress fibers and in the rapid and transient remodeling of the actin cytoskeleton that promotes the formation of highly dynamic membrane protrusions in response to growth factor treatment.

**Characterization of Cellular Titin in Human Megakaryocyte and Mouse Fibroblast Cell Lines**

P. J. Cavnar, S. Olenych, T. C. Keller; Department of Biological Sciences, Florida State University, Tallahassee, FL

We previously discovered a large titin-like protein - c-titin - in chicken epithelial brush border and human blood platelet extracts that binds alpha-actinin and organizes arrays of myosin II bipolar filaments in vitro. We have investigated the molecular relationship between c-titin and striated muscle titin by RT-PCR analysis of total RNA from human megakaryoblastic (CHRF-288-11) and mouse fibroblast (3T3) nonmuscle cells. Amplified products obtained contain sequences identical to known titin gene exon sequences that encode parts of the Z-line, I-band, PEVK domain, A-band, and M-line regions of striated muscle titins. Products containing Z-line exons encode the Z-repeat domains Zr1-3 and 7 and the Zq domain, which bind alpha-actinin in striated muscle titins. I-band region sequences encode the N2A exons, but none of the exons distinctive for the N2B or Novex I and II isoforms. Products from the A-band and M-line regions contain the long titin gene exon that encodes an Ig-FN3 domain superrepeat region important for myosin filament binding and the exon that encodes the kinase domain. We found two variants containing PEVK-encoding exons not known to be expressed in muscle. These sequences are differentially spliced in patterns not reported for any striated muscle titin isoform. We used polyclonal antibodies raised against expressed protein fragments encoded by the Z-repeat region and the kinase domain region to investigate the relationship between the RT-PCR products and the c-titin protein. Both antibodies reacted with the c-titin band in Western blot analysis of platelet extracts and revealed immunofluorescent colocalization of at least some of the reactive protein with alpha-actinin, myosin, and actin in 3T3 cell stress fibers. These results suggest that differential expression of titin gene exons in nonmuscle cells yields multiple novel isoforms of the protein c-titin.

1087

**Cdk5 Modulates Pin1 Interactions with Beta and Delta-catenin Neuronal Cells**

J. P. Muñoz,[1,2] C. Huichalaf,[1,2] D. Orellana,[1,2] R. B. Maccioni[1,2]; [1]Cell Biology, Millennium Institute for Advanced Studies (CBB), Santiago, Chile, [2]Universidad de Chile, Santiago, Chile

The cdk5/p35 system has been implicated in a variety of functions related to brain development, including axonal outgrown and neuronal migration. In this study, on the basis of co-immunoprecipitation and pull-down experiments, we show that the cdk5/p35 complex associates with and phosphorylates the neuronal δ-catenin. Immunocytochemical studies of δ-catenin and the cdk5-activator p35 in primary cortical neurons indicated that these proteins co-localize in the cell body of neuronal cells. In addition, cdk5 co-localized with β-catenin in the cell-cell contacts and plasma membrane of undifferentiated and differentiated N2a cells. In this context, we identified $Ser_{191}$ and $Ser_{246}$ on β-catenin structure as the specific sites for the phosphorylation by the cdk5/p35 system. Moreover, Pin1, a peptidyl-prolyl isomerase (PPIase) directly bound to both β and δ-catenin once they have been phosphorylated by the cdk5/p35 complex. Studies indicates that the cdk5/p35 protein kinase system is directly involved in the regulatory mechanisms of neuronal β an δ catenin

**Focal Contacts and the Formation of Keratin Filaments**

R. Windoffer, A. Koelsch, R. E. Leube; Anatomy and Cell Biology, Johannes Gutenberg University Mainz, Mainz, Germany

Given the spontaneous in vitro formation of intermediate filaments, complex regulatory mechanisms are needed in living cells for the adaptation of filament organization to specific spatial requirements. Thus, we observed formation of keratin filaments primarily in the cell periphery of epithelial cell lines during interphase, after mitosis and after disruption of the filament network using hyperphosphorylating drugs. By live cell microscopy we identified globular filament precursors arising in close vicinity of the cell edge. These precursors subsequently elongated, were transported retrogradely and finally fused either to each other or to an already existing network. In an attempt to identify structures that may be of importance for keratin filament precursor formation in the cell periphery we double transfected cell lines with fluorescent keratins and fluorescent focal contact proteins. Life cell imaging revealed a close spatial and temporal relationship between focal contacts and newly forming keratin filament precursors. Focal contacts may therefore act as regulators of keratin filament formation, possibly by changing the phosphorylation of soluble keratin assemblies and/or by providing structural scaffolds.

**Constitutive Activation of Akt in Polyamine Depleted Cells Decreases Migration by Inhibiting GSK3beta and Rac1**

R. J. Vaidya, R. M. Ray, L. R. Johnson; Department of Physiology, University of Tennessee Health Science Center, Memphis, TN

The rapid migration of intestinal epithelial cells (IEC) is important for the healing of mucosal wounds. We have previously shown that polyamine depletion inhibits Rac1 and the migration of IEC-6 cells. Inhibition of Rac1 by expression of dominant negative Rac1, inhibition of Tiam1 or polyamine depletion caused the formation of thick actin cortex formation. Akt activation and its down stream target GSK3β have been implicated in the regulation of migration. In this study, we investigated whether elevated PI3-kinase/Akt signaling in response to polyamine-depletion decreases cell migration. Polyamine depleted cells had significantly higher PI3-kinase activity and Akt (Ser473/thr308) phosphorylation compared to controls. Pretreatment with 20 μM LY294002 (PI3-kinase inhibitor) inhibited phosphorylation of Akt, increased the migration, increased Rac1 activity in polyamine depleted IEC-6 cells, and restored the actin structure similar to that in cells grown in control medium. Inhibition of PI3-kinase reorganized the thick actin cortex into stress fibers. Treatment of cells with a GSK3β inhibitor altered actin cytoskeleton and inhibited migration, mimicking the effects of DFMO. Thus, our results indicate that sustained activation of Akt in the absence of polyamines inhibits migration through direct phosphorylation and inactivation of Rac1 or through GSK3β dependent signaling. (Supported by NIDDK grant DK-52784)

## Cytoskeleton-Membrane Interactions I (1090-1103)

**Mechanotransduction in Fibroblasts is Mediated by the Na-H exchanger NHE1**

A. Shubov,[1] L. LeClaire,[1] N. Madson,[1] E. Almeida,[2] D. L. Barber[1]; [1]Cell and Tissue Biology, University of California, San Francisco, San Francisco, CA, [2]NASA Ames Research Center, Moffett Field, CA

Mechanical forces regulate development, tissue growth and remodeling, and reparative responses. Our understanding of how cells sense and transduce mechanical force is limited compared with what we know about sensing and transducing chemical cues. In specialized sensory cells mechanotransduction units include a plasma membrane ion transport protein anchored to the actin cytoskeleton. We asked whether in fibroblasts an actin-anchored membrane ion transport protein functions in mechanotransduction. We found that the plasma membrane Na-H exchanger NHE1, which is anchored to actin filaments by binding ERM (ezrin, radixin, moesin) proteins, is mechanosensitive and functions in mechanotransduction in CCL39 fibroblasts. Cells plated on a fibronectin-coated polystyrene strip mounted in a uniaxial loading system were mechanically stimulated by applying 1% deformation. A 5 min mechanical load and elastic release induced a 2.5-fold increase in NHE1 activity and an NHE1-dependent increase in intracellular pH from 7.15 to 7.40. Mechanical loading also increased NHE1 phosphorylation, suggesting the action of a mechanosensitive kinase. Additionally, NHE1 was necessary for conserved responses to mechanical force. In CCL39 fibroblasts, mechanical loading increased activity of the focal adhesion kinase FAK 2.5-fold and recruitment of FAK to peripheral focal complexes. In NHE1-null PS120 cells derived from a parental CCL39 clone, FAK abundance and quiescent FAK activity were similar to that in CCL39 cells, but there was no increase in FAK activity or FAK recruitment with mechanical loading. The abundance of F-actin, although similar in unloaded CCL39 and PS120 cells, increased with mechanical loading of CCL39 cells ~2-fold, but was unchanged in PS120 cells. These data confirm that actin-anchored NHE1 is mechanosensitive and is necessary for transducing mechanoresponsive increases in FAK activity and F-actin assembly. Supported by NASA grant NNA04CC53A.

**Labile and Dynamic Junctions of the Red Blood Cell Membrane Skeleton - A Potential Role for Tropomyosin**

M. A. Salomao,[1] X. An,[1] X. Guo,[1] A. J. Baines,[2] M. Narla[1]; [1]Red Cell Physiology Laboratory, New York Blood Center, New York, NY, [2]Department of Biosciences, University of Kent, Canterbury, United Kingdom

The ternary complex of spectrin-actin-4.1R is a central feature of erythrocyte membrane skeleton and it plays an important role in maintaining membrane stability. In the present study, we explored the dynamic regulation of this junctional complex in situ and the potential contribution of tropomyosin in stabilizing spectrin-actin-4.1R complex. We have taken advantage of an N-terminal fragment of β-spectrin (residues 1-301) that we have previously shown to inhibit formation of the spectrin-actin-4.1R ternary complex in vitro. Resealing this polypeptide into red cell ghosts prepared in the absence of magnesium chloride, which results in loss of tropomyosin, leads to a dose-dependent integration of the polypeptide into the pre-assembled spectrin-based membrane skeleton. The functional consequence of the integration of the polypeptide into the spectrin skeleton is a dose-dependent reduction in membrane mechanical stability. Furthermore, we show that when the ghosts were prepared in the presence of magnesium chloride, which maintains normal tropomyosin content of the membrane, the ability of spectrin polypeptide 1-301 to destabilize membrane skeleton is significantly reduced, suggesting spectrin-actin-4.1 complex is stabilized by tropomyosin. Importantly, reconstitution of erythrocyte tropomyosin into tropomyosin-depleted ghosts prior to addition of the 1-301 polypeptide once again resulted in reduced effectiveness of the peptide in decreasing membrane mechanical stability. By contrast, muscle tropomyosin did not protect membranes from destabilization by 1-301 peptide; evidently there is an isoform-specific requirement for tropomyosin in red cells. Based on these findings, we conclude that spectrin-actin-4.1R junctional complex is in a dynamic state in intact red blood cell membrane and that tropomyosin plays a key role in stabilizing spectrin-actin-4.1 complex.

1092

***Drosophila* Gap Junction Gene, *innexin-2*, is Required for Border Cell Migration**

S. Tazuke, M. T. Chan; CRRWH, University of Pennsylvania, Philadelphia, PA

OBJECTIVE: The mammalian gap junction gene, *connexin-43* (*cx43)*, is required for directed migration of cells such as neural crest cells during development. The specific mechanism of *cx43* mediated regulation of directed cell migration is unknown. We investigated the function of a gap junction gene in directed cell migration using Drosophila as a model organism, whose genome has reduced number of gap junction proteins, making genetic analysis far more tractable. METHOD: Genetic and phenotypic analysis of *innexin-2* (*inx-2*) loss of function in *Drosophila* ovaries. RESULTS: The migration of the border cells, a small group of follicle cells in the *Drosophila* ovary, provides a model system to study directed cell migration *in vivo*. We have found that *inx-2* gene product is expressed in the border cells. To investigate the function of *inx-2* , we transiently

expressed *hsp70-innexin2-EGFP* transgene during embryogenesis to rescue the embryonic lethality of *inx-2* null animals. We have found that loss of *inx-2* results in delayed border cell migration during stage 9-10 of *Drosophila* oogenesis. Notably, we found that *inx-2* function is required specifically for *par-6* expression and localization to the polarized apical membrane of the follicle epithelium. This is specific to *par-6* since other polarity proteins, *Drosophila* par-3, E-cadherin, *armadillo, atypical PKC* remain apically localized in *inx-2* null follicle cells. In mammalian cells, *Par-6* has recently been shown to regulate the disassembly of tight junctions during epithelial mesenchymal transition (Science. 2005 ;307:1603-9) . Our results suggest that *inx-2* mediated gap junctional intercellular communication play a role in cell migration by effecting *par-6,* which is required for the remodeling of cell-cell junctions during cell migration.

**Effect of Colchicine on Acrosomal Biogenesis in Mouse Sperm**

W. Huang,[1] H. Ho[2]; [1]Life Science, National Taiwan University, Taipei, Taiwan Republic of China, [2]Anatomy, Tzu Chi University, Hualien, Taiwan Republic of China

The acrosome has a distinct shape and size depending on the species. The mechanisms regulating the attachment, shaping, and spreading of the acrosome over the nucleus is unclear. It is well known that microtubules play a key role in organelle and membrane-bound vesicle transportation in cells. Besides, spermatid nuclear shaping is dependent on manchette microtubules, it is possible that shaping and spreading of acrosome over the nucleus also depends on microtubules. In this study, colchicine, which binds to free tubulins and causes microtubule depolymerization, was used to evaluate the effects of microtubule disruption on acrosome formation in mouse spermatids. Control and colchicine-treated seminiferous tubules were investigated by thin sectioning, cytochemistry, and cryofracturing methods. In control cap phase spermatids, coated vesicles were always seen on the apex and caudal margins of the developing acrosome. The increase of volume and the accumulation of materials in the acrosome during Golgi and cap phases occurred via fusion of vesicles at various sites on the growing acrosome. By studying the acid phosphatase localization pattern and colchicine-treated spermatids, the role of clathrin-coated vesicles became clear. Coated vesicle formation at the caudal margin of the acrosome appeared to be responsible for spreading and shaping of the acrosome over the surface of the nucleus and also established distinct regional differences in the acrosome. In colchicine-treated spermatids, Golgi apparatus lost its typical membranous stack conformation and disintegrated into many small vesicles. Acrosome formation was retarded and there was discordance of spreading of the acrosomal cap with that of the modified nuclear envelope. Colchicine treatment indicated that microtubule-dependent vesicle trafficking between the Golgi apparatus and the acrosome plays vital role in acrosomal biogenesis. In addition, both anterograde and retrograde vesicle trafficking are extensively involved and equally important in acrosome formation.

**Sun1, an Inner Nuclear Membrane Protein, Mediates the Anchorage of Nesprin-2 to the Nuclear Envelope**

W. Lu; Institute for Biochemistry, Koeln, Germany

Nesprins form a novel class of nuclear envelope anchored spectrin repeat proteins. We show that a direct association of their highly conserved C-terminal luminal domain with the inner nuclear membrane protein Sun1 mediates their nuclear envelope localization. In Nesprin-1 and Nesprin-2 the conserved C-terminal amino acids PPPX are essential for the interaction with a C-terminal region in Sun1. In fact, Sun1 is required for the proper nuclear envelope localization of Nesprin-2 as shown with dominant negative mutants and by knockdown of Sun1 expression. Sun1 itself does not require functional A-type lamins for its localization at the inner nuclear membrane in mammalian cells. our findings propose a conserved nuclear anchorage mechanism between *C. elegans* and mammals and suggest a model in which Sun1 serves as a “structural bridge” connecting the nuclear interior with the actin cytoskeleton.

1095

**Cytoskeletal Organization Surrounding the Nucleus Mediated by Bpag1**

K. Young, R. Kothary; Ottawa Health Research Institute, Ottawa, ON, Canada

Bullous pemphigoid antigen 1 (Bpag1) proteins are large cytoskeletal organizing proteins. They are critical for normal architecture in the skin, muscle and nervous system, with neuromuscular dysfunction and early postnatal death occurring in Bpag1 mutant (dystonia musculorum - dt) mice. One of the characteristic abnormalities observed early on in neurons from dt mice was eccentricity of the nuclei. In this study, we have characterized an isoform of Bpag1 (Bpag1 isoform 2) which contains a novel N-terminal transmembrane domain and associates with membranous structures surrounding the nucleus. Bpag1 isoform 2 primarily associated with actin filaments, and accumulated F-actin around the nucleus and Golgi apparatus in Cos-1 and C2C12 cells. This indicates a role in nuclear tethering and structural organization around the nucleus. Bpag1 isoform 2 can also enter into the nucleus, and may mediate structure within the intranuclear space. Comparisons of Bpag1 isoform 2 are made to the isoform 1 variant and distinct features are noted. The overall structure and localization of Bpag1 isoform 2 indicates that it is a nesprin-like protein, with possible similar or overlapping roles.

1096

**Distinctive Distribution of Protein 41 Homologs in *Mouse* Adrenal Gland**

C. Liu, X. An, Y. Wu, G. Debnath, M. Narla; Red Cell Physiology, New York Blood Center, New York, NY

Protein 4.1 is an adapter protein that links the actin-based cytoskeleton to various transmembrane proteins. The family of 4.1 proteins is encoded by four homologous genes, 4.1R, 4.1G, 4.1N, and 4.1B, which undergo complex alternative splicing. Both in situ hybridization and Northern blot analysis show that various protein 4.1 homologs are expressed in adrenal gland. However, the cellular and sub-cellular localization of these proteins in the adrenal gland has not been defined. As a first step in defining the function of protein 4.1 homologs in adrenal gland, we systemically examined the distribution and localization of these proteins in the gland by staining formaldehyde-fixed paraffin-embedded mouse adrenal gland sections with antibodies highly specific for each of the four 4.1 protein homologs. We find that all four 4.1 protein homologs are expressed in all adenocortical and adenomedulla zones but not in zona reticularis. However, we noted distinct subcellular localization of the various homologs. While 4.1R is restricted to nuclei, 4.1N accumultaed in peri-nuclear region. 4.1G is diffusely distributed in the cytoplasm while 4.1B exhibited both cytoplasmic and membrane localization. Furthermore, immuno-gold electron microscopy showed that 4.1B is present in the granules of chromaffin

cells of adrenal medulla. The diverse cellular distribution and distinct expression pattern of 4.1 proteins in mouse adrenal gland indicates diverse roles for 4.1 proteins in endocrine functions of adrenal gland.

### Morphological Analysis of Native Membrane Cytoskeleton under Cryo-electron Microscope

J. Usukura,[1] M. Makihara,[2] T. Watanabe,[3] N. Arimura,[3] N. Tanaka,[2] K. Kaibuchi[3]; [1]Anatomy and Cell Biology, Nagoya University, Nagoya, Japan, [2]Applied Physics, Nagoya University, Nagoya, Japan, [3]Cell Pharmacology, Nagoya University, Nagoya, Japan

**Purpose:** This study aims to elucidate molecular interaction between membrane and cytoskeleton by *in situ* morphological analysis. Now we established a new method to observe directly hydrated membrane cytoskeleton in native state under cryo-electron microscope while identifying constituent molecules by immuno-labeling. **Methods:** The grid meshes covered with carbon coated Formval film and treated subsequently with 1% Alucian blue were employed for sticking the cell membrane. Apical cell membranes stuck on the gird by contacting such grids on the cell surfaces were immediately frozen by plunging it into liquid ethane for morphological observation. For identification of protein molecules, membrane stuck on the grid was fixed briefly with 1 % glutaraldehyde and incubated with primary and subsequent secondary antibodies prior to quick freezing as described elsewhere. **Results and Discussion:** Even in hydrated and frozen state without any treatments, actin filaments, microtubules, clathrin coat and ER were clearly identified within 5 to 10 micron defocus. In particular, microtubules just beneath the membrane appeared to be abundant and flexible or curved. The average thickness of actin filaments, microtubules and clathrin coat in hydrated state were 7.6nm, 25.1nm and 6.8nm respectively. On considering regulation mechanism of morphogenesis, IQGAP1, an effector of Rac1 and actin-binding protein, accumulates at lamellipodia. Indeed, IQGAP1 was localized more dominantly on actin filaments closely attached to the cell membrane, but not on actin stress fibers. Those results were well compatible with the observation by imnuno-replica method. **Conclusion:** New methods consisting of membrane acquisition and cryo-techniques was available for structural analysis of membrane cytoskeleton in hydrated native state.

1098

### Proteomic Analysis of the Membrane Skeleton of *Tetrahymena thermophila*

P. C. Anderson,[1] A. L. Wentland,[1] D. J. Beussman,[1] R. B. Fulton,[2] M. Murakami,[2] E. S. Cole,[2] H. Said,[3] J. E. Honts[3]; [1]Chemistry, St. Olaf College, Northfield, MN, [2]Biology, St. Olaf College, Northfield, MN, [3]Biology, Drake University, Des Moines, IA

The membrane skeleton of the ciliated protozoan *Tetrahymena* contributes to the shape and cortical organization of this complex eukaryotic cell. The availability of genomic sequence data for *Tetrahymena thermophila* has facilitated a proteomic analysis of the non-microtubular portion of this cell's cortical cytoskeleton. Shape-preserving cortical residues, depleted of microtubules, can be prepared by extraction of *Tetrahymena* cells with potassium iodide in the presence of Triton X-100. The membrane skeletal residues obtained by this treatment were fractionated into distinct sets of proteins by selective extraction and precipitation procedures. Bands containing the constituent proteins were excised from preparative SDS-polyacrylamide gels. These proteins were reduced, alkylated and trypsin digested in-gel and the resulting enzymatic peptide fragments analyzed by LC-MS using electrospray ionization. The observed peptide molecular weights were used to search a database of predicted *Tetrahymena* proteins in order to identify the protein in the original gel band. Further confirmation was obtained by sequencing several enzymatically-derived peptides in the mass spectrometer. Two major components were identified - epiplasmin C and epiplasmin A - both of which are predicted to be coiled coil proteins. A related protein, epiplasmin B, was also detected. The other major protein identified was TCBP-25, an EF-hand calcium-binding protein. Intriguingly, among minor components present in these membrane skeletal residues were proteins related to protein and lipid kinases, as well as another EF-hand containing protein. These minor constituents suggest the possibility of a linkage between the structural cytoskeletal proteins that comprise the membrane skeleton and regulatory proteins involved in cellular signaling processes.

1099

### A Novel Role of Calpain in Membrane Ruffling Involves Deregulation of Cofilin 1, Tropomyosin 1 and RhoGDI-1

A. K. Larsen,[1] R. Lametsch,[1] T. B. Farre,[1] J. S. Elce,[2] M. Larsen,[3] B. Thomsen,[4] P. Ertbjerg,[1] M. A. Lawson[1]; [1]Department of Dairy and Food Science, Royal Veterinary and Agricultural University, Frederiksberg C, Denmark, [2]Department of Biochemistry, Queen's University, Kingston, ON, Canada, [3]Department of Biochemistry and Molecular Biology, University of Southern Denmark, Odense, Denmark, [4]Department of Genetics and Biotechnology, Danish Institute of Agricultural Sciences, Tjele, Denmark

Accurate regulation of the actin cytoskeleton is essential for a number cell motility processes including migration, spreading and the formation of lamellipodia, filopodia and membrane ruffles. The proteases µ- and m-calpain are involved in integrin-mediated cytoskeletal rearrangements, required for cell migration and cell spreading, by their modulation of focal adhesion components and signalling molecules. Here, we provide evidence that calpains are also essential in membrane ruffling. Calpain-deficient (*capn4*$^{-/-}$) fibroblasts ruffled significantly less than wild type (*capn4*$^{+/+}$) fibroblasts, in live cells grown on uncoated glass-surfaces. Active, GFP-tagged m-calpain was expressed in *capn4*$^{-/-}$ fibroblasts and fully restored the ruffling phenotype, as determined by time-lapse fluorescence microscopy. As shown previously, expression and activity of m-calpain-GFP in *capn4*$^{-/-}$ fibroblasts required co-expression of exogenous calpain small subunit. The fusion protein localized diffusely in the cytoplasm of *capn4*$^{-/-}$ fibroblast both under un-stimulated and $Ca^{2+}$-stimulated conditions, indicating that no major translocation of m-calpain to cell membranes occurred. To asses which proteins might influence the ruffling phenotype, proteome analysis of the two cell lines was carried out. Interestingly, a markedly increase in the level of tropomyosin 1, and decreased levels of cofilin 1 and RhoGDI-1 was detected in *capn4*$^{-/-}$ cytoplasmic lysates, compared with the wild type cells. Cofilin and tropomyosins are key regulators of actin filament dymamics, whereas RhoGDIs regulates activities of Rho-family GTPases. Together these data suggest that deregulation of these proteins is linked with the observed differences in ruffling, mediated by calpain.

### Integrins and Platelet Glycoprotein Ibα Interact with Distinct Filamin A Domains and Crystal Structures Reveal that They Have Similar Binding Interfaces

T. Kiema,[1] R. Pudas,[1] Y. Lad,[2] F. Nakamura,[3] P. Jiang,[4] K. L. Wegener,[4] I. D. Campbell,[4] O. Heikkinen,[5] P. Permi,[6] I. KIlpeläinen,[5,6] J. H. Hartwig,[7,8] T. P. Stossel,[7,8] D. A. Calderwood,[2] J. Ylanne[1,9]; [1]Department of Biochemistry, University of Oulu, Oulu, Finland, [2]Department of

Pharmacology, Yale University, New Haven, CT, [3]Hematology Division, Department of Medicine, Brigham and Women's Hospital, Boston, MA, [4]Department of Biochemistry, University of Oxford, Oxford, United Kingdom, [5]Department of Chemistry, University of Helsinki, Helsinki, Finland, [6]Institute of Biotechnology, University of Helsinki, Helsinki, Finland, [7]Hematology Division, Brigham and Women's Hospital, Boston, MA, [8]Medical School, Harvard University, Boston, MA, [9]Department of Biological and Environmental Sciences, University of Jyvaskyla, Jyvaskyla, Finland

Cytoskeletal association with transmembrane proteins permits transmission of biochemical signals and mechanical force across the plasma membrane and is essential to the development and functioning of multicellular animals. Here we report the first atomic level characterization of interactions of filamin A with the cytoplasmic face of transmembrane receptors, integrin and glycoprotein Ibα (GPIbα). The binding studies showed that a major interaction site with the cytoplasmic tail of integrin resides at the filamin A immunloglobulin-like domain 21 (FLNa21) and that the GPIbα binds to the filamin A domain 17 (FLNa17). The crystal structure of the FLNa21 with the integrin β7 cytoplasmic tail peptide showed that the integrin peptide forms an additional β-strand next to the β-strand C of the FLNa21 and that several hydrophobic residues of the integrin are involved in the interaction. Mutation and NMR studies confirm that the interaction seen in the crystal also takes place in solution and in cells. The complex structure of the FLNa17 with the GPIbα peptide showed a similar extension of the β-sheet and similar hydrophopic contacts as were observed for integrin-filamin interaction, but also some specific hydrophopic contacts were seen. Point mutations in the FLNa17 abrogated full-length filamin A binding to GPIbα in co-immunprecipitation studies. The striking similarity of the interaction of integrin and GPIbα peptides with the filamin domains seen in the crystal structures suggests that it is a general mode of ligand binding by immunoglobulin-like filamin repeats and could enlighten the analysis of the many other reported filamin-ligand interactions. Furthermore, the structures suggest mechanisms how integrin-FLNa interaction could be regulated by phosphorylation or by competition with talin, and why sulfhydryl modifications abrogate the GPIbα filamin interaction.

## Pecam-1 Cytosolic Domain Regulates Endocytosis and Actin Reorganization Triggered by Pecam-1 Clustering

A. Thomas,[1] C. Garnacho,[1] S. Muro,[1,2] S. Albelda,[3] M. Koval,[4] V. Muzykantov[1,2]; [1]Institute for Environmental Medicine, University of Pennsylvania Medical School, Philadelphia, PA, [2]Department of Pharmacology, University of Pennsylvania Medical School, Philadelphia, PA, [3]Division of Pulmonary, Allergy and Critical Care Medicine, University of Pennsylvania Medical School, Philadelphia, PA, [4]Division of Pulmonary, Allergy and Critical Care Medicine, Emory University, Atlanta, GA

Platelet-Endothelial Cell Adhesion Molecule (PECAM)-1 is an Ig-superfamily transmembrane glycoprotein involved in endothelial layer integrity, angiogenesis and leukocyte transmigration. We found that nanocarriers carrying PECAM antibodies (anti-PECAM/NCs) enable intracellular drug delivery into endothelium via CAM-mediated endocytosis, induced by PECAM-1 clustering. These findings suggest dynamic signaling from PECAM-1 to the actin cytoskeleton. Using fluorescence microscopy, we explored the role of the PECAM cytosolic domain in actin reorganization required for CAM-mediated endocytosis of FITC-labeled anti-PECAM/NCs. We used REN cells transfected with either full length PECAM containing cytosolic exons 10-16, PECAM mutants with the cytosolic tail truncations Δ10-16, Δ11-16, Δ15-16, or mutated at two candidate signaling residues (Y663F in exon 13 or Y686F in exon 14). Endocytosis of anti-PECAM/NCs and actin reorganization into stress fibers were observed in REN cells expressing full-length PECAM-1, as well as Δ15-16 and Y663F mutants. However, both processes were inhibited in cells expressing Δ10-16, Δ11-16, and Y686F PECAM-1 mutants. Activated Rac was detected in REN cells expressing full-length PECAM-1, which was enhanced upon binding of anti-PECAM/NCs to the cells, while activated Rac was undetectable in Δ10-16 PECAM-1 mutant. In addition, anti-PECAM/NCs induced Rho activation in REN-PECAM-1 cells, but this was attenuated by Δ10-16 truncation. These data indicate that PECAM-1 cytosolic domain regulates actin cytoskeleton in response to extracellular ligands (anti-PECAM/NCs), which is likely mediated by PECAM-1 tyrosine residue Y686, and operates through Rac and Rho. Actin-mediated changes in endothelial cell shape, which contribute to transmigration (induced by PECAM-1-adhered leukocytes), or angiogenesis (induced by integrin-mediated PECAM-1 de-phosphorylation) may operate by a similar pathway.

1102

## Comparative Studies of Erythroid Spectrin and Non-erythroid Spectrin Repeats

X. An, X. Guo, M. Salomao, X. Zhang, Y. Wu, A. Baines, N. Mohandas; Red Cell Physiology Laboratory, The New York Blood Center, New York, NY

Spectrins are long rod-like, flexible molecules with multiple functions. Spectrins are composed of α- and β-spectrin subunits which form anti-parallel dimers through lateral association, and tetramers through head-to-head association of dimers. Two α-subunits (αI, αII) and five β-subunits (βI-V) have been identified in humans. The structure and function of erythroid spectrin (αIβI) have been well studied, while the structure and function of other spectrins is less well defined. In the present study, we performed a series of analyses to compare αIβI with αIIβII-spectrin, an isotype abundant in most non-erythroid tissues. We compared the conformational stability of individual triple-helical repeats, the ability of individual repeats to bind phosphatidylserine and their dimerization characterisitics. Our findings are as follows. (1) αIIβII single repeats are more conformationally stable than their counterparts in erythroid spectrin. (2) During temperature induced unfolding of tandem repeats, αIIβII repeats unfold more cooperatively than those of erythroid spectrin. (3) Of the 10 phosphatidylserine binding repeats in the erythroid spectrin chains, 5 are conserved in αIIβII; one cluster of 3 consecutive structural repeating units in αI-spectrin (repeats 8-10) is displaced by one repeat in αII-spectrin (repeats 9-11). Repeat 1 of αII-spectrin binds phosphatidylserine, unlike the corresponding repeat of αI-spectrin. (4) The interaction of α and β polypeptides to form dimers requires β repeats 1-2 and α repeats 20-21 in all cases. However, the interaction between αII-βII dimerization peptides appears to be significantly stronger than that of erythroid spectrin. Our data suggests that αI/αII and βI/βII polypeptides have been subfunctionalized in evolution. αIβI is evidently adapted to the flexible, elastic nature of erythrocyte membranes; αIIβII is adapted to provide stability to membrane structures in complex tissues.

**The Blood Group Antigen-carrying Protein XK is Linked to Red Cell Membrane Skeleton Through its Interactions with Protein 41R and Alpha Spectrin**

X. Zhang, X. An, X. Guo, Y. Wu, M. Narla; Red Cell Physiology, New York Blood Center, New York, NY

The red blood cell membrane is a composite structure in which spectrin-actin based membrane skeletal network is linked to lipid bilayer. The attachment of membrane skeleton to lipid bilayer is mediated either by direct interaction of skeletal protein with lipids (such as the interaction of spectrin and 4.1R to phosphatidylserine) or by interaction of skeletal proteins to cytoplasmic domains of transmembrane proteins. To date, two such vertical protein linkages have been well studied. One is band 3-ankyrin-spectrin interaction and the other is Glycophorin C-protein 4.1R interaction. Recent evidence indicates that many other transmembrane proteins such as XK, Kell, Lu, Rh/RhAG are also linked to membrane skeleton. However, much less is known regarding molecular basis for these interactions. In the present study, we show that the expression of XK is significantly reduced in red blood cells of 4.1R knockout mice: this is analogous to an earlier finding that glycophorin C content of these membranes is markedly reduced, and strongly implies that XK interacts with 4.1R in situ. In vitro pull down assay demonstrated that the cytoplasmic domain of XK binds to the N-terminal 30 kDa membrane-binding domain of 4.1R. Importantly, the interaction of XK with protein 4.1R is regulated by $PIP_2$. We also show that the cytoplasmic domain of XK binds to alpha spectrin; the binding site on spectrin is located within the EF hands at the C-terminus of alpha spectrin. These findings enable us to identify new protein linkages in the red cell membrane and thus further our understanding of its structural organization.

## Cell Attachment to the Extracellular Matrix (1104-1124)

**Bifunctional Peptides Derived from Homologous Loop Regions in the Laminin α Chain LG4 Modules Interact with Both α2β1 Integrin and Syndecan-2**

F. Yokoyama,[1,2] N. Suzuki,[1] Y. Kadoya,[3] Y. Kikkawa,[2] M. Haruki,[1] H. K. Kleinman,[4] M. Nomizu[2]; [1]Graduate School of Environmental Earth Science, Hokkaido University, Sapporo, Japan, [2]School of Pharmacy, Tokyo University of Pharmacy and Life Science, Tokyo, Japan, [3]Department of Anatomy, Kitasato University School of Medicine, Sagamihara, Japan, [4]National Institute of Dental and Craniofacial Research, National Institutes of Health, Bethesda, MD

Laminin α chains show diverse biological functions in a chain-specific fashion. The laminin G-like modules (LG modules) of the laminin α chains consist of a 14-stranded β-sheet sandwich structure with biologically active sequences found in the connecting loops. Previously, we reported that connecting loop regions between β-strands E and F in the mouse laminin α chain LG4 modules showed chain-specific activities. In this study, we focus on the homologous loop regions in human laminin α chain LG4 modules using five synthetic peptides (hEF-1-hEF-5). These homologous peptides induced chain-specific cellular responses in various cell types. Next, in order to examine dual-receptor recognition model, we synthesized chimeras (cEF13A-E) derived from peptides hEF-1 and hEF-3. All of the chimeric peptides promoted fibroblast attachment as well as the parental peptides. Fibroblast attachment to cEF13A and cEF13B was inhibited by anti-integrin α2 and β1 antibodies and by heparin, while cell adhesion to cEF13C, cEF13D, and cEF13E was blocked only by heparin. Actin organization of fibroblasts on cEF13C was not different from that on hEF-3, but cEF13B induced membrane ruffling at the tips of the actin stress fibers. These results suggest that cEF13B had bifunctional effects on cellular behaviors through α2β1 integrin and heparin/heparan sulfate proteoglycan. We conclude that the approach utilizing chimeric peptides is useful to examine cellular mechanisms in dual receptor systems.

1105

**Characterization of α-Dystroglycan Binding Sequence Derived from the Laminin α2 Chain LG4-5 Module**

T. Yoshimura,[1] N. Suzuki,[1,2] F. Yokoyama,[1,2] Y. Kikkawa,[1] J. Yamada,[1] M. Nomizu[1]; [1]School of Pharmacy, Tokyo University of Pharmacy and Life Science, Tokyo, Japan, [2]Graduate School of Environmental Earth Science, Hokkaido University, Sapporo, Japan

Laminins are major components of basement membranes and have various biological activities. Laminins consist of α, β, and γ chains. The C-terminal globular domain of the α chain (G domain) consists of five LG modules (LG1-5) and plays a critical role for the biological activity. The laminin α2 chain, which is a component of laminin-2/4/12, is mainly expressed in skeletal muscles or peripheral nerves and interacts with dystroglycan and heparan sulfate proteoglycans. Here, we focused on the laminin α2 chain LG4-5 module and to identify their heparin and dystroglycan binding activities to better understand the biological function of the molecule. We prepared a recombinant laminin α2 chain LG4-5 module (rec-α2LG4-5) using 293T cells. The rec-α2LG4-5 showed heparin and α-dystroglycan binding activities. To identify the binding sites in the laminin α2 chain LG4-5 module, we synthesized 42 overlapping peptides covering the entire molecule. First, we examined the effect of the peptides on the heparin binding of rec-α2LG4-5. The A2G78 peptide (GLLFYMARINHA, mouse laminin α2 chain 2796-2807) inhibited the heparin binding of rec-α2LG4-5. A2G78 showed heparin binding activity in a solid phase binding assay. The minimal active sequence of A2G78 for heparin binding was found to be LLFYMARI. Next, we tested the α-dystroglycan binding activity of the A2G78 sequence. The A2G78 peptide showed inhibitory effect on α-dystroglycan binding to the rec-α2LG4-5 protein. These results suggest that the A2G78 site plays an important role in the interaction of rec-α2LG4-5 with heparin/heparan sulfate and α-dystroglycan.

**A Role for $\alpha_4\beta_1$ Integrin-Specific Fibronectin Peptides in Enhancing Small Intestinal Submucosa (SIS) Vascular Graft Biocompatibility**

E. J. Rodenberg,[1] M. C. Hiles,[2] F. M. Pavalko[1]; [1]Cellular and Integrative Physiology, Indiana University School of Medicine, Indianapolis, IN, [2]Cook Biotech, Inc., West Lafayette, IN

The limited availability of autologous vessel transplant grafts and high failure rates of current-day synthetic graft prostheses create the need to engineer a more compatible, implantable vascular biomaterial. We propose using acellular, Type I collagen-enriched porcine small intestinal submucosa (SIS) as an ideal biomaterial. Previously, we demonstrated that human endothelial cells cultured on SIS “condition” the surface and render it more biocompatible to subsequent endothelial cell adhesion through the secretion of a fibronectin-rich extracellular matrix. However, platelets express integrins which recognize and bind the Arg-Gly-Asp-Ser (RGDS) tetrapeptide within intact fibronectin and collagen. Others have

shown the $\alpha_4\beta_1$ integrin receptor recognizes two specific peptide sequences, Leu-Asp-Val (LDV) and Arg-Glu-Asp-Val (REDV), within human plasma fibronectin (Komoriya *et al*., Mould *et al*.). We hypothesize that crosslinking SIS with non-platelet specific fibronectin binding peptides can increase endothelial adhesion and decrease platelet binding. To test this hypothesis, we first wanted to determine if platelets, endothelial cells, and human fibroblasts express $\alpha_4\beta_1$. Immunoprecipitation and Western blot analyses demonstrated surface expression of $\alpha_4$ and $\beta_1$ integrin subunits on human umbilical vein endothelial cells (HUVEC), human coronary artery endothelial cells (HCAEC), and human foreskin fibroblasts (HFF). Fluorescence-activated cell sorting (FACS) analysis confirmed that neither non-activated nor thrombin-activated human platelets express the $\alpha_4$ integrin subunit. Currently, we are investigating the ability of HUVEC, HCAEC, HFF, and platelets to recognize and bind to fibronectin peptide fragments, including REDV, RGDS, and LDV, immobilized on 96-well microplates. To quantitate total binding, immunofluorescence labeling and Image Tool® software analysis are being used. In conclusion, cross-linking $\alpha_4\beta_1$ integrin-specific peptides to SIS may yield a more compatible vascular biomaterial that would allow for endothelial attachment while significantly minimizing platelet attachment. Funding: Cook Biotech, Inc. and NIH R01 AR-049728 (FMP).

**Determination of the Critical Amino Acid Residues within the EIIIA (ED-A) Segment of Fibronectin that Bind Integrins α9β1 and α4β1**

A. V. Shinde,[1] C. Bystroff,[2] C. Wang,[2] P. Vincent,[3] L. Van De Water[1]; [1]Center for Cell Biology and Cancer Research, Albany Medical College, Albany, NY, [2]Department of Biology, Rensselaer Polytechnic Institute, Troy, NY, [3]Center for Cardiovascular Sciences, Albany Medical College, Albany, NY

Fibronectins (FNs) are a family of extracellular glycoproteins that mediate cellular adhesion, migration and differentiation. The FNs are disulfide-bonded, dimeric proteins with each chain composed of homologous repeats of three prototypical types, termed FN-I, FN-II, FN-III. Each FN monomer contains a contiguous array of 15-17 of the ~90 amino acid FN III repeats. Increased expression of cellular FNs that contain the alternatively spliced EIIIA and/or EIIIB FN III segments is a prominent feature during embryogenesis, wound healing, tumor progression and inflammation. We previously reported that two integrins, α9β1 and α4β1, ligate the EIIIA segment (Liao et al J. Biol. Chem. 2002) and that the epitopes for function-blocking monoclonal antibodies lie within the C-C' loop of EIIIA (Liao et al J. Biol. Chem. 1999). We have now created a library of point mutants within rat EIIIA and performed cell adhesion assay on these single and double mutants. We find that the Asp41 and Gly42 within the C-C' loop are critical in mediating integrin binding. We designed synthetic peptides based on the predicted important amino acid sequence from the C-C' loop, characterised their structure by NMR and identified peptides that inhibit α9β1 and α4β1-mediated cell adhesion, using SW480 α9-transfected cells and α4β1-expressing HFF-2 and HFL-1 cells. Our data provide an important basis for understanding the functions of the alternatively spliced FNs in normal and pathogenic settings.

**The Structures of the Thrombospondin-1 N-terminal Domain and its Complex with a Synthetic Pentameric Heparin**

K. Tan,[1] M. Duquette,[2] J. Liu,[1] J. Wang,[1] J. Lawler[2]; [1]Department of Medical Oncology, Dana-Farber Cancer Institute, Boston, MA, [2]Department of Pathology, Beth Israel Deaconess Medical Center, Boston, MA

The N-terminal domain of thrombospondin-1 (TSPN-1) mediates the protein's interaction with (1) glycosaminoglycans, calreticulin and integrins during cellular adhesion and migration, (2) low-density lipoprotein receptor-related protein (LRP) during uptake and clearance and (3) fibrinogen during platelet aggregation. The structure of TSPN-1, as determined by X-ray crystallography to 1.8 Å resolution, is a b-sandwich with 13 anti-parallel b strands and one irregular strand-like motif comprising a concaved front sheet and a convex back sheet. Topologically, it belongs to the concanavalin A-like lectins/glucanases superfamily. However, its unique structural features at the N- and C-terminal regions, and the disulfide bond location distinguish TSPN-1 from other members of this superfamily. Binding sites for calreticulin, fibrinogen and a4b1 integrin that have been identified using synthetic peptides map to the various edges of the domain and appear to be available for binding to these ligands. The crystal structure of the complex of TSPN-1 and a pentameric heparin indicates that residues R29, R42 and R77 in an extensive positively charged patch at the bottom of the domain specifically associate with the sulfate groups of heparin. The TSPN-1 structure also identifies a flexible linker between the globular TSPN-1 domain (N1-C214) and the coiled-coil sequence region that serves as the trimerization site. The TSPN domain is found in various extracellular matrix molecules including TSPs, NELLs, many collagens, TSPEAR and kielin. Whereas the sequence identity of the TSPN domains is relatively low for these proteins, the hydrophobicity pattern of key positions that define the b strands of TSPN-1 and the positions of the two cysteine residues that form a disulfide bond are similar in all of them. These data indicate that the TSPN domain represents a distinct subclass of the concanavalin A-like lectins/glucanases superfamily.

**KGF Gene Transfected Colorectal Cancer Cells Induced Cell Adhesion to Extracellular Matrix**

M. Kudo, T. Ishiwata, N. Nakazawa, K. Kawahara, T. Fujii, Y. Kawamoto, K. Teduka, T. Suzuki, Z. Naito; Department of Integrative Pathology, Nippon Medical School, Tokyo, Japan

It has been reported that, in the case of colorectal cancer, keratinocyte growth factor (KGF) was expressed in neuroendocrine cells which were found to be both in close proximity to tumor cells, and also in tumor cells and as well as in the adjacent stromal fibroblasts. KGF is suggested to act either in an_autocrine or in paracrine manner to regulate colorectal cancer cell functions and cell behaviors. In the present study, we examined the role of KGF in adhesion activities of colorectal cancer cells by using a KGF gene transfected- and stably expressing-cell line HCT-15KGF that had been constructed from a colorectal cancer cell line, HCT-15. The original HCT-15 expresses KGFR and a very low level of KGF. HCT-15KGF cells also express KGFR and secrete 2.0 ± 0.06 ng/ml of KGF in the culture medium. Expression levels of integrin mRNAs such as β-1, α-5 and α-v that were relevant to the adhesion of cells to fibronectin showed no significant difference between HCT-15KGF and mock-transfected HCT15-MOCK cells. HCT-15KGF cells showed markedly increased adhesiveness to ECM; such as fibronectin, laminin and type IV-collagen. Activity of a mitogen-activated protein kinase (MAPK), ERK1/2, was increased in HCT-15KGF compared with HCT-15MOCK cells. The adhesion of the cells to fibronectin was inhibited by the treatment of the cells with ERK1/2 inhibitor, U0126, implying that a MAPK pathway is involved in adhesiveness of the cells to fibronectin. The data indicates that over-expression of KGF in colorectal cancer cells induces the cell adhesion to ECM through the MAPK pathway.

**AFM Measurements of Forces Linking Hyaluronic Acid to CD44 Show Change in its Cytoskeletal Association in Glioma U-373**

C. Lamontagne-Carpin, M. Grandbois; Department of Pharmacology, Université de Sherbrooke, Sherbrooke, PQ, Canada

Glioblastomas are invasive cells that infiltrate very aggressively brain tissues and surgical interventions have therefore little chances of success. Hyaluronic acid (HA), a linear high molecular weight glycosaminoglycan, is a major component of the extra-cellular matrix in the brain and has been shown to be involved in cellular migration of highly invasive gliomas through is interaction with the cell receptor CD44. However the regulation of cell avidity for this polysaccharide is controlled by a large number of molecular mechanisms, which are still little understood. In the so-called force spectroscopy mode, the atomic force microscope (AFM) permits mechanical characterization of single bimolecular events. Here, HA / CD44 interactions were measured by allowing an AFM tip functionalized with HA molecules to contact the surface of glioblastomas U-373 expressing the CD44 receptor. The unbinding forces, when reported on a histogram, clearly exhibit two populations. First, in the low force regime (15 pN), we can appreciate the disrupt ion of HA / CD44 interaction. A second population (25 pN) with force elongation profile characteristic of membrane tether pulled from the cell surface can be observed. This finding is supported by the extent of the high force population (membrane tethers) that can be modulated through the interaction of the cytoskeleton with the cell membrane. Hence, cytoskeleton disruption by latrunculin, increase the high force regime population whereas the PMA treatment, which has shown to reorganize the actin network increasing CD44 / cytoskeleton interactions, leads to ruptures corresponding to the low force regime. As a conclusion, it is likely that both interactions will have a deep influence on the cell behavior toward HA, therefore foreseeing interesting principles in gliomas invasiveness.

**Adsorption of Distinct ECM Proteins and Subsequent Remodeling Control the Osteogenic Differentiation of Mesenchymal Stem Cells on Polymeric Scaffolds**

A. K. Kundu, A. J. Putnam; Chemical Engineering and Materials Science; Biomedical Engineering, University of California, Irvine, Irvine, CA

Several recent studies highlight the use of multipotent adult bone marrow-derived mesenchymal stem cells (MSCs) for tissue engineering applications. Predictably controlling MSC differentiation is vital to widen their clinical use. While the roles of various soluble factors in promoting osteogenic differentiation have been studied, very little is known about the effect of the extracellular matrix (ECM) on MSC differentiation. In the present study, we compared the osteogenic potential of MSCs cultured on thin films of poly(lactide-co-glycolide) (PLGA) or poly(caprolactone) (PCL), two polymeric biomaterials widely used in tissue engineering as synthetic ECM analogs and that have been previously reported to differentially support osteogenic differentiation. We hypothesized that the adsorption of distinct ECM proteins present in serum-containing culture medium and subsequent differences in integrin-mediated adhesion account for the differential abilities of these materials to support osteogenesis. Supporting this hypothesis, significant amounts of fibronectin and vitronectin deposited onto both materials in serum-containing osteogenic media, with type-I collagen present in lower amounts. Adhesion-blocking studies revealed that MSCs adhere to PCL primarily via vitronectin, while type-I collagen mediates their attachment to PLGA. Moreover, de novo synthesis of ECM proteins by the MSCs occurred after prolonged periods of culture, suggesting that ECM remodeling plays an important role in the osteogenic process in vitro. These distinctions in the initial adhesive mechanisms and subsequent cell-mediated remodeling of the ECM correlated with higher levels of alkaline phosphatase activity and osteopontin expression after 2 weeks of monolayer culture in MSCs grown on PLGA rather than PCL. Together, these data suggest the initial integrin-mediated adhesion and subsequent matrix remodeling are critical regulators of osteogenesis, and stress the need for an improved molecular understanding of cell-ECM interactions in stem cell-based therapies.

1112

**Directed Cell Growth on Protein Functionalized Hydrogel Surfaces**

M. R. Hynd, J. Frampton, N. Dowell-Mesfin, J. N. Turner, W. Shain; Department of Health, Wadsworth Center, Albany, NY

Biochemical surface modification has been used to direct cell attachment and growth on a biocompatible gel surface. The spatial patterning of cells was based on the microcontact printing of protein molecules onto a gel surface. Acrylamide-based hydrogels were photopolymerized in the presence of an acroyl-streptavidin monomer to create planar, functionalized surfaces capable of binding biotin-labeled proteins. Microcontact printing was used to transfer the biotinylated extracellular matrix proteins, fibronectin and laminin, and the laminin peptide, IKVAV, onto modified surfaces. Proteins were patterned using PDMS stamps possessing a variety of surface designs. As a biological assay, LRM55 astroglioma cells and primary hippocampal neurons were plated on stamped hydrogels. Fluorescence, light and confocal microscopy were used to quantify cell attachment and cell morphology on modified surfaces. Cells were found to selectively adhere to areas stamped with biotin-conjugated proteins only. No cell attachment was observed within the un-patterned areas. Cells remained attached to the patterned areas for >4 weeks. Results from this study suggest that hydrogel surfaces can be patterned with multiple proteins to direct cell growth and attachment. This technique may be used to modify nanofabricated neural prosthetic devices to enhance biocompatibility. *This work was supported in part by the Nanobiotechnology Center (NBTC), an STC Program of the National Science Foundation under Agreement No. ECS-9876771.*

1113

**Crosslinked Hyaluronan with PEG Nanostents Inhibits Collagen Gel Contraction: A Potential Preventative of Burn Contracture**

K. Ghosh,[1] T. Mehra,[1] X. Z. Shu,[2] G. D. Prestwich,[2] R. A. F. Clark[3]; [1]Biomedical Engineering, State University of New York at Stony Brook, Stony Brook, NY, [2]Medicinal Chemistry and Center for Therapeutic Biomaterials, The University of Utah, Salt Lake City, UT, [3]Biomedical Engineering, Dermatology and Medicine, State University of New York at Stony Brook, Stony Brook, NY

Adult burn wounds, which lack hyaluronan (HA), often undergo excessive tissue remodeling and contraction. In contrast fetal wounds, which contain large amounts of HA, undergo remodeling that culminates in a scarless repair or regeneration. Therefore, adding a HA derivative to burn wounds would better mimic the fetal extracellular matrix (ECM) and may prevent excessive contraction. As a first step toward testing this hypothesis, we determined the effects of three HA moieties, i.e. high molecular weight (HMW)-HA, thiol-functionalized HA (HA-DTPH) and poly (ethylene glycol) diacrylate (PEGDA)-crosslinked HA (HA-DTPH-PEGDA), on fibroblast-mediated, collagen gel contraction. This assay has been widely used to mimic the in vivo wound contraction. Results showed that all the additives were cytocompatible. Interestingly, HMW HA facilitated collagen gel contraction while HA-DTPH weakly and HA-DTPH-PEGDA strongly inhibited contraction. The inhibitory effect was more

pronounced at higher concentrations of either HA-DTPH or PEGDA. However, varying the PEGDA MW showed no significant effect. The supernatant of contracted collagen-HMW HA gels contained greater amounts of HA, as compared to those containing HA-DTPH-PEGDA, suggesting that HMW HA facilitates fibroblast contraction of collagen gels by acting as a lubricant where it is effectively squeezed out of the gels. Crosslinking renders HA-DTPH-PEGDA the structural stability required to resist the fibroblast contractile forces. Such biomaterials that inhibit excessive contraction of collagen gels in vitro may also prevent severe wound contraction in vivo.

1114

### A Novel Surface Patterning Method for Protein-Cell Interaction Studies

M. P. Lynch,[1] S. R. Nettikadan,[1] A. Sethuraman,[1] J. C. Johnson,[2] E. R. Henderson[1,3]; [1]BioForce Nanosciences, Ames, IA, [2]Dept. of Microbiology, Des Moines University, Des Moines, IA, [3]Dept. of GDCB, Iowa State University, Ames, IA

A common technique for studying protein-cell interactions involves patterning an ECM protein or other signaling molecule onto a surface that is suitable for cell growth and subsequent analysis. Current methods of molecular surface patterning include bulk coating, photolithography, microcontact printing, and microarraying. Of these methods, only microarraying can facilitate multiplexed printing of different molecules on the same surface. Features created using pin-tool or ink-jet microarrayers are, however, many times larger than most cells. It was our objective to develop a flexible method of directly patterning multiple molecules onto a surface at the same (or smaller) spatial scale as a single cell. Briefly, we used an instrument (NanoArrayer™) equipped with microfabricated Surface Patterning Tools (SPTs) to draw multiple parallel lines of laminin and a negative control, bovine serum albumin (BSA), on a glass surface. Proteins were loaded into reservoirs on the SPT that connect to microfluidic channels that dispense liquid onto the surface via a process known as FEMTO (Fluidics Enhanced Molecular Transfer Operation). Laminin lines were 600 µm long, 5 µm wide, with a pitch of 40 µm. The BSA lines were 1000 µm long, 10 µm wide, with a pitch of 40 µm. Proteins were incubated on the surface overnight, then the surface was blocked and washed to prevent non-specific adhesion of cells. Adherent cells were cultured on the patterned surface and found to adhere specifically to the laminin lines. Subsequent labeling of the proteins with fluorescent antibodies confirmed their presence and identity. We have concluded that this technique is superior to existing surface patterning methods with respect to multiplexing, flexibility of pattern design, and spatial scale. Future studies using cell signaling molecules to direct differentiation or induce proliferation of individual stem cells hold great potential for human health.

### Robust Differentiation of PC12 Cells and ES-D3 Murine Embryonic Stem Cells on Substrates Coated with Photo Reagents

T. J. Naqvi, G. W. Opperman, M. A. Lodhi; Diagnostics and Drug Discovery, SurModics, Inc., Eden Prairie, MN

In the past several years there has been a paradigm shift in developing synthetic biomaterials to grow cells or harvest cell products, primarily for applications in tissue culture, tissue engineering and regenerative medicine. For *in vitro* applications, physical and chemical properties as well as the structure of the substrate have been modified to closely mimic the natural microenvironment found *in vivo*. Cell attachment, proliferation, differentiation and cell-cell interaction are greatly affected by these physical and chemical properties of the substrate. We designed several experiments to test the effect of surface properties on the differentiation of PC12 and ES-D3 cells. PuraMatrix™ and Matrigel™ were used as substrates in addition to the substrates coated with photo-reagents containing 3-aminopropylmethacrylate (APMA), polyethylenimine (PEI), fibronectin, laminin, collagen and RGD peptides. Quantitatively better cell differentiation was achieved in PC12 cells grown on substrates coated with photo reagents compared to the other products: photo-laminin (80%) photo-APMA (60%), photo-collagen (30%), photo-PEI (20%) photo-RGD and PuraMatrix (10%), Matrigel (5%) and uncoated polystyrene control (1%). In addition, ES-D3 stem cells attach and divide well on surfaces coated with photo-APMA while remaining totipotent in the presence of FGF. With the proper change in growth conditions, cells differentiated into neurons, oligodendrocytes and type I and type II astrocytes. Moreover, photo-APMA proved to be an effective substrate in long-term maintenance and growth of the cells. PC12 and ES-D3 cells grown on APMA-coated substrate were robust and displayed their respective morphologies even after 60 and 30 days in cultures respectively, without being passaged onto fresh substrate. In conclusion, an APMA-coated surface provides a robust synthetic substrate for cell attachment, differentiation and long-term culture of the cells.

1116

### Probing the Role of Syndecan-Based Spreading on Cell Structure

J. Kubicek,[1] M. DiGiacomo,[2] A. Kamien,[2] P. LeDuc,[1] R. Bellin[2]; [1]Department of Mechanical and Biomedical Engineering, Carnegie Mellon University, Pittsburg, PA, [2]Department of Biology, Holy Cross College, Worcester, MA

Syndecans have been implicated in a wide variety of processes including both cell signaling and adhesion. Members of this superfamily of heparan sulfate proteoglycans are located at the cell surface and have known binding affinities for the extracellular matrix and the actin cytoskeleton. Because syndecans are linked to both the internal components of the cell and the external cellular environment, their transmembrane role in attachment and spreading is critical. Here, we present studies demonstrating our ability to control the spreading of NIH-3T3 fibroblasts by growing cells on modified polydimethylsiloxane (PDMS) membranes. These polymer membranes have been used in a variety of other cell studies to probe cell motility and mechanotransduction. In order to assay the effects of cell adhesion based on syndecans alone, we have developed a method to conjugate syndecan ectodomain-specific antibodies to the surface of PDMS membranes. After conjugating the syndecan antibodies to the polymer surface through plasma oxidation modification, cells were cultured on these membranes and allowed to attach and spread. Cells were then stained and visualized to probe the resulting cell structure including the actin cytoskeleton. The effects of controlling the concentration of the antibodies on cell spreading were also investigated. These results were compared to parallel studies on cell attachment and spreading using fibronectin conjugated PDMS, which is known to support cell adhesion via both syndecans and integrins. Overall, these studies have a variety of potential applications, which include studying cell structure and motility.

1117

### Forces Exerted by Epithelial Cells are Proportional to the Substrate Rigidity

B. Ladoux,[1] A. Saez,[1] A. Buguin,[2] P. Silberzan[2]; [1]University Paris 7-CNRS, MSC, Paris, France, [2]CNRS/IC, Institut Curie, Paris, France

We have developed a substrate composed of a closely spaced array of elastomeric microposts to measure traction forces exerted by cells on their

substrate (PNAS 2005). Previous studies have shown that cell movement and focal adhesions are regulated by physical interactions at the cell-substrate interface. We show that traction forces and focal adhesions are strongly correlated to the rigidity of the substrate by analyzing the force *versus* rigidity depending relation. We characterize quantitatively this effect on MDCK epithelial cells by using our micro-fabricated force sensor consisting of a high density array of soft pillars whose stiffness can be tailored by changing their height and radius. We find that the forces exerted by the cells are proportional to the spring constant of the pillars. Such a behavior supports the existence of a cellular integrated mechanism allowing cells to control the deformation of their substrate in response to a probing force. These dynamic observations are correlated with the reinforcement of focal adhesions that increases with the substrate rigidity.

1118

**Cell-Matrix Entanglement and Mechanical Anchorage of Fibroblasts in Three Dimensional Collagen Matrices**

H. Jiang, F. Grinnell; Cell Biology, UT Southwestern Medical Center, Dallas, TX

Fibroblast-3D collagen matrix culture provides a physiologically relevant model to study cell matrix interactions. In tissues, fibroblasts are phagocytic cells, and in culture they have been shown to ingest both fibronectin and collagen-coated latex particles. Compared to cells on collagen coated coverslips, phagocytosis of fibronectin-coated beads by fibroblasts in collagen matrices was found to be reduced. This decrease could not be explained by integrin reorganization, tight binding of FN beads to the collagen matrix, or differences in overall bead binding to the cells. Rather, entanglement of cellular dendritic extensions with collagen fibrils appeared to interfere with the ability of the extensions to interact with the beads. These extensions began to protrude as early as cells could be observed to interact with the collagen matrix and increased in length within the porous collagen network, eventually becoming difficult to distinguish by scanning electron microscopy from the collagen fibrils themselves. Entangled dendritic extensions were strongly anchored in the collagen matrix since treatment of attached cells with 0.25% trypsin/1mM EDTA caused breaks between the cell bodies and extensions rather than detachment of cells from the matrices. Similarly, although 10 mM EDTA inhibited cell adhesion to collagen matrices, once the cells were attached they no longer were sensitive to EDTA treatment even though cells on collagen-coated coverslips detached completely under similar conditions. These findings suggest that entanglement of dendritic extensions in the collagen matrix represents an integrin-independent form of adhesion. In conclusion, we suggest that cell-matrix entanglement provides a novel mechanism of cell anchorage not previously recognized and uniquely reliant on the three dimensional character of the matrix.

1119

**Mechanical Strain Enhances ECM Induced Cell Fate Determination and Promotes Osteogenic Differentiation of Human Mesenchymal Stem Cells Through the ERK MAPK Pathway**

D. F. Ward; Biology, Rensselaer Polytechnic Institute, Troy, NY

Human mesenchymal stem cells (hMSC) are a population of multipotent bone marrow cells, capable of differentiating through multiple lineages. In addition to bone, some of the other pathways lead to cartilage, fat, or smooth muscle. The role of mechanical strain in influencing the lineage specific cell fate determination and promoting osteogenic differentiation of hMSC is not known. Current research in our lab is focused on determining the effects of mechanical strain on extracellular matrix (ECM) induced osteogenic differentiation including the cell fate determination and passage through a specific lineage. We hypothesize that strain is transduced by specific cell surface transmembrane integrins to a MAPK signaling pathway cascade leading to the activation of transcription factor(s) which induce expression of osteogenic genes and result in increased extracellular matrix deposition and mineralization. Our data indicate that cells subjected to a 5% mechanical strain on COL-I coated silicone rubber membranes have increased expression levels of well-established osteogenic marker genes and reduced expression levels of marker genes from alternate lineages. Additionally, the extracellular matrix was shown to have increased levels of mineralization in response to mechanical strain. Our data suggests that the extracellular signal-related kinase (ERK) MAPK pathway is involved in this activation of bone lineage specific transcription factor(s) that control osteogenic gene expression during differentiation. These results suggest that mechanical strain enhances ECM induced cell fate determination and promotes osteogenic differentiation in hMSC through the ERK MAPK signal transduction pathway.

**A Novel Platelet-endothelial Secreted Protein SCUBE1 is Present in Human Atheromas and Supports Platelet Adhesion via its Amino-terminal Epidermal Growth Factor-like Repeats**

R. Yang, C. Tu, Y. Su, B. Wu, M. Tsai; Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan Republic of China

We have previously identified a full-length cDNA encoding a secreted, membrane-anchored protein from human endothelial cells, termed SCUBE1 for signal peptide, CUB and epidermal growth factor-like (EGF)-like domain containing protein 1. Here, we further investigated its protein expression and function in the vasculature system. Immunohistochemical and flow cytometrical analyses demonstrated that SCUBE1 is an endogenous, surface-tethered endothelial protein that could be secreted as a soluble form and cleaved by a serum-associated protease. We also found that SCUBE1 is expressed in human platelets both at the mRNA and protein levels. Confocal microscopy and immunogold labeling revealed that while present at the surface, this protein is predominantly found in membranes of α-granules and elements of the open-canalicular system in the platelet. Interestingly, the platelet SCUBE1 is translocated to the surface upon thrombin stimulation and its immunoreactivity is localized within the extracellular matrix of human advanced atherosclerotic lesions. Studies of platelet adhesion to the surface-bound SCUBE1 fragments showed that only fragments containing the amino-terminal EGF-like repeats were able to support adhesion. We also found that plasma hSCUBE1 levels are significantly elevated in patients with acute coronary syndromes. Together, SCUBE1 protein released from platelets and/or the endothelium may contribute to the pathogenesis of atherosclerosis through its deposition and subsequent recruitment of activated platelets at the lesion sites.

**Na,K-ATPase Mediated Cell-substratum Attachment Involves Fak and Src Signaling**

S. P. Barwe, S. A. Rajasekaran, A. K. Rajasekaran; Pathology and Laboratory Medicine, University of California, Los Angeles, Los Angeles, CA

Na,K-ATPase is a ubiquitous plasma membrane bound enzyme that is mainly composed of two non-covalently linked subunits, a 110 kDa α-subunit (Na,K-α) and a 55 kDa β-subunit (Na,K-β). Na,K-ATPase pump activity catalyzes an ATP-dependent transport of three sodium ions out

and two potassium ions into the cell per pump cycle, thereby generating a sodium gradient across the membrane. The Na,K-α is the catalytic subunit where as the Na,K-β plays a regulatory role and is required for the maturation of Na,K-α. Recently, we showed that Na,K-β is involved in the suppression of cell motility in carcinoma cells by a novel mechanism involving a cross talk between the two subunits of Na,K-ATPase and the members of the PI3-kinase signaling pathway. We found that Na,K-ATPase is localized to the lamellipodia, an actin rich microdomain generally found in cells with increased cell motility. In this study, we present evidence that decreased cell motility of Na,K-β expressing cells is due to increased attachment of these cells to the substratum. Furthermore, we found that activation of focal adhesion kinase by Src is involved in the increased attachment of Na,K-β expressing cells to the substratum. These results thus provide further understanding towards the mechanism of motility suppressor role of Na,K-β.

1122

**Light Chain 3 (LC3), a Microtubule Associated Protein Increases mRNAs Associated with Cell Adhesion**

L. Ying, M. Rabinovitch; Pediatrics, Stanford University, Stanford, CA

We reported increased migration of smooth muscle cells related to enhanced translation of Fibronectin (FN) mRNA, via an interaction between LC3 and an AU-rich element (ARE) in the 3' UTR of FN mRNA. To identify LC3 dependent functions in other cells, we investigated HT1080 fibrosarcoma cells that produce little FN and no detectable LC3 protein. Transfection of HT1080 cells with LC3 (WT-LC3) confirmed heightened FN mRNA translation by polysome analysis, and further transfection with a wild type (WT) and mutant rat FN mRNA, confirmed ARE dependence. We next compared WT-LC3 and vector-control cells with respect to invasion, and adhesion and determined whether these features were FN dependent. Using a matrigel assay, WT-LC3 cells were more invasive by 30% (n=8, P<0. 01) and adhesion to plastic was ~3-fold (n=3, P<0.002) higher than that of vector-control cells. Addition of FN to vector-control cells increased adhesion (p<0.001), to values approaching those in WT-LC3. However, addition of collagen IV or poly-D-lysine but not laminin similarly increased their adhesion. To determine whether enhanced FN mRNA translation was sufficient to explain the increased adhesion of WT-LC3 cells, we added CS-1 peptides and FN antibodies. This only resulted in a trend toward decreased adhesion, suggesting that factors additional to FN were to be considered. Microarray analysis of heavy polysomes in WT-LC3 vs. vector-control cells revealed significant increase in expression of genes associated with adhesion such as cdc42, a ras oncogene and small GTPase activating protein, and microarray analysis of total RNA revealed other genes confirmed by qRT-PCR to be higher in WT-LC3 cells but not induced by cell adhesion to FN, and these included thrombospondin-1, connective tissue growth factor and inhibin A. In conclusion, LC3 increases FN mRNA translation and modulates cell motility.

**Second-hand Cigarette Smoke in the Eye: Stimulation of Inflammation and Delay in Corneal Re-epithelialization**

C. Ma, M. Martins-Green; Cell Biology and Neuroscience, University of California Riverside, Riverside, CA

Corneal re-epithelialization is a key process in preventing abnormal cornea wound healing. For example, delays in corneal re-epithelialization can result in pathogen invasion and their contribution to damage of the underlying stroma. Therefore, identification of factors that promote corneal re-epithelialization, and their mechanisms of action, will provide insights into improving and accelerating epithelial healing. Over the past two decades, it has been shown that environmental cigarette smoke delays skin wound healing, but very little is known about its effects on healing of cornea wounds. To address this question, we used mice that have been smoking for a prolonged period of time in an established system that mimics second-hand smoking by humans. Mechanical injury of the epithelium was done by removal of the corneal epithelium using a trephine and a scalpel. The mice continued to smoke during the healing process. We found that second-hand cigarette smoke delays the re-epithelialization process; the epithelium at the front edge of the wound does not adhere to the basal matrix and the cells show stronger F-actin staining. Immunolabeling shows that there is an accumulation of neutrophils in the wounded area in the smoking mice, and that many of the ECM molecules critical for epithelial cell migration are not present. Immunoblot analysis confirmed these findings. In addition, both, by immunoblotting and zymography, we find that MMP-7 levels are much higher in the wounds of the mice exposed to smoke. Furthermore, inflammatory cytokines, such as IL-1, TNF-alpha, and GRO-alpha increase in the corneal stroma and epithelium. These results suggest that second-hand cigarette smoke inhibits epithelial cell migration and enhances the inflammatory response during cornea wound healing, and that, in combination, these effects result in delayed corneal re-epithelialization.

**Measuring pH in Very Close Proximity to the Outer Leaflet of the Plasma Membrane of Human Melanoma Cells**

C. Stock, A. Schwab; Institute of Physiology II, University of Münster, Münster, Germany

Migration of human melanoma (MV3) cells (i) is based on a coordinated formation and release of focal adhesion contacts mediated by integrin receptor molecules, (ii) requires the activity of the $Na^+/H^+$ exchanger NHE1 and (iii) depends on extracellular pH ($pH_e$). We favour the idea that, at focal adhesion sites, a local pH is created by protons extruded by the NHE1 together with protons provided by the extacellular solution. The local pH may then influence the strength of cell adhesion, i.e. of the integrin/extracellular matrix bond, and thereby modulate cell migration. In order to prove this hypothesis we developed an efficient method that enabled us to measure the pH in very close proximity to the plasma membrane ($pH_{em}$). MV3 cells were labeled with the phosphoethanolamine fluorescein DHPE. The labeled cells were continuously superfused with prewarmed HEPES-buffered Ringer solutions of various pH values. The fluorometrically determined $pH_{em}$ was slightly higher than the given $pH_e$ indicating that the glycocalix functions, at least conditionally, as a buffer. $pH_{em}$ decreased or increased as soon as $pH_e$ was lowered or elevated by changing the pH of the superfusion solution. Moreover, $pH_{em}$ of cells initially treated with the specific NHE1 inhibitor cariporide (HOE642) decreased by up to 0.1 units as soon as HOE642 was washed out. From these results we conclude that the fluorescein DHPE was incorporated only in the outer leaflet of the membrane. Thus, we were able to measure $pH_{em}$ locally at the focal adhesion sites located at the leading edges of lamellipodia.

## Extracellular Matrix & Cell Signaling II (1125-1149)

### Role of Cell to Cell Signaling in Virulence of *Pseudomonas Aeruginosa* in Murine Model of Experimental Pyelonephritis

R. Mittal, S. Chhibber, S. Sharma, K. Harjai; Department of Microbiology, Panjab University, Chandigarh, India

Quorum sensing signals have been proposed to play most important role in the pathogenesis of respiratory tract and burn wound infections caused by *Pseudomonas aeruginosa*. This pathogen has been reported to monitor its cell density as well as expression of virulence determinants by quorum sensing signal mechanisms operative through autoinducers. However no reports are available in literature where role of these signals have been studied in relation to *P. aeruginosa* induced pyelonephritis. The present investigation was planned to study role of quorum sensing molecules in experimental pyelonephritis employing standard parent strain (PAO1) possessing functional quorum sensing systems (both *las* and *rhl*) and its isogenic mutant strains, single mutant deficient in production of *las*I and double mutant deficient in production of both *las*R and *rhl*R. It was observed that quorum deficient mutant strains were significantly less virulent as compared to quorum sensing producer parent strain during the course of infection assessed in terms of renal bacterial load and alteration in renal pathology. The present study brings out that cell to cell signaling plays most significant role in development of pyelonephritis caused by *P. aeruginosa.*

### The Matrix Protein CCN1 Enhances FasL-Induced Apoptosis

V. Juric, C. C. Chen, L. F. Lau; Department of Biochemistry and Molecular Genetics, University of Illinois at Chicago College of Medicine, Chicago, IL

The extracellular matrix protein CCN1 (CYR61) regulates diverse cellular functions through direct binding to integrins receptors. CCN1 expression is induced in tissue response to injury and in pathological contexts where angiogenesis and inflammation play central roles. The recent discovery that CCN1 can either induce apoptosis or protect cells from death in a cell type-specific manner prompted us to investigate whether CCN1 can modulate the cytotoxicity of known apoptotic inducers. One such factor is FasL, a member of the TNF family of inflammatory cytokines, which triggers cell death through the extrinsic pathway upon binding to its cell surface receptor Fas. Whereas no killing was observed in primary human fibroblasts treated with recombinant CCN1 alone, CCN1 significantly augmented FasL-induced cell death. CCN1 and FasL together induce apoptosis, rather than necrosis, as judged by flow cytometry following Annexin V/PI labeling. Pre-incubation of cells with function-blocking integrin antibodies and soluble heparin identified integrin $\alpha_6\beta_1$ and cell surface heparan sulfate proteoglycas (HSPGs) as receptors for CCN1 in this process. Consistently, mutant CCN1 proteins deficient in binding $\alpha_6\beta_1$ and/or HSPG failed to enhance FasL-induced apoptosis. CCN1 does not change the caspase requirement of FasL-mediated apoptosis, but is able to sensitize cells to FasL treatment. Pre-incubation of cells with CCN1 leads to a significant reduction in the time required by FasL to trigger cell death. In summary, the extracellular matrix protein CCN1 positively regulates FasL-induced apoptosis in fibroblasts. This is the first demonstration that FasL-induced programmed cell death can be enhanced by a matrix protein via an integrin and HSPG-dependent mechanism.

### Cell Adhesion Regulates Serum Response Element Activity

C. Q. Cheng, D. M. Pirone, C. S. Chen; Department of Bioengineering, University of Pennsylvania, Philadelphia, PA

The Serum Response Element (SRE) is a key transcriptional regulator that links growth factor stimulation to many downstream functions including proliferation, differentiation, and migration. While the molecular pathways that link growth factor stimulation and SRE activity have been well described, in many contexts cell adhesion to extracellular matrix (ECM) acts as a critical cooperative component to growth factor signaling. Here we have examined the role of cell adhesion on SRE activity. To modulate cell adhesion, we seeded cells onto surfaces coated with different densities of the ECM protein fibronectin. Cells seeded on low density fibronectin attached but did not spread and flatten against substrates, and when exposed to serum these cells exhibited dramatically attenuated SRE activity compared to cells on the high density fibronectin substrates, as measured by luciferase reporter assays. Because altering fibronectin density modulates cell adhesion at several levels, affecting not only integrin ligation and clustering, but also cell spreading and flatterning against the substrate, we used micropatterned substrates to precisely and quantitatively modulate cell spreading without altering fibronectin density. On the micropatterned substrates, unspread cells were unable to transduce serum or growth factor signals into SRE activity. We have begun to characterize the molecular signaling pathways by which cell adhesion and spreading mediate SRE activity. Early results suggest that both ERK and RhoA signaling pathways are involved. These data highlight the importance of the adhesive microenvironment in transcriptional signaling and may yield insights into understanding the mechanisms by which adhesion and growth factor signaling pathways cooperate to regulate gene expression.

1128

### CD47-mediated Inhibition of Phagocytosis: Effects on Circulation Time of Polystyrene Microspheres in Mice

R. Tsai, D. Discher; University of Pennsylvania, Philadelphia, PA

CD47 reportedly inhibits the phagocytic clearance of red blood cells and platelets as shown in mouse. This inhibition is mediated by interaction between CD47 and its natural ligand, SIRPa present on macrophages. By removing CD47 from red blood cells it resulted in an increased clearance. However by using the knockout strategy employed may have caused other perturbations introduced to theses cells that may complicate the generalization of CD47 role. We propose animal experiments employing strategies to determine if the addition of CD47 to synthetic particles will inhibit their phagocytic clearance. Oriented immobilization of recombinant Ig-domain of mouse CD47 to polystyrene microspheres was performed using biotin-avidin chemistry. These modified microspheres were shown to bind to the extracellular domain of mouse SIRPa. Experiments are currently being conducted to clearly understand the effect of CD47 on the clearance of these microspheres in mice. The density will be varied in order to determine if there is a balance between adhesion and signaling. From these results we can demonstrate the role of CD47 in phagocytosis inhibition; paving the way for use in drug delivery for extending circulation times.

1129

**The Role of LIMD1 in Osteoclast Development and Function**

H. Epple,[1] Y. Feng,[1] R. Faccio,[2] G. D. Longmore[1]; [1]Medicine and Cell Biology, Washington University in St. Louis, St. Louis, MO, [2]Pathology and Immunology, Washington University in St. Louis, St. Louis, MO

Bone remodeling and homeostasis is a complex process requiring the balanced actions of bone forming osteoblasts and bone resorbing osteoclasts. Abrogation of either action leads to disorganization of the bone environment and osteoporotic or osteopetrotic phenotypes. The process of osteoclast differentiation is regulated by receptor activator of nuclear factor kappa B (RANK) signaling and requires formation of multinucleated cells with distinct apical basal polarity. The ruffled membrane at the basal surface of the osteoclast and an organized actin ring are required for efficient bone resorption. TRAF6 is an important signaling molecule downstream of RANK, promoting both the differentiation and resorptive functions of osteoclasts. The LIM protein, LIMD1, is present at chromosome 3p21, a locus that has been linked to bone density in humans. Here we show that LIMD1 interacts with TRAF6 to regulate RANKL stimulated osteoclast development. Like TRAF6, LIMD1 expression is upregulated during osteoclast differentiation. Genetic inactivation of LIMD1 in mice results in impaired osteoclastogenesis *in vivo* in the presence of excess RANKL, without affecting basal bone homeostasis. In developing osteoclasts, LIMD1 is an activator of AP-1 and thus, NFAT2 expression is inhibited in LIMD1 null cells. LIMD1 and other LIM proteins are important components of adhesion complexes and contribute to cell adhesion and migration. We observe that LIMD1 also localizes to sites of adhesion in mature osteoclasts including podosomes and the actin ring. Interestingly, LIMD1 null pre-osteoclasts have impaired adhesion to vitronectin and decreased migration in response to M-CSF in vitro. Src is a major regulator of osteoclast adhesion, migration, and bone resorption. LIMD1 null cells exhibit decreased Src activation in response to integrin engagement. In conclusion, these results suggest that LIMD1, in conjunction with TRAF6 regulates osteoclast development and may regulate osteoclast function by modulation of Src activity.

1130

**Signal to Polarize the *Drosophila* oocyte Involves Down-regulation of Dystroglycan**

J. Poulton, W. Deng; Biological Science, Florida State University, Tallahassee, FL

In the *Drosophila* oocyte, establishment of the anterior-posterior (AP) axis requires activation of the EGFR pathway in the posterior follicle cells (PFC) of the developing egg chamber. Therefore, the PFC are believed to provide a signal to the oocyte necessary for proper AP axis formation. The nature of this signal and the targets of EGFR activation in the PFC remain elusive. Here we demonstrate that one critical facet of this signaling event is down-regulation of Dystroglycan (DG), an extracellular matrix receptor, in the PFC. In support of this, we show that disruption of the EGFR pathway in the PFC results in failure to down-regulate DG in those cells, and more importantly, DG knockdown via RNAi can rescue an oocyte polarity defect caused by disruption of EGFR signaling in the PFC. In addition, we demonstrate that overexpression of DG in the PFC is capable of disrupting oocyte polarity. These findings indicate that the polarizing cue from the PFC to the oocyte utilizes an atypical signaling mechanism involving the down-regulation of DG.

1131

**A Role for Diastrophic Dysplasia Sulfate Transporter (DTDST) and Sulfation in Fibronectin Matrix Assembly**

L. L. Galante, K. Huang, J. E. Schwarzbauer; Molecular Biology, Princeton University, Princeton, NJ

Fibroblasts and many adherent cells produce and assemble the adhesive glycoprotein fibronectin (FN) into an extensively branched extracellular matrix. In cancer, the ability to deposit fibronectin into a matrix is often reduced or lost. Decreased FN assembly by the human fibrosarcoma cell line HT1080 is recovered by treatments that activate the integrins, inhibit MEK signalling, or stimulate transcription as with addition of the glucocorticoid dexamethasone. A microarray analysis was performed to determine genes whose expression changed in HT1080 cells upon induction of FN assembly by either MEK inhibition or dexamethasone stimulation. One of the genes, significantly upregulated by both treatments, was diastrophic dysplasia sulfate transporter (DTDST). DTDST is a transmembrane sulfate transporter, whose mutation in human patients results in reduced sulfate uptake by fibroblasts and histologically in an under-sulfation of cartilage proteoglycans. Proteoglycans are extensively sulfated on their glucosaminoglycan (GAG) side chains and these chains interact with several sites on FN. Chlorate and xyloside treatments, that inhibited sulfation or GAG chain synthesis, respectively, GAG degrading enzymes, and competition experiments using soluble heparin or chondroitin sulfate chains caused a reduction in FN matrix assembly. By contrast, excess soluble N- or O-desulfated heparin failed to inhibit matrix assembly as monitored by immunofluorescence microscopy and FN matrix insolubility in deoxycholate detergent. Thus, sulfated GAG chains are necessary for formation of a detergent-insoluble FN matrix. Blockade of DTDST expression with siRNAs also significantly reduced FN matrix, linking this sulfate transporter to the FN assembly process. Ongoing work is aimed at identifying a specific sulfated proteoglycan that is required for FN matrix formation.

1132

**Chondroitin Sulfate Proteoglycans are Involved in Modulating the Indian Hedgehog Signaling Pathway in the Mouse Growth Plate**

M. Cortes,[1] N. B. Schwartz[2]; [1]Biochemistry and Molecular Biology, U. of Chicago, Chicago, IL, [2]Department of Pediatrics, U. of Chicago, Chicago, IL

The functional role of heparan sulfate proteoglycans (HSPGs) in regulating signaling pathways such Hedgehog (Hh), Wingless-type (Wnt) and fibroblast growth factor (FGF) has been previously described. In contrast, the role of chondroitin sulfate proteoglycans (CSPGs) in these signaling pathways remains elusive. PAPS synthetase 2 (PAPSS2) is one of the two isoforms responsible for the synthesis of PAPS, the universal sulfate donor in all cells. The brachymorphic (bm) mouse is a PAPSS2 kinase domain mutant characterized by preferential undersulfation of CS chains and 50% reduction in limb length. *In situ* hybridization of the bm mouse growth plate with various markers, performed to determine whether signaling pathways regulating chondrocyte proliferation and differentiation are affected by undersulfation, revealed reduced mRNA levels of Indian hedgehog (Ihh), Patched. Immunostaining with hedgehog antibody (5E1) and Parathyroid hormone related peptide (PTHrP) antibody showed diminished extracellular diffusion of both signaling molecules in the bm mouse compared to wildtype. Consistent with reduction in Ihh and PTHrP protein, there was less cell proliferation in the bm mouse growth plate by PCNA antibody staining. In order to determine if CSPGs interact directly with Ihh, preliminary binding experiments with recombinant N-terminal Ihh and various forms of CS and HS chains revealed that both

HSPGs and CSPGs bind Ihh, with different affinities. In sum, undersulfated CSPGs may contribute to limb reduction in the bm mouse by affecting chondrocyte proliferation via the Ihh signaling pathway. .

1133

**CD44-hyaluronan Interactions Decrease FAK Activation**

J. I. Lopez, J. A. Schroeder; Molecular and Cell biology, The University of Arizona Cancer Center, Tucson, AZ

CD44 is a membrane bound adhesion molecule present on a variety of cell types, including mammary epithelial tumor cells. The role of CD44 in tumor progression and disease prognosis is a controversial one. While some believe CD44 to promote tumor progression, others believe that CD44 is not involved in tumor progression and may even be protective against invasion. We have recently demonstrated through the use of mouse models of breast cancer and CD44 null mice that CD44 expression confers protection from pulmonary metastatic disease while not affecting the growth of primary breast tumors. In the current study we examine mechanisms by which CD44 may impede cellular movement through extracellular matrices. The metastatic human breast cancer cell line MDA-MB-231 was allowed to invade into collagen gels cast in the presence or absence of 0.075µg/ml hyaluronan. CD44 was immunoprecipitated from invaded cells and western blots were probed for the presence and activation of coimmunoprecipitated signaling molecules. Preliminary results show that CD44 has decreased associations with activated FAK in the presence of hyaluronan, which may be indicative of decreased focal contacts in invading cells or increased apoptosis. In future experiments we will use Caspase-3 assays to measure cell death and imaging to examine cell morphology during invasion as well as the activation of other CD44 associated signaling molecules such as Src or ErbB2. Furthermore, constructs expressing the FAK inhibitor FRNK will be used to assess the functional significance of FAK activation in the context of CD44 signaling.

1134

**Ras Regulates Focal Adhesion Formation in 3D Matrices in a Manner Opposite of its Effects for on 2D Matrices**

M. A. Wozniak, P. J. Keely; Pharmacology, University of Wisconsin, Madison, WI

It is well established that activation of the small GTPases H-, N-, or K-Ras decreases focal adhesion formation. The Ras-induced inhibition of focal adhesion formation is commonly hypothesized to be advantageous in cancer, allowing cells to weaken their interaction with the extracellular matrix to promote migration and metastasis (Hughes et al., 1997). We also observe a decrease in focal adhesion formation in breast epithelial cells expressing activated K-Ras (12V). These cells show enhanced migration compared to control cells when plated on collagen-coated petri plates. In contrast, cells expressing activated R-Ras (38V), another small GTPase of the Ras superfamily, display enhanced focal adhesion formation and decreased cell migration. However, these experiments performed on 2D surfaces differ greatly from the *in vivo* 3D environment that cells normally encounter. When T47D cells are cultured in floating 3D collagen gels, they down-regulate focal adhesion formation and differentiate into duct-like tubules (Wozniak et al, 2003). We used this system to analyze how expression of oncogenes affects focal adhesion formation in a more relevant 3D environment. We find that expression of either activated K-Ras (12V) or R-Ras (38V) blocks tubulogenesis. Consistent with results in 2D culture, expression of activated R-Ras (38V) enhanced focal adhesions in cells cultured in 3D collagen gels. However, expression of activated K-Ras (12V) surprisingly also increased focal adhesion formation in cells cultured in 3D gels. These data demonstrate the significant differences between 2D and 3D culture. Furthermore, these results imply that in a more relevant 3D environment, K-Ras activation likely regulates signal transduction pathways differently, which has important implications for understanding the mechanisms by which oncogenes enhance invasion through complex matrices *in vivo*.

1135

**DDR1 Inhibits Collagen-induced Cell Spreading via Suppression of Cdc42 Activation**

Y. Yeh, M. Tang; Physiology, National Cheng Kung University, Tainan, Taiwan Republic of China

Discoidin domain receptor (DDR) is a receptor tyrosine kinase for collagen. We previously showed that over-expression of DDR1 in MDCK cells prevented cell spreading, whereas dominant negative DDR1 induced cell spreading trigger by collagen. However, the mechanism whereby DDR1 inhibits cell spreading has been unidentified. Cell spreading involves organization of actin cytoskeleton, which is mainly regulated by Rho family-GTPases. In order to examine whether Rho family-GTPases are involved in collagen gel-regulated cell spreading, we employed pull-down assay and transient transfection of constitutive active or dominant negative GTPases in MDCK cells and observed whether they could alter collagen-induced cell morphological changes. The results showed DDR1 decreased the activation of Rac1 and Cdc42, but had no effects on RhoA activity. Neither constitutive active nor dominant negative Rac1 could alter DDR1-inhibited cell spreading. However, constitutive active Cdc42 rescued the DDR1-inhibited cell spreading and dominant negative Cdc42 inhibited cell spreading in cells overexpressing dominant negative DDR1. These results indicate that DDR1-inhibited cell spreading is mediated by inactivation of Cdc42. With the use of 5E8, a potent $\alpha_2\beta_1$ integrin blocking antibody, we found that collagen-induced activation of Cdc42 is mediated by $\alpha_2\beta_1$ integrin. FRNK completely blocked collagen-induced decrease in Cdc42 activity, but DDR1 did not influence the phosphorylation levels of FAK. Taken together, DDR1 inhibits collagen-induced cell spreading by suppression of Cdc42 activation, which is mediated by $\alpha_2\beta_1$ integrin through FAK.

1136

**p120 is Required for Rac1-Induced Anchorage-Independent Cell Growth**

M. R. Dohn, A. B. Reynolds; Cancer Biology, Vanderbilt University, Nashville, TN

p120 expression is frequently reduced in human tumors, but the consequences *in vivo* are not yet well understood. To investigate the role of p120 loss in MDCK cells, we used siRNA techniques to knock down p120 and examined cell growth in soft agar, an assay generally used to predict tumorigenicity *in vivo*. Surprisingly, we found that p120 is required for Rac1-induced, but not H-Ras-induced, growth of MDCK cells in soft agar. p120 has previously been reported to inhibit RhoA in NIH3T3 cells. Similarly, we found that knock down of p120 in MDCK cells results in elevated RhoA activity. Inhibition of a downstream RhoA effector, ROCK, with the specific inhibitor Y-27632, rescues the ability of Rac1 to induce soft agar growth in the absence of p120. These data suggest that in MDCK cells, p120 plays an essential role in Rac1-mediated anchorage-independent growth by negatively regulating RhoA activity.

1137

**Role of RhoA/ROCK-Dependent Actin Contractility in the Induction of Tenascin-C by Cyclic Strain**

A. Sarasa-Renedo, V. Tunç-Civelek, M. Chiquet; ITI Research Institute, University of Bern, Bern, Switzerland

Objective: Here we explored the function of the actin cytoskeleton and of its RhoA/ROCK-controlled contractility in the induction of the extracellular matrix protein, tenascin-C, by cyclic tensile stress. Methods: Chick embryo fibroblasts were cultured on fibronectin coated silicone membranes and subjected to equibiaxial cyclic strain (10%, 0.3Hz). We have shown previously that this results in a 2-fold increase in tenascin-C mRNA within 6 hours; this response is attenuated by the ROCK inhibitor Y27632. Results: We now found that chemical activation of RhoA/ROCK by thrombin or LPA is sufficient to double the amount of tenascin-C mRNA in fibroblasts within 6 hours. When cells were pretreated with these drugs for 30 min, cyclic strain (6h) caused a super-induction (3.5-fold) of the tenascin-C mRNA level; the additional increase was again suppressed by Y27632. Microtubule disruption, which is known to trigger ROCK-dependent actin contraction, also induced tenascin-C mRNA. Conversely, disorganization of the actin cytoskeleton with latrunculin-A completely abolished induction of tenascin-C mRNA by either chemical RhoA/ROCK activators, mechanical stress, or both. Cyclic strain itself increased the amount of active RhoA in fibroblasts after 5 min as measured by a pulldown assay, and within 30 min triggered ROCK-dependent contraction of a collagen gel layer by the cells. Moreover, myosin II activity was shown to be required for tenascin-C induction by mechanical stress. Conclusions: From our results we conclude that RhoA/ROCK-mediated contractility of the actin cytoskeleton has a mechanosensory function in fibroblasts that relates directly to the expression level of the tenascin-C gene. Furthermore, we suggest that prior activation of actin contraction, by either chemical or mechanical signals, renders fibroblasts more sensitive to further external mechanical stress. This principle might be important in connective tissue regeneration and wound healing.

1138

**Substrate Stiffness Modulates Vascular Smooth Muscle Cell Response to PDGF: Involvement of Lipid Rafts**

X. Brown, R. Arjoon, J. Wong; Biomedical Engineering, Boston University, Boston, MA

More than 12 million Americans suffer from arterial occlusive disease. *In vivo* and *in vitro* studies have identified platelet-derived growth factor (PDGF) as the major stimulus for the abnormal vascular smooth muscle cell (VSMC) migration and proliferation during the development of the disease. However, therapies simply blocking the function of PDGF have limited success in clinical trials because the pathology of the disease is complex and highly dynamic. An engineered model system that recapitulates the biomechanical properties of the vessel was used to test the hypothesis that increased vessel stiffness during the development of the disease leads to an increase in the sensitivity of VSMCs to PDGF. The polyacrylamide based model system allows the stiffness to be systematically changed from 20 kPa to 80 kPa. while maintaining a constant ligand density of 5800 molecules of GRGDSP/ $\mu m^2$. With increased substrate stiffness, VSMCs have higher levels of FAK phosphorylation, increased cell-spread area, more defined stress fibers and increased rate of proliferation. VSMCs on stiffer substrate also have increased sensitivity to PDGF-BB stimulations. PDGF receptor is phosphorylated to higher levels in VSMCs on stiff substrate when exposed to the same concentrations of PDGF. This increased sensitivity is not due to increased protein level of PDGF receptor, but rather increased localization of PDGFR to the lipid rafts in the cell membrane.

1139

**Nanonewton Forces Applied to Individual Adhesions Causes Global, Dynamic Changes in Cellular Traction Forces**

M. T. Yang, N. J. Sniadecki, C. S. Chen; Department of Bioengineering, University of Pennsylvania, Philadelphia, PA

Mechanical forces exerted through the extracellular matrix are transmitted to cells, and transduced into biochemical responses through focal adhesions. A potentially important feedback loop may exist in which the mechanically-induced signaling could in turn regulate actomyosin-mediated traction forces, amplifying the mechanotransduction process. To measure the contractile forces of cells, our lab has developed a microfabricated array of elastomeric microposts which can report traction forces generated by cells spread across the posts. Here, we used a micromanipulator to direct a glass needle to deflect individual posts and therefore apply forces ranging from 15 to 32 nN to single NIH 3T3 fibroblasts, and subsequently measured their mechanical response. Early experiments indicate the presence of a baseline contractile tone in unperturbed cells, and that a step application of stretching force on peripheral adhesions causes a rapid, synchronized global loss of traction force. Within minutes the contractile tone in cells fell to nearly half of baseline levels. Under certain conditions, we observed a synchronized, global increase in contractility following this relaxation. We are currently identifying the molecular basis for these events. Understanding the role, if any, of these active mechanical changes in the biochemical response of cells to applied forces may provide insight into the mechanotransduction process.

**Matrix Elasticity Directs Adult Mesenchymal Stem Cell Differentiation**

A. J. Engler,[1] M. F. Berry,[2] S. Sen,[1] H. Sweeney,[2] D. E. Discher[1]; [1]Biophysical Engineering Lab, University of Pennsylvania, Philadelphia, PA, [2]Physiology, University of Pennsylvania, Philadelphia, PA

Many different cell types respond to matrix stiffness as sensitively as more well studied soluble or immobilized ligands, yet mechanisms by which mechanical cues are transduced to cells have been far less explored. Here we demonstrate that expression of lineage markers in pluripotent mesenchymal stem cells (MSCs) requires not only growth factor stimulus but also proper matrix elasticity, $E$, in a myosin-dependent mechanism. Indeed, MSC morphology after one week, in the absence of growth factors, is highly mechano-sensitive; neuronal-like branched networks occur on soft matrices near $E_{\text{Nerve}}$ (<1 kPa), myoblast-like elongated morphology is observed at $E_{\text{Skeletal Muscle}}$ (8-17 kPa), and osteoblast-like polygonal morphology is observed on stiff matrices near $E_{\text{Osteoblast}}$ (>20 kPa). Oligonucleotide arrays of 120 neuronal, myogenic, and osteogenic genes show early marker expression for each MSC lineage on their specific matrices only, but western blots confirm that only partial expression of early markers relative to myoblast or osteoblast control cells; incomplete expression can be augmented by the addition of hydrocortisone or L-acetate-2-phosphate for myogenic or osteogenic commitment, respectively, thus inducing *full* lineage commitment; chemical or physical stimulus alone cannot. Mechano-senstive signaling for such differentiation pathways proves tension-based, involving non-muscle myosin II contractility: myosin II inhibition blocks lineage marker expression. However, similar myosin levels in myogenic differentiation factor 1- and core binding factor α1-expressing MSCs imply different Rho-induced tension-generating pathways, identified here as Rho GTPase signaling proteins mDia and ROCK,

respectively. Overall, this data implies that, in addition to chemical stimulus, tissue and/or matrix stiffness is critical for development.

**Mechanical Stimulation of C2C12 Cells Increases m-calpain Expression and Activity, Focal Adhesion Plaque Degradation and Cell Fusion**

A. Grossi, A. H. Karlsson, M. A. Lawson; Department of Dairy and Food Science, Royal Veterinary and Agricultural University, Frederiksberg C, Denmark

Myogenesis is a complex sequence of events, including the irreversible transition from the proliferation-competent myoblast stage into fused, multinucleated myotubes. During embryonic development, myogenic differentiation is regulated by positive and negative signals from surrounding tissues. Stimulation due to stretch- or load-induced signaling is now beginning to be understood as a factor which affects gene sequences, protein synthesis and an increase in $Ca^{2+}$ infux in myocytes. Evidence of the involvement of $Ca^{2+}$ dependent activity in myoblast fusion, cell membrane and cytoskeleton component reorganization due to the activity of ubiquitous proteolytic enzymes known as calpains has been reported. Whether there is a link between stretch- or load induced signaling and calpain expression and activation is not known. Using a magnetic bead stimulation assay and C2C12 mouse myoblasts cell population, we have demonstrated that mechanical stimulation via laminin receptors leads to an increase in m-calpain expression, but no increase in the expression of other calpain isoforms. Our study revealed that after a short period of stimulation, m-calpain relocates into focal adhesion complexes and is followed by a breakdown of specific focal adhesion proteins previously identified as substrates for this enzyme. We show that stimulation also leads to an increase in calpain activity in these cells. These data support the pivotal role for m-calpain in the control of muscle precursor cell differentiation and thus strengthen the idea of its implication during the initial events of muscle development.

**Human Type IV Collagen Induces STAT5 Activation in MCF7 Breast Cancer Cells**

L. A. Arriaga-Pizano, T. Robledo, M. Lopez-Perez, E. Perez Salazar; Biologia Celular, Cinvestav-IPN, Mexico DF, Mexico

Background/Aims. Extracellular matrix (ECM), including basement membrane (BM), is a complex network of interacting molecules such as collagens, fibronectin, and laminin. Signals from BM regulate morphology, growth, differentiation and apoptosis in mammary epithelial cells. The signal transducers and activators of transcription (STATs) can be activated by a number of cytokines, growth factors and ECM components. STAT proteins are normally involved in a variety of cellular processes. In particular, STAT5 plays a key role in mammary epithelial cell growth and differentiation. However, the participation of BM components in the activation of STAT5 in breast cancer cells, remain to be studied. Our aim was to study whether the BM component, type IV collagen (Col-IV), is able to induce STAT5 activation and the role of Src kinase family members activity. Methods/Results. By Western blotting with an anti-STAT5 antibody (Ab) and a phosphospecific Ab against the Tyr-694 of STAT5, electrophoretic mobility shift assay (EMSA) and the use of a Src kinase inhibitor (PP-2). We demonstrated that Col-IV induces phosphorylation of endogenous STAT5 at Tyr-694, nuclear translocation of STAT5 and an increase in STAT5-DNA complex formation in MCF7 cells. Treatment with the selective Src kinase inhibitor PP-2 inhibited all these effects induced by Col-IV. Conclusion Our findings delineate a signal transduction pathway from the cell surface to the nucleus in which Col-IV stimulation results in signaling through Src kinase to STAT5, which in turns translocates to the nucleus and binds to DNA. It remains to be determined the role of STAT5 activation in biological processes. This work has been accepted to publication in Matrix Biology. 2005

**Collagen-induced Epithelial-to-Mesenchyme Transition in Pancreatic Cancer Cells**

Y. Shintani, K. R. Johnson, M. J. Wheelock; Oral Biology, University of Nebraska Medical Center, Omaha, NE

When epithelial cells change their relative position, they convert to motile fibroblastic cells, which is referred to as an epithelial-to-mesenchyme transition (EMT). We have shown that N-cadherin often becomes up-regulated in invasive tumor cell lines, which is critical to tumor invasion and metastasis. In addition, integrins play a central role in cell migration through their roles as adhesive receptors for ECM components. For migration in cancer cells, intercommunication between integrin-mediated cell motility and cadherin-based cell-cell adhesion is important. Our overall hypothesis is that integrin-mediated cell motility is coordinated with N-cadherin up-regulation through EMT-related signaling. BxPC-3 pancreatic cancer cells became flatter and more scattered, and showed increased N-cadherin, fibronectin and vimentin when cultured on collagen. Integrin ß1 inhibitory antibody (P4C10) prevented both the morphological changes and N-cadherin up-regulation. To elucidate signaling pathways active in collagen-induced EMT, we used signaling inhibitors such as SU6656 (SFK inhibitor), LY294002 (PI3K inhibitor), SP600125 (JNK inhibitor), SB203580 (p38MAPK inhibitor), and Y27632 (Rho kinase inhibitor). Only SP600125 inhibited collagen-induced cell scattering and N-cadherin up-regulation when BxPC-3 cells were cultured on collagen. These data suggest that integrin-JNK signaling is correlated with EMT and N-cadherin up-regulation induced by collagen. To establish a role for N-cadherin in collagen induced EMT, we generated N-cadherin over-expressing and knockdown BxPC-3 cells. Cell scattering was inhibited by N-cadherin knockdown. Furthermore, the transfectants that over-expressed N-cadherin were significantly more motile than mock-transfected cells in assays using transwell filters coated with collagen, while N-cadherin knockdown BxPC-3 cells showed a reduction in motility. Thus, we showed that N-cadherin up-regulation correlates with increased motility in collagen-induced EMT.

1144

**Focal Adhesion Kinase Signaling Pathways Regulate the Osteogenic Differentiation of Human Mesenchymal Stem Cells**

R. M. Salasznyk,[1] R. F. Klees,[1] A. Boskey,[2] G. E. Plopper[1]; [1]Biology, Rensselaer Polytechnic Institute, Troy, NY, [2]Mineralized Tissues Laboratory, Hospital for Special Surgery, New York, NY

The intracellular signaling events controlling human mesenchymal stem cell differentiation into osteoblasts are not entirely understood. We recently demonstrated that contact with extracellular matrix (ECM) proteins is sufficient to induce osteogenic differentiation of human mesenchymal stem cells (hMSC) through an extracellular signal-related kinase (ERK)-dependent pathway. We hypothesized that focal adhesion kinase (FAK) signaling pathways provide a link between activation of ERK 1/2 by ECM, and stimulate subsequent phosphorylation of the Runx2/Cbfa-1 transcription factor that controls osteogenic gene expression. To test this hypothesis, we plated hMSC on purified collagen I (COLL-

I) and vitronectin (VN) in the presence or absence of FAK-specific small inhibitory RNAs (siRNA), and assayed for phosphorylation of Runx2/Cbfa-1 as well as expression of established osteogenic differentiation markers (bone sialoprotein 2, osteocalcin, alkaline phosphatase, calcium deposition, and mineral:matrix ratio). We found that siRNA treatment reduced total endogenous FAK protein by ~40%, and reduced FAK phosphorylation on Y397 by 2.7-fold and 2-fold in cells plated for 30 minutes on COLL-I and VN, respectively. hMSC transfected with siRNA also exhibited a 3.3-fold and 3.8-fold decrease in ERK 1 phosphorylation on COLL-I and VN, respectively, after 1 hr. Serine phosphorylation of Runx2/Cbfa-1 was significantly reduced in treated cells. Finally, FAK inhibition blocked osteogenic differentiation of hMSC, as assessed by lowered expression of osteogenic genes (RT-PCR), decreased alkaline phosphatase activity, greatly reduced calcium deposition, and a lower mineral:matrix ratio after 28 days in culture. These results suggest that FAK signaling plays an important role in regulating ECM-induced osteogenic differentiation of hMSC.

1145

**Hyaluronan-CD44 Interaction with the Cytoskeleton and Signaling Molecules in Lipid Rafts Promotes $Ca^{2+}$ Mobilization, Oncogenesis and Tumor Progression**

L. Y. Bourguignon, A. Brightman, P. A. Singleton; Department of Medicine and VA Medical Center, University of California at San Francisco, San Francisco, CA

CD44 expression is closely associated with the progression of solid tumor cancers. The external portion of CD44 binds to an extracellular matrix (ECM) component [e.g., hyaluronan (HA)] while the intracellular domain interacts with cytoskeletal proteins and various signaling molecules. Our recent studies indicate that ankyrin, a cytoskeletal protein, and certain signaling molecules [e.g., Rho-Kinase (ROK) and PI3-kinase] are significantly enriched in CD44-containing lipid rafts [characterized as caveolin-rich plasma membrane microdomains] isolated from MDA-MB-231 cells (breast tumor cells), SK-OV-3.ipl cells (ovarian tumor cells) and SCC4 cells (HNSCC cells). This CD44 association with ankyrin and signaling molecules in lipid rafts is functionally coupled with HA-induced calciosome-cytoskeleton interaction, $Ca^{2+}$ mobilization, and tumor cell-specific behaviors (e.g., cell survival, growth and migration). Disruption of lipid rafts by the depletion of cholesterol from the raft membrane (using methyl-β-cyclodextrin treatment) not only abolishes the recruitment of ankyrin and various signaling molecules [e.g., Rho-Kinase (ROK) and PI3-kinase] into CD44-containing lipid rafts, but also impairs HA-mediated calciosome translocation, $Ca^{2+}$ signaling and tumor cell behaviors. These findings suggest that HA-CD44 interaction in lipid raft plays an important role in promoting ankyrin-based calciosome translocation/$Ca^{2+}$ signaling and activating intracellular signaling pathways (e.g., ROK-adducin signaling and PI3 kinase-AKT activation) leading to the onset of tumor cell-specific behaviors. These findings provide new insights into HA/CD44 interaction with the cytoskeleton and signaling molecules, which appears to regulate the malignancy of various human cancers including breast, ovarian and head/neck cancers.

**Protein Tyrosine Phosphatases, Adhesion, and MEC Morphogenesis and Malignancy**

K. R. Johnson,[1] J. N. Lakins,[2] V. M. Weaver[2]; [1]Bioengineering, University of Pennsylvania, Philadelphia, PA, [2]Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA

Tumors, which are characterized by enhanced cell growth and adhesion-dependent invasion, exhibit a profound tissue desmoplasia that has been strongly implicated in malignant transformation. However, the molecular link between tissue desmoplasia and aberrant tumor growth and invasion remains poorly defined. Cell growth and invasion are regulated by crosstalk between integrins and growth factor receptors through protein tyrosine kinase signaling that is tempered by protein tyrosine phosphatase (PTP) activity. Although much is known about adhesion-dependent kinases, little information exists regarding links between PTPs and adhesion. Here, we explored the role of PTPs in adhesion-dependent invasion and growth using degenerate RT-PCR to amplify PTPs differentially regulated in mammary epithelial cells (MECs) in 2D versus reconstituted basement membrane (rBM)-differentiated mammary acini. We identified and validated the differential expression of several adhesion/morphogenesis-regulated PTPs and further characterized a subgroup of the Band 4.1 PTP family members as key regulators of normal and malignant MEC behavior. Using nonmalignant human MECs (HMT-3522 S-1 and MCF10A), we showed that during early mammary morphogenesis, when acini are rapidly forming, PTP-MEG1 and D1 mRNA expression is high, coincident with accelerated growth, actin reorganization, assembly of E-cadherin/β-catenin adherens junctions, and decreased matrix adhesion. Following morphogenesis, when adhesion remodeling and growth have ceased, MEG1 mRNA and protein expression is significantly repressed. Interestingly, malignant MECs (HMT-3522 T4-2) that fail to assemble adherens junctions and exhibit dynamic actin remodeling also show elevated and sustained levels of PTP MEG1 and D1. Consistently, ectopic expression of wild-type MEG1 dramatically enhanced matrix adhesion and accelerated growth of nonmalignant MECs within rBM. Because we found that MEG1 localizes to membrane-associated punctae, we are currently investigating a possible link between Band 4.1 PTPs, dynamic remodeling of adhesion/cytoskeletal complexes, and matrix-dependent MEC growth and morphogenesis. **Inhibition of Laminin-5 Alpha 3 G4-5 Domain Selectively Disrupts Epidermal Tumorigenesis But Not Epithelial-mesenchymal Cohesion**

M. M. Tran,[1] P. Rousselle,[2] P. Nokelainen,[1] N. Nguyen,[1] E. F. Fincher,[1] M. P. Marinkovich[1]; [1]Epithelial Biology, Stanford University, Stanford, CA, [2]Chimie des Proteines, Institut de Biologie, Lyon, France

Laminin 5 is essential for epithelial-mesenchymal cohesion in many normal tissues, but also plays a critical role in epidermal tumorgenesis. Laminin 5 is secreted as a trimer (α3-β3-γ2) with subsequent processing of the α3 chain at residue 1337, removing the G4-5 domain. As a result, the G4-5 domain is largely absent in the basement membranes of fully developed normal tissues. However the G4-5 domain continues to be expressed in epidermal carcinomas. Our study sought to further characterize the role of the G4-5 domain in epidermal carcinomas. Retroviral transfer of full length (WTα3) or truncated (Tr1337) laminin α3 cDNA to laminin α3 null epidermolysis bullosa keratinocytes restored expression, trimeric assembly and deposition of laminin-5 in a polarized fashion. WTα3 cells transformed with Ras/IKB cDNA showed normal PI3-kinase activity, aggressive in vitro Matrigel invasion and significant in vivo tumor formation after SQ injection to nude mice. Ras/IKB transformed Tr1337 cells showed deficient PI3-kinase activity, and a lack of ability to invade Matrigel or form tumors in nude mice. G4-5 cDNA restored PI3-kinase activity and Matrigel invasion in transformed Tr1337 cells. G4-5 polyclonal antibody was shown to ablate tumor formation in mice injected

with normal Ras/IKB keratinocytes. Extensive necropsy analysis of multiple organs and electron microscopy demonstrated no epithelial adhesive defects and no basement membrane abnormalities associated with G4-5 pAb treatment. These results suggest that G4-5 domain of laminin α3 chain is essential for epidermal carcinogenesis and antibodies against the G4-5 domain represent an attractive potential cancer therapy.

**The Activation of PKB/AKT Survival Pathway by Osteopontin in Prostate Cancer Cells**

B. Robertson, M. A. Chellaiah; Department of BMS, University of Maryland, Baltimore, MD

Osteopontin (OPN) is recognized as a key mediator of tumorigenesis and progression of cancer in experimental cell culture models as well as in clinical studies. Osteopontin interacts with $\alpha_v\beta_3$ integrins through its RGD domain. As an autocrine factor, OPN has been shown to increase cell motility and adhesion, affecting a wide range of down stream signaling molecules in osteoclasts. OPN/αvβ3-mediated signaling exhibited similar effects on actin cytoskelatal reorganization and migration in prostate cancer cells (PC3). Since, PC3 cells lack tumor suppressor, PTEN and OPN has been shown to be the cancer progression and survival factor in cancer cells, we analyzed the effects of OPN on the phosphorylation state of cell survival factor AKT. PC3 cells kept in serum-free medium were stimulated with OPN and mutated OPN (RGA). An increase in AKT phosphorylation was observed in PC3 cells treated with OPN and not in OPN (RGA). Similar increase was observed in PC3 cells over expressing OPN and not in PC3 cells over expressing mutated OPN (RGA). Inhibition of AKT phosphorylation by PI3-kinase inhibitor wortmannin suggests that PIP3-mediated membrane targeting of AKT/PKB as well as subsequent phosphorylation by the phosphoinositide dependent kinase-1 (PDK-1) may be required for the phosphorylation of AKT at Thr 308. *In-vitro* kinase assays reveal that OPN activation of the Akt phosphorylation at Thr-473 is ILK mediated while ILK inhibitor (KP392) analysis substantiate this observation. Our observations suggest that partial activation and phosphorylation by phosphoinositide dependent kinase -1(PDK1) on Thr 308 and subsequent phosphorylation by ILK at 473 may be required for the activation and phosphorylation of PKB/AKT.

**Human Uterine Leiomyoma-Derived Fibroblasts Promote Proliferation of Uterine Leiomyoma Cells in a Coculture System**

L. Yu,[1] A. B. Moore,[1] C. D. Swartz,[2] X. Zheng,[1] L. Wang,[1] G. E. Kissling,[3] D. K. Walmer,[4] S. J. Robboy,[5] D. Dixon[1]; [1]Laboratory of Experimental Pathology, National Institute of Environmental Health Sciences, RTP, NC, [2]Environmental Carcinogenesis Division, US Environmental Protection Agency, RTP, NC, [3]Biostatistics Branch, National Institute of Environmental Health Sciences, RTP, NC, [4]Department of Obstetrics and Gynecology, Duke University Medical Center, Durham, NC, [5]Department of Pathology, Duke University Medical Center, Durham, NC

Uterine Leiomyomas (fibroids: myomas) are the most common benign tumors diagnosed in women. Fibroids consist of benign smooth muscle cells and an extracellular matrix (ECM) component. We hypothesize that interactions between the smooth muscle tumor cells and fibroblasts of the ECM are important in the growth of fibroids, and in the production of ECM proteins. In this study, we used a coculture system to determine the effects of human uterine leiomyoma-derived fibroblasts (FB) on the growth of uterine leiomyoma cells (UtLM), the induction of growth factors (GFs), the activation of GF receptors, and the production of ECM. Cell counts and proliferating cell nuclear antigen staining revealed increased proliferation of cocultured UtLM compared to UtLM cultured alone. As determined by ELISA or Western blot analysis, there was a significant increase (p=0.03 or less) in the secretion of TGF-β1, TGF-β3, VEGF, EGF, FGF-2, and PDGFα/β in the coculture media compared to media of UtLM and FB cultured alone. The TGF-βI receptor from cocultured UtLM cell lysates had increased phosphoserine and downstream phospho-Smad2 protein levels compared to non-cocultured UtLM. There was increased expression of phosphorylated protein tyrosine kinase (pPTK) receptors for VEGF, FGF-2, PDGFα/β, and downstream effector protein phophorylated 44/42MAPK confirming that these GFs were signaling through tyrosine kinases. There was a significant increase (p=0.03) in collagen-I, IGF-BP3 and IGF-BP4 in the media of UtLM cocultured with FB; this was not seen in FB cocultured with normal myometrial cells. In summary, tumor-derived FB stimulate the growth of UtLM, most likely by increased induction of GFs and activation of their receptor signaling pathways, and by enhanced production of ECM. These data support the role of GFs and ECM in the pathogenesis of fibroids.

## Cell-Cell Interactions II (1150-1163)

**Cell Confluence-Induced Activation of Stat3 Triggers Dome Formation via Augmentation of NHE3 Expression in MDCK Cells**

H. Su, M. Tang; Physiology, Institute of Basic Medical Science, National Cheng-Kong University, Tainan, Taiwan Republic of China

The signal transducers and activators of transcription 3 (Stat3) is generally activated by cell confluence and cell-cell adhesion. However, the biological implication and associated regulatory mechanism remain unclear. Our study found that the activation of Stat3 by cell confluence preceded the dome formation in Madin-Darby canine kidney (MDCK) cells. Here we sought to elucidate how Stat3 activation triggered dome formation, particularly which transepthelial transport system was involved. Immunofluorescence and confocal microscopy studies showed that Stat3tyr705 was phosphorylated at the pre-dome forming area and the nuclei of dome forming cells, suggesting a tight association of nuclear signal of Stat3 tyr705 phosphorylation with dome formation. To further elucidate the relationship, we established MDCK cell lines over-expressing inducible active form of Stat3 (Stat3-C) or dominant negative Stat3 (Stat3-D). Dome formation was promoted by expression of Stat3-C and inhibited by Stat3-D. Moreover, levels of NHE3 but not NHE1 were increased in confluent cells. Interestingly, NHE3 expression levels could be up-regulated by Stat3-C and inhibited by Stat3-D, whereas NHE1, $Na^+$, $K^+$-ATPase or ENaC were not affected by Stat3 expression. Application of NHE3 inhibitors, EIPA and HOE694, could suppress confluence-induced dome formation. These results strongly indicate that activation of Stat3 by cell confluence triggers dome formation through regulation of NHE3 expression.

1151

**Heterocellular Communication Enhances Mammary Epithelial Cell Differentiation**

M. E. El-Sabban,[1] R. Mroueh,[2] M. Mokaled,[2] R. Talhouk[2]; [1]Human Morphology, American University of Beirut, Beirut, Lebanon, [2]Biology, American University of Beirut, Beirut, Lebanon

The link between gap junction intercellular communication (GJIC) and mouse mammary epithelial cell differentiation in vitro is investigated. SCp2

mammary epithelial cell clone differentiate in a basement membrane and hormone dependent manner. In the absence of exogenous basement membrane components, heterocellular interaction between the SCp2 epithelial and the SCg6 myoepithelial cell clones is critical for differentiation. We have recently demonstrated that the expression of connexin 30 correlates with the course of lactation in the gland. The expression profile of Cx30 is concurrent with SCp2 epithelial cell differentiation in vitro. Furthermore, connexins 30, 32, 43 associations with junctional proteins, catenins and Zonula Occludens, are enhanced in differentiation-permissive conditions, especially in heterocellular co-cultures of SCp2 and SCg6. These findings corroborate the importance of heterocellular gap junctions in mammary differentiation.

1152

**Differential Sub-cellular Localization of NGEP, a Prostate Specific Protein in Two Prostate Cancer Cell Lines**

S. Das, S. Nagata, T. Bera, I. Pastan; Laboratory of Molecular Biology, National Cancer Institute, Bethesda, MD

NGEP, New Gene Expressed in Prostate, identified through EST clustering is expressed only in normal prostate and prostate cancer. It is encoded in chromosome 2 on the human genome and there are two alternative splicing products (NGEP-L and NGEP-S). The long transcript of NGEP (NGEP-L) encodes a protein of 933 amino acids. Our previous study using the transient expression of the myc-epitope tagged NGEP-L in 293T cells shows that NGEP-L is a transmembrane protein expressed on plasma-membrane. Because of its exclusive expression in prostate and prostate cancer and also its cell surface localization, NGEP is a promising target for immunotherapy. In this study, we evaluated the effect of forced expression of NGEP on two prostate cancer cell lines, PC3 and LnCaP. Immunofluorescence using NGEP antibody revealed that NGEP is differentially localized in these cell lines. In case of LnCaP, NGEP is localized in the plasma membrane of the cell and preferentially in the cell-cell junction regions of the plasma-membrane. In contrast in PC-3 cells, intracellular accumulation of NGEP could be observed. Dual labeling of the PC3 cell with cis-golgi network antibody shows that NGEP is co-localized with the cis-golgi network. In PC3 cells, NGEP was also located in the cell surface derived endocytic vesicles, suggesting intracellular accumulation of NGEP is not due to the impaired trafficking to the cell surface. Macroscopically, expression of NGEP in LnCaP cells tended to form clumps. However in case of PC3 cells, the morphology was similar to that on the control cells. These results confirm that NGEP is a cell surface protein and suggest it might a have a role in cell contact- dependent interactions in the epithelial cells of the prostate.

1153

**Generation of a Functional Model for Normal Intestinal Epithelial Cell Differentiation**

C. R. Lussier, F. Boudreau; Anatomy and Cell Biology, Université de Sherbrooke, Sherbrooke, PQ, Canada

INTRODUCTION: As an ongoing renewal system in which proliferation, differentiation, migration and apoptosis are tightly regulated, intestinal epithelium is an excellent model to study these cellular processes at the molecular level. However, normal intestinal epithelial cell model able to recapitulate these processes in culture is not yet available. The aim of this work was to produce a normal model of intestinal epithelial cell differentiation. METHODS AND RESULTS: An IEC-6 cell line that stably expressed Cdx2 was seeded on a monolayer of human fetal intestine fibroblasts. Co-cultures were maintained for 12 days. At day 4 after seeding, up-elevated structures appeared and multiplied through day 12. Electron microscopy revealed that these structures consisted in a monolayer of polarized epithelial cells presenting characteristics of differentiated enterocytes such as brush border and all types of cell-cell junctions. Western analysis showed an up-regulation of Cdx2, GATA-4 and HNF 1$\alpha$, transcription factors known as regulators of specific intestinal genes associated with differentiation such as sucrase-isomaltase (SI). At day 12, SI mRNA expression was detectable by RT-PCR analysis. Moreover, an important matrix deposition between the epithelial and the fibroblastic cell layers was observed by electron microscopy. This matrix accumulation corresponded to an over expression of collagen IV $\alpha$1 chain by fibroblasts as demonstrated by RT-PCR analysis. CONCLUSION: Our results suggest that IEC-6 cells expressing exogenous Cdx2 are able to normally differentiate in a co-culture system with human intestinal fibroblasts. This model will be utilized to investigate molecular mechanisms involved in intestinal epithelial cell differentiation. Furthermore, the heterologous nature of the two cell compartments will make this co-culture system useful for epithelial-mesenchymal interactions studies.

**Search of the Instrumental Feedback Mechanism in Biochemical Networks: A simple Linear Approach**

J. Ferreira,[1] S. Mondié,[2] R. Lozano,[1] A. Friboulet[3]; [1]Heuristique et Diagnostic des Systèmes Complexes (HEUDIASYC) UMR-CNRS 6599, Université de Technologie de Compiègne, Compiègne, France, [2]Department of Automatic Control, Centro de Investigación y de Estudios Avanzados del IPN (CINVESTAV-IPN), México, Mexico, [3]Laboratoire de Génie Enzymatique et Cellulaire, UMR-CNRS 6022, Université de Technologie de Compiègne, Compiègne, France

**Motivation:** The comprehension of several phenomena and its physiological significance in complex networks of living cells is a challenge for scientists from different fields of science. Experimentalist and theoretician are summoned to join their interdisciplinary efforts with view to contribute to the understanding of the complexity in biology. **Objective:** We analyse interactions in a dynamic model of a biochemical network driving the cell division cycle in Xenopus eggs in order to determine the structural components and interconnections that cause the complex behaviour. **Method:** We propose and implement a numerical solution for the system of nonlinear ordinary differential equations that represents the model. A linearization technique is used to approximate the system's behavior in the vicinity of the equilibrium point. A small perturbation is introduced in a given element of the Jacobian matrix and then a interactive algorithm is used to compute the smallest absolute value for which the stability/instability is induced. Bifurcation diagram is used to sketch special points considered useful in the analysis of system's eigenvalues. **Results:** Qualitative assessment of the results indicates the three most important proteins among the nine studied. Our results are confronted with a recent work of a different author who utilizes other technique and same mathematical model. The comparison shows that the two approaches point out the same three proteins as responsible for the phenomena. **Conclusions:** *in silico* experiments demonstrates that the proposed technique is a very useful alternative in identification of the key proteins and interactions that govern the oscillations in the Xenopus frog egg at high values of the rate of cyclin synthesis. This verification highlights that computer simulations associated with system theory constitute a powerful strategy in the comprehension of a biological systems as a whole.

**TGF-Beta Effects on Desmosomal Components in MCF10A Cells**

S. A. Keim, K. R. Johnson, M. J. Wheelock; Oral Biology, University of Nebraska Medical Center, Omaha, NE

TGF-β Effects on Desmosomal Components in MCF10A cells. Epithelial to mesenchymal transition (EMT) is a normal part of embryonic development, and is a potential mechanism in carcinoma progression. During EMT, epithelial cells decrease cell-cell interactions and acquire an invasive phenotype. Epithelial cells interact with one another via several junctional complexes including the adherens junction and the desmosome. Changes in the adherens junction have been characterized during EMT, but desmosomes have received only limited attention. Our hypothesis is that, in addition to the known alterations in cadherin-mediated adherens junctional adhesion, MCF10A cells, which undergo TGF-β induced EMT, also alter their desmosomes. Punctate staining of desmoplakin at cell borders is used as a marker of desmosomes. Immunofluorescence of desmoplakin in MCF10A cells shows punctate cell-cell border staining in the control cells, whereas after treatment with TGF-β it becomes cytosolic. This change in desomoplakin implies desmosomes are being disassembled during EMT. Immunoblot analysis reveals that desmocollins, desmogleins, plakophilins, and plakoglobin all decrease after four days of TGF-β treatment. However, the behavior of these proteins is not uniform. Both plakoglobin and desmocollin 2 increase within the first two days, and then decrease beginning at three days of treatment with TGF-β. In contrast, desmoglein 2 and 3 and plakophilin 2 and 3 steadily decrease with TGF-β treatment. mRNA levels of these proteins do not decrease with TGF-β treatment suggesting that the mechanism for the decrease in protein levels is due to a posttranscriptional mechanism. These data characterize the disassembly of desmosomes after treatment with TGF-β and point to a posttranscriptional modification of the desmosomal proteins.

**Nitric Oxide Induces Formation of Nanometer Membrane Tubulovesicular Extensions in Neutrophils, Establishing Cell-Cell Contacts Between Neutrophils and Binding Erythrocytes and Bacteria over a Distance**

S. I. Galkina,[1] Y. M. Romanova,[2] G. F. Sudina[1]; [1]Moscow State University, A. N. Belozersky Institute of Physico-Chemical Biology, Moscow, Russian Federation, [2]The Gamaleya Research Institute of epidemiology and microbiology RAMS, Moscow, Russian Federation

Nitric oxide is known to reduce integrin-dependent (but not selectin-dependent) leukocyte adhesion to endothelial cells and to relief endothelium damage induced by adherent leukocytes upon ischemia/reperfusion or sepsis. Previously we have shown that neutrophils (polymorphonuclear leukocytes) possess a capacity to develop highly dynamic thin and long (several cell diameters in length) tubulovesicular extensions, connecting cells to substrata in β1-, β2-integrin-independent, but L-selectin-dependent manner. Recently we found that nitric oxide donor diethylamine NONOate caused appearance and growth of similar in size and behaviour tubulovesicular extensions in neutrophils upon adhesion to fibronectin-coated substrata. In the presence of nitric oxide synthase inhibitor Nω-nitro-L-arginine methyl ester neutrophils spread on fibronectin and had no microextensions. Scanning electron microscopy revealed that diethylamine NONOate-induced extensions connected neutrophils over a distance and have the uniform diameter along the entire length. Flexible and strait extensions connected cells. Diameter of strait (tubular) extensions varied from 125 to 160 nm, diameter of flexible (consisted of tubular and vesicular fragments of the same diameter) varied from 180 to 290 nm. Strait extensions could be derived from flexible ones under tension. Tubulovesicular extensions of neutrophils also effectively bound and kept serum opsonized bacteria (*Salmonella typhimurium*), thus making them available for bactericidal substances secreted by neutrophils extracellularly. Leukocytes are known to scavenge old erythrocytes from the blood stream by phagocytosis. Neutrophil extensions induced by diethylamine NONOate bound erythrocytes over a distance and increased the number of bound erythrocytes for neutrophil. Membrane tubulovesicular extensions are supposed to represent protrusions of an intracellular exocytotic trafficking. Nitric oxide seems to impair fusion of exocytotic trafficking with the plasma membrane, thus inducing development of tubulovesicular extensions altering neutrophil contact interactions with other cells.

**Repatterning the T Cell Immunological Synapse with Nanofabricated Supported Membranes**

A. L. DeMond,[1,2] K. D. Mossman,[1,3] B. Rossenova,[1,2] J. P. Hickey,[2] M. L. Dustin,[4] J. T. Groves[1,2,3]; [1]Biophysics Program, UC Berkeley, Berkeley, CA, [2]Chemistry, UC Berkeley, Berkeley, CA, [3]Physical Biosciences Division, Lawrence Berkeley National Labs, Berkeley, CA, [4]Pathology Dept., New York University, New York, NY

Spatial regulation of signaling is emerging as a dominant paradigm in intercellular communication. The junction between a T cell and an antigen presenting cell, called the immunological synapse (IS), has been established as a site rich in spatially regulated molecular interactions. Using total internal reflection fluorescence (TIRF) microscopy, we have visualized the movement of small clusters of T cell receptor (TCR) on the surface of T cell blasts during IS formation as they interact with planar supported bilayers displaying mobile peptide-major histocompatibility complex (pMHC) and intracellular adhesion molecule (ICAM-1). We have developed a technique using nanofabricated lateral constraints on the substrate to frustrate molecular motion in the interacting T cell (K.D. Mossman et al., *submitted*). On unpatterned substrates, TCR clusters were seen to migrate centripetally. The introduction of lateral constraints, such as grids, interrupted centripetal TCR motion, causing the clusters to change direction and track along the grid lines at a reduced velocity. We conclude that TCR transport is active and is restricted by the lateral constraint of its ligand, pMHC.

1158

**Modeling TCR Mobility and T Cell Repolarization**

O. Dushek, D. Coombs; Mathematics, The University of British Columbia, Vancouver, BC, Canada

T cells adhere to antigen presenting cells bearing appropriate antigenic stimuli, forming immunological synapses - well defined regions enriched in certain surface receptors and signaling molecules. In experiments where a T cell forms a synapse with a particular antigen presenting cell, and then encounters a second cell presenting a higher antigen load, the synapse reorients towards the second cell and eventually may detach from the first, over the course of several minutes. The receptors detecting antigen are T cell receptors, which are known to be mobile on the cell surface from FRAP experiments. We use computational modeling to show that thermodynamics and pure diffusion of cell surface receptors fails to explain the data. Directions for future exploration of this problem are indicated.

**Analysis of Mice Lacking p120ctn or Small GTPases Expression in Hepatocytes**

J. van Hengel,[1] C. Van den Broeke,[1] P. D'hooge,[1] X. Wu,[2] A. Reynolds,[3] C. Brakebusch,[2] F. van Roy[1]; [1]Molecular Biomedical Research, VIB - Universtiy of Gent, Zwijnaarde - Gent, Belgium, [2]Junior group "Cytoskeletal Organization", Max Planck Institute for Biochemistry, Martinsried, Germany, [3]Department of Cancer Biology, Vanderbilt University, Nashville, TN

Analysis of Mice Lacking p120ctn or Small GTPases Expression in Hepatocytes Acquisition of invasive and metastatic capabilities is frequently associated with loss of cell-cell adhesion. The major constituents of the cell-adhesion complex in adherens junctions are cadherins, transmembrane proteins involved in homotypic cell-cell adhesion. The p120 catenin (p120ctn) protein is a member of the Armadillo protein family and a key component of adherens junctions, where it interacts with the juxtamembrane part of the cytoplasmic tail of several cadherins. Cytoplasmic p120ctn promotes cell motility, and probably also other activities, through inhibition of RhoA and activation of Rac1 and Cdc42. We generated mice lacking p120ctn expression in hepatocytes. Mutant mice were born at Mendelian ratios. Their phenotypic analysis is ongoing. The small GTPase Cdc42 regulates many different aspects of cell polarity, such as axon formation in neurons, orientation of the Golgi apparatus in the direction of migration, and directed secretion to the basal side of epithelial cells. To understand the role of Cdc42 in the establishment and maintenance of cell polarity in vivo, we generated mice lacking Cdc42 expression in hepatocytes. The regular liver plates were completely absent at age 2 months. The normally tight contacts between neighboring hepatocytes were often widened and the E-cadherin expression pattern was changed. Analysis of serum samples indicated a cholestatic phenotype characterized by at least fourfold elevated levels of AP, tenfold increased concentrations of total and conjugated bilirubin, and increased activities of GPT/GOT. Further analysis of the in vivo roles of p120ctn and Rho GTPases in the liver, and the relevance of their loss to the causation of hepatocellular carcinoma (HCC), one of the most common solid tumors worldwide, is underway.

**Primary Neural Culture to Identify the Factors Controlling the Differentiation of Ependymal Cells**

N. Spassky; Inserm UMR-711, Hopital Pitié Salpetriere, Paris, France

In adult mammals, the cerebral ventricles are normally lined by a layer of ependymal cells. Most of these cells are cuboidal and multiciliated. These cells are at the interface between the brain parenchyma and the ventricular cavities and play an essential role in the propulsion of CSF through the ventricular system. During embryogenesis, we have previously demonstrated that they are derived from radial glial cells. The aim of our study is to identify the cellular and molecular mechanisms governing the differentiation of ependymal cells. We have set up an in vitro assay in which radial glial cells from the lateral walls of the lateral ventricles of newborn mice are purified to 98%, and allowed to differentiate in different culture conditions. After 10 days in culture in fœtal bovine serum (FBS)-free medium, 70% of radial glial cells differentiate into multiciliated ependymal cells, compared to 20% in FBS containing medium. To further investigate the putative roles of soluble secreted factors on the differentiation of ependymal cells, purified radial glial cells were cultured in FBS-free medium which was either renewed every 2 days to dilute all secreted factors or left unchanged. In both cases, 70% of radial glial cells differentiate into multiciliated ependymal cells after 10 days in culture. We obtained similar results in the presence of a gap junction blocking agent (carbenoxolone), perhaps suggesting that neither contact or soluble secreted factors induce the differentiation of ependymal cells in our culture model. We are now in the process of testing the influence of other contact factors such as notch/delta and BMP signalling on the differentiation of ependymal cells.

**Studies of Cytoskeleton during the Interaction of *Sporothrix schenckii* - Epithelial cells**

M. Sabanero López,[1] G. Sandoval,[1] A. Carabez,[2] J. C. Villagómez,[1] E. López-Romero,[1] H. Torres- Guerrero[2]; [1]Instituto de Investigación en Biología Experimental, Universidad de Guanajuato, Guanajuato, Mexico, [2]Instituto de Neurobiología, Universidad Nacional Autónoma de México, México City, Mexico

Adherence of pathogenic microorganisms to host tissues is regarded as a pre requisite for dissemination. Microbial adherence has been studied extensively in pathogenic bacteria and fungi such as *C. albicans*, *A. fumigatus*, and *B. dermatitidis*, but little is known about the adherence mechanism in *S. schenckii*. This study was undertaken to examine the cytoskeleton in the host cell during the interactions and invasion of *S. schenckii* strains MP - 109. We found that yeast ($10^5$ cells /ml) and mycelium ( 100µl/ml) adhered and invaded (6 to 24 h) culture human cervix epithelial cells. The invasion abilities of mycelium were much hight that the yeast. Immunofluorescence microscopy studies showed that the adherence of mycelium and yeast induced cytoskeletal alterations. Under the adherent sites calcofluor studies showed an intimate association between cell wall of fungus and epithelial cells. These results indicate that surface of fungus plays important roles in the invasion of epithelial cells, and the alterations of cytoskeleton in host cell for invasion. The work was support by the Universidad de Guanajuato. (Grant No. 18 to MSL)

**Cytogenetic Mechanism of Cytoplasmic Incompatibility in the Uzifly, *Exorista sorbillans* (Diptera: Tachinidae)**

H. P. Puttaraju, B. M. Prakash; Sericulture, Bangalore University, Bangalore, India

Vertically transmitted bacteria of the genus *Wolbachia* are responsible for the early death of embryos in crosses between *Wolbachia* infected males and uninfected females in a number of insect species studied to date. This mechanism is known as unidirectional cytoplasmic incompatibility. This mechanism when occur between males and females harboring different strains of *Wolbachia* termed as bi-directional cytoplasmic incompatibility. The *Wolbachia* is found in the uzifly, *Exorista sorbillans*, a serious endoparasite of silkworm, *Bombyx mori* L, express both the types of cytoplasmic incompatibility (CI). In the present paper, we investigated cytological mechanism of CI. The results revealed that, in crosses between infected males and infected females when the sperm entered the egg, the sperm chromatin condenses to form the paternal pronucleus. Subsequently, the chromosomes condense for mitosis and spindle attachment occurs and then paternal and maternal pronucleus fuses to form the diploid zygote. In eggs from crosses between infected males and uninfected females only the maternal pronucleus forms individual chromosomes. Whereas the paternal pronucleus does not condense in individual chromosome, but scattered near maternal pronucleus and in some eggs reappear as a diffuse tangled chromatin mass and tend to get fragmented during the first mitotic division thus, the failure of syngamy. However, abnormal behavior of paternal chromatin does not interfere with mitotic division of maternal chromosomes. From these result it is evident that the *Wolbachia* induced CI leads to chromosome destruction and subsequent death of embryo. The mechanism is now implicated widely in the management of

medical and agricultural important pests.

1163

### A 3-D Model to Study Interplay of Cell Adhesion and Chemotaxis in Multicellular Systems

E. Palsson; Biology, Simon Fraser University, Burnaby, BC, Canada

I will introduce a biologically realistic 3-dimensional mathematical model that facilitates visualizing the effect cell adhesion, stiffness, active force generation and chemotaxis have on the movement and signaling of cells in multicellular systems. The building blocks of the model are individual cells; each cell having certain given properties. The basic properties of a cell are: it is ellipsoidal and can deform under force, while conserving its volume, it adheres to other cells, and can generate active motive force. The response of a cell depends on its internal parameter state, and on the information it receives from its external environment, including neighbor cells, the extracellular matrix, and chemical signals. Since the model is based on known processes, the parameters can be estimated or measured experimentally. The cellular slime mold *Dictyostelium discoideum* is a widely used model system for studying a variety of basic processes in development, including cell-cell signaling, signal transduction, pattern formation and cell motility. Simulations of the cell movements during various stages of *Dictyostelium* development are shown and compared with experimental data. These include the chemotactic behavior of single cells, streaming during aggregation, and the collective motion of an aggregate of cells driven by a small group of pacemakers. The model predicts that the motion of two-dimensional slugs results from the same behavior that is exhibited by individual cells; it is not necessary to invoke different mechanisms or behaviors. I will also demonstrate how differences in adhesion between pre-stalk and pre-spore cells, affect the sorting and separation of those cell types, that occurs during the slug stage. I suggest and explain why chemotaxis alone might not be sufficient to achieve complete sorting and how including cell type specific adhesion contributes to much better cell sorting.

## Organization and Regulation of the Extracellular Matrix (1164-1172)

1164

### Phylogenetic Analysis of the Tenascin Gene Family

R. P. Tucker,[1] R. Chiquet-Ehrismann,[2] J. C. Adams[3]; [1]Cell Biology and Human Anatomy, University of California at Davis, Davis, CA, [2]Friedrich Miescher Institute for Biomedical Research, Basel, Switzerland, [3]Department of Cell Biology, Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, OH

Tenascins are extracellular matrix glycoproteins that influence cell adhesion and motility during development and disease. In order to learn more about their origins and relationships to each other we have compared the tenascins encoded in the genomes of the pufferfish *Tetraodon nigroviridis* and *Takifugu rubripes* with those of tetrapods. Unlike amphibians, birds and mammals, which have four tenascin genes, the pufferfish each have five tenascins, including two tenascin-C paralogs: tenascin-CA and tenascin-CB. The predicted tenascin-R protein is identical in repeat and domain organization in each vertebrate class. All tenascin-W genes examined from pufferfish to man are found immediately adjacent to and on the opposite strand from the tenascin-R gene. The predicted tenascin-Ws encode variable numbers of fibronectin type III domains. This variation comes from duplications of the third fibronectin type III domain: *Tetraodon* has one, *Takifugu* two, chicken three, human six and mouse nine. Both pufferfish have tenascin-X genes found between the same genes that flank or overlap tenascin-X in birds and mammals. The predicted tenascin-X proteins contain nine (*Tetraodon*) or 20 (*Takifugu*) unique repeats (GKEQKKXTEGXNTLSP) between a single EGF-like repeat and three fibronectin type III domains. Phylogenetic trees confirm that there are four conserved members of the tenascin gene family: tenascin-R, tenascin-C, tenascin-W and tenascin-X. Tenascin-C and tenascin-R are the most closely-related, and may be derived from an ancestral gene duplication that also gave rise to tenascin-W. Tenascin-Xs are the most diverse group and the most distantly-related to other members of the family.

### Studies on the Improvement of Skin Structure, Cell Adhesion, Differentiation, and ECM Synthesis by a Collagen-Like Peptide

N. Domloge,[1] C. Dal Farra,[1] E. Bauza,[1] A. Perrin,[1] J. Sabatier[2]; [1]Vincience, Sophia antipolis, France, [2]Faculté de médecine nord, CNRS, Marseille, France

Collagen plays a crucial role in tissue remodeling, in wound healing, and in maintaining the structural integrity of the skin. Being interested in the beneficial effects of collagen, we developed a synthetic oligo collagen-like peptide and studied its effect on cultured human skin cells and *ex vivo* models. Cell adhesion assay using HaCaT cells showed that when the cells were seeded in the presence of 10-6 M of the peptide, their adhesion to the microplates was clearly enhanced. Moreover, no evidence of increased cell migration caused by the peptide was observed after the cell migration assay. The peptide's role in enhancing cell adhesion was confirmed by time course studies and H&E staining of cultured fibroblasts. These studies revealed a nice uniform cell sheet in treated wells. Immunofluorescence studies on subconfluent fibroblasts showed that treatment of the cells with 10-6 M of the peptide increased the expression of ECM molecules (such as fibronectin, collagen I and III). Enhanced synthesis of keratin and adhesion molecules such as integrins (alpha 6, beta 1) and laminin 5, was observed in peptide-treated A431 cells. Moreover, *ex vivo* studies showed that human skin samples treated with the peptide, exhibited a remarkably better epidermal and dermal structure than control samples. In the peptide-treated samples, no signs of stress were seen in the epidermis. Interestingly, immunofluorscence studies of the expression of differentiation markers in skin samples, such as filaggrin, showed an increased expression of filaggrin in peptide-treated samples. These studies show that the peptide can be of great use in the area of tissue regeneration and in topical skin care products. The results reveal that the new collagen-like peptide stimulates ECM biosynthesis and offers a large number of beneficial collagen-like effects.

1166

### Three Dimensional Culture Regulates Raf-1 Expression to Modulate Fibronectin Matrix Assembly

B. S. Winters, B. K. Mohan Raj, E. E. Robinson, R. A. Foty, S. A. Corbett; Surgery, Robert Wood Johnson Medical School, New Brunswick, NJ

HT-1080 human fibrosarcoma cells possess one activated allele of N-*ras* and lack the ability to assemble a fibronectin (FN) matrix when grown in two-dimensional (2D) culture. Recently, we showed that culturing HT-1080 cells as three-dimensional (3D) aggregates restored FN matrix assembly to these cells. We hypothesized that the culture environment may influence matrix assembly by altering the expression of Ras signaling

intermediates, such as Raf-1. We show that HT-1080 cells grown as 3D aggregates down-regulate Raf-1 protein expression when compared to cells grown in monolayer culture. Diminished Raf-1 protein expression in 3D is associated with reduced Raf-1 mRNA levels as determined by quantitative RT-PCR and not proteasome-mediated degradation of endogenous Raf-1. Interestingly, transient expression of a Raf-1 promoter-reporter construct demonstrates increased Raf-1 promoter activity in 3D when compared to 2D culture, suggesting that the transition to 3D culture may modulate Raf-1 mRNA stability. Finally, to confirm that altered Raf-1 expression correlates with the increase in FNA matrix assembly, we used siRNA knockdown of Raf-1. This restored the ability of HT-1080 cells in 2D culture to assemble a FN matrix. Moreover, over-expression of Raf-1 prevented FN matrix assembly by HT-1080 cells cultured in 3D and resulted in decreased aggregate compaction. This work provides new insight into how Raf-1 expression may be regulated, allowing the identification of new molecular targets that could rescue the transformed phenotype.

1167

**Integrin β4 Regulates Migration Behavior of Keratinocytes by Determining Laminin-5 Matrix Organization**

B. U. Sehgal,[1] S. Matzno,[1] P. J. DeBiase,[1] T. Chew,[1] S. B. Hopkinson,[1] A. Russell,[2] M. P. Marinkovich,[3] J. C. R. Jones[1]; [1]Cell and Molecular Biology, Northwestern University, Chicago, IL, [2]Molecular and Cell Biology, Cytokinetics, Inc., South San Francisco, CA, [3]Program in Epithelial Biology, Stanford University, Stanford, CA

In hemidesmosomes, α6β4 integrin mediates stable matrix adhesion. Whether α6β4 integrin also regulates migration remains controversial. Here, we analyzed β4 integrin-deficient keratinocyte motility in vitro. Intriguingly, β4 integrin-deficient cells lack a polarized actin cytoskeleton, exhibit reduced levels of activated cofilin, and move in circles, a behavior that mirrors the circular arrays of laminin-5 in their matrix. Upon expression of wild-type β4 integrin, rescued cells show polarized actin and activated cofilin, lay down laminin-5 tracks, and exhibit directed migration, the behavior of wild-type keratinocytes. The subunits of laminin-5 in the matrices of both β4 integrin-deficient and wild-type cells appear identical, which suggests that laminin-5 organization regulates motility. In support of this, directed migration of β4 integrin-deficient keratinocytes is restored when they are plated on the laminin-5-rich matrix of wild-type keratinocytes, whereas wild-type keratinocytes show circular migration on matrix of β4 integrin-deficient keratinocytes. Laminin-5 antagonists inhibit these motility behaviors. To dissect the mechanism via which β4 integrin regulates laminin-5 matrix assembly and hence specifies motility behavior, we have investigated the role of the small GTPases RhoA, Rac1 and Cdc42. β4 integrin-deficient keratinocytes exhibit low Rac1 activity compared with their wild-type counterparts. Moreover, dominant negative Rac1 and Cdc42 both impact the motile behaviors of wild-type keratinocytes while dominant negative RhoA does not. However, only wild-type keratinocytes expressing dominant negative Rac1 exhibit the circular migration of β4 integrin-deficient cells. In summary, the migration behavior of keratinocytes is regulated by the precise organizational state of laminin-5 matrix. Directed migration of keratinocytes is determined by tracks of laminin-5 whose assembly is β4 integrin-dependent and involves remodeling of the actin cytoskeleton via a Rac1/cofilin signaling cascade.

1168

**Effects of Cell Traction Force Patterns and Focal Adhesion Distribution on Fibronectin Assembly**

C. A. Lemmon,[1] C. S. Chen,[2] L. H. Romer[3]; [1]Biomedical Engineering and Anesthesiology and Critical Care Medicine, Johns Hopkins University, Baltimore, MD, [2]Bioengineering, University of Pennsylvania, Philadelphia, PA, [3]Anesthesiology and Critical Care Medicine, Cell Biology, and Pediatrics, Johns Hopkins University, Baltimore, MD

Extracellular matrix (ECM) proteins are assembled into a structured matrix by cell traction forces applied at focal adhesions. We have hypothesized that it is not only the magnitude but also the directionality and distribution of these traction forces which drive successful matrix assembly. We have previously demonstrated the use of microfabricated post array detectors (mPADs) to measure both cell traction forces and assembly of fibronectin. Here, we examine the effects of the distribution of focal adhesions and cell traction forces on fibronectin assembly. We have quantified the surface area of focal adhesions contiguous to the cell edge and focal adhesions located in the interior of the cell. We have also separated vectors of cell tension at the cell edge from tension vectors beneath the interior of the cell. Using these sorting techniques, we have examined the relationship between cell traction distribution and fibronectin fibrillogenesis. Our results indicate that cells with a higher percentage of interior traction forces assemble fibronectin into fibrils more efficiently. We have also investigated the role of Focal Adhesion Kinase (FAK) expression in the distribution of focal adhesions and cell traction forces. Using FAK-null and FAK-re-expressing mouse embryo fibroblasts, we have shown that the absence of FAK expression leads to a significant decrease in the percentage of adhesions in the interior of the cell as well as a significant decrease in fibronectin assembly. Thus we demonstrate that fibronectin assembly is dependent upon FAK-regulated modulations of focal adhesion distribution and cell traction force patterning.

1169

**Regulation of Integrin Activation and Fibronectin Fibrillogenesis by Galectin-3 Binding to Mgat5-modified N-glycans**

J. G. Goetz,[1] A. Lagana,[2] P. Cheung,[3] A. Raz,[4] J. W. Dennis,[3] I. R. Nabi[1]; [1]Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, Canada, [2]Pathology and Cell Biology, University of Montreal, Montreal, PQ, Canada, [3]Samuel Lunenfeld Research Institute, Toronto, ON, Canada, [4]Karmanos Cancer Institute, Detroit, MI

Oncogenic signalling stimulates the dynamic remodelling of actin microfilaments and substrate adhesions that is essential for cell spreading and motility. Transformation is also associated with the increased expression of β1,6GlcNAc-branched N-glycans, products of Golgi β1,6-acetylglucosaminyltransferase V (Mgat5) that represent the favored ligand for galectins. Fibronectin fibrillogenesis, fibronectin-dependent cell spreading and cell motility are deficient in Mgat5-/- mammary epithelial tumor cells and exogenous galectin-3 stimulates RGD-independent, PI3K-dependent fibronectin matrix remodelling. Using Latranculin-A, an inhibitor of actin polymerization, we found that galectin-3 mediated fibronectin fibrillogenesis was associated with increased actin microfilament turnover that occurred even in the presence of RGD. Treatment with both RGD and galectin-3 was associated with the reduction of a latrunculin resistant actin pool. Galectin-3 induced fibronectin fibrillogenesis was associated with the formation of β1-integrin positive fibrillar adhesions labeled with a conformation-dependent anti-alpha5 monoclonal antibody SNAKA51, which extend and elongate along actin stress fibers. Moreover, formation of β1-integrin positive fibrillar adhesions was also induced by treatment of Mgat5+/+ cells with an anti-galectin-3 antibody. Our results indicate that endogenous galectin-3 binding to Mgat5-modified N-glycans results in

β1-integrin clustering that increases the off-rate for RGD-dependent binding to FN and disrupts an RGD-stabilized F-actin pool within focal contacts. Galectin-3-stimulated recruitment of integrin to the galectin lattice regulates the translocation of fibrillar adhesion along actin stress fibers and fibronectin fibril stretching by increasing both integrin mobility and actin filament turnover. Supported by the CIHR.

### Fibulin-5 is Expressed By RPE Cells and is Found in Drusen

E. C. Tolhurst,[1] S. T. Leu,[1] W. C. Wayne,[1] K. L. Wingerd,[1] J. Davis,[1] W. P. Schiemann,[2] D. O. Clegg[1]; [1]MCDB, University of California, Santa Barbara, CA, [2]National Jewish Medical Center, Denver, CO

Mutations in genes encoding fibulin-5 (Fib-5) have been associated with Age-Related Macular Degeneration (AMD), yet little is known about its distribution or function in the eye. Expression of Fib-5 mRNA and protein were assessed in human donor eyes with and without AMD, and in cultured ARPE-19 cells. mRNA levels were measured using real time RT-PCR, and protein was localized in sections using antibodies to unique peptides and imaging with a confocal microscope. Adhesion of ARPE-19 cells to recombinant Fib-5 was measured, and secretion of mutant Fib-5 proteins from 293-T cells was analyzed. In cultured ARPE-19 cells, and in RPE-choroid tissue samples, Fib-5 mRNA could be readily detected by quantitative RT-PCR. Individuals with AMD did not have significantly higher levels of Fib-5 mRNA in samples of RPE-choroid. In tissue sections, Fib-5 protein immunoreactivity was detected in Bruch's membrane, RPE, choroid, and some drusen. Recombinant wildtype Fib-5 supported adhesion of cultured ARPE-19 cells. Some mutations in Fib-5 associated with AMD altered their secretion properties when expressed in 293-T cells. These results show that Fib-5 is synthesized by RPE cells and deposited in Bruch's membrane and some drusen. Fib-5 may be a novel adhesion molecule for RPE cells, and mutations may alter secretion of Fib-5, which could contribute to AMD.

1171

### Detection of Extracellular Proteasome in the Human Alveolar Space

S. U. Sixt,[1] D. Spyrka,[1] J. Hakenbeck,[1] M. Beiderlinden,[1] H. P. Jennissen,[2] J. Peters[3]; [1]Klinik für Anästhesiologie und Intensivmedizin, Universitätsklinikum Essen, Essen, Germany, [2]Physiologische Chemie, Universitätsklinikum Essen, Essen, Germany, [3]Klinik für Anästheiologie und Intensivmedizin, Universitätsklinikum Essen, Essen, Germany

We tested the hypothesis that biologically active proteasome is present in the alveolar space of healthy humans and plays a role in the intraalveolar protein degradation. Methods: Following approval of the local ethic commitee and informed written consent, a bronchoalveolar lavage (BAL) was performed in 8 healthy humans during intravenous anesthesia. Proteasomal activity was measured using specific proteasomal fluorogenic substrates [BZ-VGR-AMC, Suc-LLVY-AMC and Suc-LLE-AMC] and $J^{125}$ albumin, with or without the specific proteasome inhibitor epoxomicin. Molecular weight of the BAL-supernatant were determined by gelfiltration and the revealed hydrolyzing activity at a molecular weight of 700 kDa were analyzed by ESI-QqTOF- mass spectrometry. Results: All proteasomal fluorogenic substrates were hydrolyzed by the supernatant and cell pellet of the BAL and were significantly inhibited by epoxomicin, with the major proteolytic activity detected in the supernatant. No correlation was found between the proteasomal hydrolysis in the BAL supernatant and LDH activity, the total cell count in cell pellet and the fraction of avital cells in cell pellet, ruling out an artifact by cell lysis. Gelfiltration revealed hydrolyzing activity in the supernatant (700 kDa) shows after analyzing by ESI-QqTOF- mass spectrometry proteasome subunit α 3 (PSMA3), PSMA4 and PSMA6. Incubation with $J^{125}$ albumin showed an ATP and ubiquitin independent albumin degradation, inhibited by epoxomicin with a high mean cleavage rate of 101.8 µg/ml x h lavage of $J^{125}$ albumin. Conclusion Thus a biologically active and albumin degrading extracellular proteasome is present in the human alveolar space suggesting that it may play a role in protein degradation and maintainance of a low oncotic pressure in the alveolar space.

1172

### The Characterization of Hyaluronidase in *C elegans*

A. R. Chatel, D. C. Merz; Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, MB, Canada

Hyaluronidases are endoglycosidases that degrade glycosaminoglycans (GAGs) such as chondroitin and hyaluronan. In mammals, at least six genes encoding hyaluronidases have been identified. An additional gene, meningioma expressing antigen 5 (MGEA5), is unrelated to hyaluronidase by sequence but degrades hyaluronan *in vitro*. Hyaluronidases regulate levels of GAGs in many biological processes such as wound healing, inflammation and cancer and are being used during *in vitro* fertilization, therapeutic drug injections and surgical procedures. The objective of this study is to determine the developmental roles and GAG substrate specificity of hyaluronidase and MGEA5 in the nematode *C.elegans.* Deletion mutations in the *C.elegans* genes have been generated. The mutant strain resulting from a deletion in the single hyaluronidase gene is *hya-1(dm12)* and in the putative MGEA5 is *mge-1(ok1207)*. *hya-1(dm12)* is a presumed null allele with a deletion spanning 848 bp and eliminating most of the catalytic glycoside hydrolase domain. *mge-1(ok1207)* is also a presumed null allele with an estimated 1700 bp deletion. *hya-1(dm12)* and *mge-1(ok1207)* animals are viable and grossly normal, although brood sizes of *hya-1(dm12)* are reduced relative to wild type, suggesting a role in germline development or fertilization. Enzyme activity assays performed *in vitro* with total protein extracts prepared from wild type and mutant strains showed no detectable hyaluronan-degrading activity *in vitro.* However, similar enzyme assays performed with chondroitin as a substrate showed degradation by wild type and *hya-1(dm12)* mutant strains, with the *hya-1(dm12)* mutant exhibiting greatly reduced levels of degradation. Chondroitin, the most abundant GAG in *C.elegans,* is essential for reproduction and morphogenesis. Our results suggest that HYA-1 has a possible role in the germline and that its substrate in *C.elegans* is chondroitin. Double mutant strains are being generated to further examine genetic interactions and GAG substrate specificities.

### Defective TNF-receptor 1 Signalling and NFκB Activation in TRAPS Patients

B. S. Nedjai,[1] G. A. Hitman,[1] M. F. McDermott,[2] A. Ranki,[3] S. Stjernberg-Salmela,[3] R. J. Coughlan,[4] K. Minden,[5] P. Arkwright,[6] S. McKee,[7] Y. Chernajovsky,[8] M. D. Turner[1]; [1]Centre for Diabetes and Metabolic Medicine, Bart`s and the Royal London, Queen Mary's School of Medicine and Dentistry, London, United Kingdom, [2]Clinical Science Building, St James Hospital, Leeds, United Kingdom, [3]Department of Dermatology and

Venereal Diseases, Helsinki University Central Hospital, Helsinki, Finland, [4]Department of Medicine, National University of Ireland, Galway, Ireland, [5]Rheuma-Forschungszentrum, Deutsches Rheuma-Forschungszentrum Berlin, Berlin, Germany, [6]Academic Unit of Child Health, St Mary's Hospital, Manchester, United Kingdom, [7]Department of Medical Genetics, Belfast City Hospital, Belfast, Ireland, [8]Bone and Joint Research Unit, Bart`s and the Royal London, Queen Mary's School of Medicine and Dentistry, London, United Kingdom

Objectives Tumour necrosis factor-alpha (TNF) is a key molecule in inflammatory disease, mediating its actions through two receptors, TNF receptor 1 and 2 (TNFR1 and TNFR2). Over 40 *TNFRSF1A* (TNFR1) mutations have been described which lead to the autoinflammatory disorder TNFR-associated periodic fever syndrome (TRAPS). We addressed whether *TNFRSF1A* variants cause defective TNFR1 signalling and NF-κB activation. Methods Nuclear and cytosolic fractions were generated from peripheral blood leukocytes (PBLs) from 7 TRAPS patients (*TNFRSF1A* C73R, T37I, R92Q, P46L, ΔD42, T50M, T50K mutations) and 7 healthy controls. Western blot and ELISA analysis were performed using antibodies against NF-κB subunits. Electromotility shift assay (EMSA) analysis was performed using a $^{32}$P-labelled NF-κB probe. Statistical significance was determined using T-test. Results The pattern of subcellular RelA (p65) NF-κB subunit localisation in both controls and the TNFR1 mutants, T37I, R92Q and ΔD42 was primarily cytosolic. However, T50K, P46L and T50M mutation led to a pattern of RelA expression that was equally partitioned between the nucleus and cytosol. More significantly, major differences were observed from C73R cells where RelA protein was localised almost entirely within the nucleus. Western blot using antibody against IκB-α also revealed complete localisation of this protein to the nuclear fraction of C73R cells. EMSA and ELISA analysis confirmed an elevated level of NF-κB in the nucleus of C73R cells ($p$ = 0.006 for p65; $p$ = 0.0001 for p50) relative to controls. Conclusions These findings suggest that there is inappropriate NF-κB activation in some TRAPS patients, particularly the non-conservative substitution of arginine for cysteine (C73R) in exon 3 of the *TNFRSF1A* gene which leads to a defect in NF-κB signalling. Hyperactivation of NF-κB may explain some of inflammatory processes which occur in TRAPS and could therefore open new routes for therapeutic intervention

## The Role of Arrestins in CCR7 Internalization

M. A. Byers, P. Calloway, C. M. Vines; Micro., Molec. Genetics & Imm., University of Kansas Medical Center, Kansas City, KS

G protein-coupled receptors (GPCRs) are transmembrane proteins that span the cell membrane seven times and couple to heterotrimeric GTP-binding (G) proteins. Following receptor activation, a conformational change in the receptor leads to activation of the heterotrimeric G-proteins, receptor phosphorylation and arrestin binding. This arrestin binding to GPCRs prevents further association of the receptor with G-proteins and thereby, plays an important role in GPCR desensitization. Arrestins regulate receptor trafficking during both internalization and during receptor recycling, wherein arrestins serve as adapters between GPCRs and endocytic proteins such as clathrin and AP-2. The CCR7 GPCR, is a chemokine receptor that is capable of binding to two distinct ligands, CCL19 and CCL21. To examine the role of arrestins in trafficking of CCR7 following binding of either of its ligands, we expressed CCR7 in a mouse embryonic fibroblast cell line (MEF) that lacked endogenous arrestin 2 and arrestin 3 (arrestin-deficient). We compared CCR7 internalization and recycling kinetics in these cells to congenic wild type MEF cell lines following exposure to CCL19 or CCL21. We found that receptor internalization following binding to the CCL21 ligand is regulated by arrestins. In contrast, CCR7 internalization following binding to CCL19 is an arrestin independent process. These results suggest that CCR7 is internalized via distinct pathways in response to exposure to its two cognate ligands.

## Cellular Localization of Neutral Amino Acids Transporter ASCT2, EGF Receptor (EGFR) and Growth Hormone Receptor (GHR) in Human Enterocytes

N. E. Avissar,[1] L. Toia,[1] S. J. Frank,[2] C. K. Ryan,[3] H. C. Sax[1]; [1]Surgery, University of Rochester, Rochester, NY, [2]Medicine, Cell Biology and Endocrinology, University of Alabama at Birmingham, Birmingham, AL, [3]Pathology, University of Rochester, Rochester, NY

Treatment with EGF plus GH of rabbits with short gut or of monolayers of human $C2_{BBe}1$ increases Gln transport. The response is variable depending on the route of administration, likely due to receptors location. EGFR in human intestine is a basolateral (Bl) protein while in cancer it is also apical (Ap). It has been suggested that human GHR and ASCT2 (Gln transporter) are Bl, while in rabbit intestine ASCT2 protein is Ap. We investigated the membranal location of ASCT2 and EGFR in human intestine, Caco-2 and its subclone, $C2_{BBe}1$. GHR location was evaluated in the cell lines only. Cells were grown on Transwells until tight junctions were formed. Membrane proteins were biotinylated on Bl or Ap side and were isolated from cell extracts by avidin precipitation. The isolated proteins were subjected to immunoblotting for ASCT2, GHR, EGFR and $Na^+/K^+$ ATPase (a control Bl protein). Immunohistochemistry was used to establish the location of ASCT2 and EGFR in human intestine. In both cell lines, ASCT2 was present on both membranes with higher levels on the Bl membrane. EGFR and GHR were present mainly on the Bl membrane; there were smaller amounts of EGFR on the Ap side. GHR staining was negligible on the Ap side. In the human ileum, EGFR was confined to the Bl membrane of the crypts, while ASCT2 was located on the brush border membrane (Ap) of the villi tip. We conclude that because there is a difference between the intestine and the cell lines in EGFR and ASCT2 membrane location, the cell lines cannot be used as an intestinal model for the side-specific regulation of ASCT2 transport by EGF. Funded by NIH 5 RO1 DK47989-10.

## Degradation of Calcium-sensing Receptors by the E3 Ubiquitin Ligase Dorfin

Y. Huang,[1] G. E. Breitwieser,[2] J. Niwa,[3] G. Sobue[3]; [1]Biology, Syracuse University, Syracuse, NY, [2]Geisinger Clinic, Weis Center for Research, Danville, PA, [3]Neurology, Nagoya University Graduate School of Medicine, Nagoya, Japan

The calcium sensing receptor (CaR) is a G protein-coupled receptor which is critical for regulation of systemic calcium homeostasis. Little is known about the mechanisms regulating CaR synthesis and degradation. Yeast two-hybrid library screening identified an E3 ubiquitin ligase dorfin as a binding partner for the intracellular carboxyl terminus of CaR. Coimmunoprecipitation was used to confirm the interaction between CaR and dorfin in HEK293 cells. Ubiquitinated CaR was observed in the presence of proteasomal inhibitor MG132; mutation of intracellular lysine residues abolished ubiquitination of CaR. Coexpression of dorfin decreased the steady-state protein level of CaR and increased ubiquitination. A dominant negative fragment of dorfin had opposite effects on CaR steady-state protein levels and ubiquitination. AAA ATPase p97/valosin-containing protein (VCP) formed a complex with CaR and dorfin in HEK293 cells, suggesting that dorfin interacts with CaR at the endoplasmic reticulum

(ER). Treatment with tunicamycin, an inhibitor of N-linked glycosylation, induced the appearance of the unglycosylated 115-kD CaR form, which was further increased by MG132. Tunicamycin also increased ubiquitination of CaR in the presence of MG132, indicating that CaR is ubiquitinated at the ER. Two more mature forms of CaR (150- and 130-kD) were unaffected by tunicamycin or MG132, suggesting that only the unglycosylated CaR is degraded by the proteasome via the endoplasmic reticulum-associated degradation (ERAD) pathway. In conclusion, CaR and dorfin interact both in vitro and in vivo, and ubiquitination and degradation of CaR is regulated by dorfin via the ERAD pathway. Funding by NIH GM58578.

## Secretin Receptor Oligomers Form Intracellularly during Biosynthesis through Receptor Core Domains

C. S. Lisenbee, L. J. Miller; Cancer Center and Department of Molecular Pharmacology and Experimental Therapeutics, Mayo Clinic, Scottsdale, AZ

Oligomerization of numerous G protein-coupled receptors has been documented, including the prototypic class B secretin receptor. Recently, we proposed that the observed dominant negative inhibition of secretin receptor function occurred via the direct interaction of wild type and misspliced receptors, the latter of which were found in gastrinomas and pancreatic cancer. In the current project, our goal was to explore the molecular mechanism of this interaction using bioluminescence (BRET) and fluorescence (FRET) resonance energy transfer and fluorescence microscopy with a variety of receptor constructs tagged with luciferase (Rlu) or cyan or yellow (YFP) fluorescent proteins. BRET signals comparable to those obtained from cells coexpressing Rlu- and YFP-tagged wild type receptors were observed for similarly-tagged secretin receptor constructs in which all or part of the N-terminal domain was deleted. As expected, neither of these constructs bound secretin, and only the partially truncated construct sorted to the plasma membrane. Tagged receptor constructs having alanine substitutions for either or both of the glycine residues of a -GxxxG- motif in transmembrane domain seven also produced BRET signals above background, as did receptors lacking the majority of the C-terminal domain, including that important for phosphorylation-mediated desensitization. Of interest, all of the receptor constructs were capable of associating with wild type secretin receptors to form heteromers. Furthermore, treatment of receptor-expressing cells with brefeldin A to inhibit trafficking of nascent receptors did not eliminate the BRET signals attributable to either homomeric or heteromeric interactions. Morphologic FRET experiments confirmed the expected subcellular localizations of receptor oligomers. Cumulatively, these findings suggest that the receptor core, and likely the transmembrane domains other than a -GxxxG- motif, are responsible for secretin receptor oligomerization, and that this can occur during biosynthesis and maturation of nascent secretin receptors.

1178

## Regulation of IgA-pIgR Transcytosis by EGFR-MEK-ERK Signaling Pathway in Epithelial Cells

T. Su,[1] F. Luton,[2,1] M. Vergés,[3,1] S. M. Ulrich,[4,5] K. Hansen,[6] A. L. Burlingame,[6] K. M. Shokat,[4] K. E. Mostov[1]; [1]Dept. of Anatomy and Biochemistry and Biophysics and Cardiovascular Research Institute, University of California San Francisco, San Francisco, CA, [2]Institut de Pharmacologie Moleculaire et Cellulaire, CNRSUMR6097, 06560 Sophia-Antipolis, France, [3]Laboratory of Epithelial Cell Biology, Genomics and Pharmacoproteomics Program Centro de Investigación Príncipe Felipe, Valencia, Spain, [4]Dept. of Cellular and Molecular Pharmacology, University of California San Francisco, San Francisco, CA, [5]Chemistry Department, Ithaca College, Ithaca, NY, [6]Dept. of Pharmaceutical Chemistry, Mass Spectrometry Facility, University of California San Francisco, San Francisco, CA

Polymeric IgA (pIgA) transcytosis mediated by the polymeric immunoglobulin receptor (pIgR) is a highly regulated process in polarized epithelial cells and hepatocytes for immune defense against pathogens and allergens. Binding of pIgA to pIgR stimulates transcytosis of pIgA-pIgR suggesting that a signaling mechanism regulates this process. Indeed, binding of pIgA to pIgR leads to activation of PKCepsilon, production of inositol 1,4,5-trisphosphate (IP3), elevation of intracellular $Ca_i$ and a rapid tyrosine phosphorylation on several proteins in pIgR transfected MDCK cells. Recently we have found that c-Yes, a Src family member of non-receptor tyrosine kinases, controls pIgA-pIgR transcytosis in rodent liver. Furthermore, we have identified that epidermal growth factor receptor (EGFR) acts as a c-Yes substrate in rat liver endosomes by using a novel technique combined with mass spectrometry. Here, we report that intravenous injection of pIgA into rats induces EGFR phosphorylation in rat liver endosomes. Similarly, pIgA binding to pIgR in cells increases EGFR and extracellular signal-regulated protein kinase (ERK) phosphorylation. The interactions among EGFR, pIgR and c-Yes are found in liver endosomes and pIgR transfected MDCK cells by co-immunoprecipitations. The intracellular co-localization of EGFR, pIgR and c-Yes is also seen by confocal microscopy. Inhibition of EGFR and ERK phosphorylation by either PD153035, a EGFR inhibitor, or U0126, a MEK inhibitor, blocks the pIgA stimulated pIgR transcytosis. Our data indicate that the signalling pathway of EGFR-MEK-ERK is involved in the pIgA-pIgR transcytosis.

## GRK 6 Regulate the Dopamine $D_1$-like Receptor-mediated Inhibition of $Cl^-/HCO_3^-$ Exchanger Activity in Rat Intestinal Epithelial IEC-6 Cells

S. Fraga,[1] P. A. Jose,[2] D. B. Mount,[3] P. Soares-da-Silva[1]; [1]Inst. Pharmacol. Ther., Faculty of Medicine, Porto, Portugal, [2]Department of Pediatrics, Georgetown University Medical Center, Washington, DC, [3]Renal Divisions, Boston VA Healthcare System and Brigham and Women's Hospital, Harvard Medical School, Boston, MA

The aim of the present study was to investigate the effect of dopamine $D_1$-like receptor stimulation on the $Cl^-/HCO_3^-$ activity in rat intestinal epithelial IEC-6 cells. IEC-6 cells are endowed with a $Cl^-/HCO_3^-$ exchanger. The pHi recovery after alkalinization imposed by the removal of $HCO_3^-$ from extracellular medium was found to be a chloride-dependent, DIDS-sensitive and niflumate-insensitive process. The presence of the SLC26A6 anion exchanger was detected by both RT-PCR and immunoblotting analysis. Activation of dopamine $D_1$-like receptors with SKF 38393 inhibited $Cl^-/HCO_3^-$ exchanger activity, this being antagonized by the $D_1$ selective antagonist SKF 83566. However, effects of SKF 38393 on the exchanger activity were maximal at 5 min of exposure to the agonist and rapidly diminished with no effect at 15 min, suggestive of agonist-induced desensitization of $D_1$-like receptors. Pretreatment of cells with heparin (1 μM), a non-selective inhibitor of G-protein coupled-receptor kinase (GRK), prevented the loss of effects upon $Cl^-/HCO_3^-$ activity after 15 min exposure to SKF 38393. Overnight treatment with the anti-GRK 6A and anti-GRK 6B, but not with the anti-GRK 4, antibodies prevented the loss of SKF 38393-mediated effects. Both PKA and PKC signaling pathways contribute to regulation of the $Cl^-/HCO_3^-$ activity mediated by dopamine $D_1$-like receptors. These findings suggest that SLC26A6 is at least one of

the anion exchanger's family members responsible for $Cl^-/HCO_3^-$ exchange in IEC-6 cells. Dopamine $D_1$ receptors in IEC-6 rapidly desensitize to $D_1$-like agonist stimulation and GRK 6, but not GRK 4, appear to be involved in agonist-mediated responsiveness and desensitization.

**Transactivation of the EGF Receptor in Human Mammary Epithelial Cells by UTP and ATP Requires Ectodomain Shedding of EGF Receptor Ligands**

D. L. Ippolito; Fundamental sciences directorate, Pacific Northwest National Laboratory, Richland, WA

Transactivation of growth factor receptors by P2Y nucleoside receptors contributes to cell migration and proliferation. This study characterizes EGF (epidermal growth factor) receptor-induced MAPK (mitogen-activated protein kinase) activation and nuclear translocation following exogenous ATP (adenosine triphosphate) and UTP (uridine triphosphate) application in a human mammary epithelial cell line. Live-cell microscopy in cells co-expressing retrovirally-transduced GFP-MAPK and nuclear-targeted RFP responded to 100-500μM UTP or ATP by nuclear translocation of GFP-MAPK within 1-2 min, with GFP-MAPK assuming perinuclear localization approximately 5 min later. Lower UTP doses (1-10μM) resulted in GFP-MAPK translocation to the nucleus in approximately 4-6 min, with most of the GFP-MAPK remaining in the nucleus up to 15-30 min post-treatment. Nuclear MAPK translocation at all UTP doses was blocked by pre-treatment with mAb225, a monoclonal antibody specific for the ligand-binding domain of the EGF receptor, suggesting transactivation of the EGFR by P2Y receptor activation. Western blot analyses probing for phosphorylated MAPK confirmed rapid activation of MAPK within 1 min after treatment with 100μM UTP, while lower UTP doses (0.01-1μM) did not induce MAPK phosphorylation until 5 min post-treatment. Further, the time course for MAPK phosphorylation was inversely proportional to UTP dose. 100μM UTP induced a rapidly reversible MAPK phosphorylation which returned to baseline by 15 min, while the lowest UTP doses tested exhibited elevated MAPK phosphorylation at 5-30 min. Phosphorylation of MAPK by all doses of UTP was significantly reduced after pre-incubation with mAb225, batimistat or AG1517. Similar results were observed when cells were treated with exogenous ATP. Taken together, our data suggest that EGFR ligand shedding mediates EGFR transactivation following P2Y receptor stimulation by ATP or UTP.

1181

**Helicobacter Pylori Vacuolating Cytotoxin, Vaca-induced Cellular Vacuolation and P38 Activation is Dependent on Translocation of its Receptor RPTPbeta to Lipid Rafts**

T. Hirayama,[1] M. Nakayama,[1] A. Wada,[1] J. Hisatune,[1] E. Yamasaki,[1] Y. Nishi,[1] J. Moss[2]; [1]Dept. of Bacteriology, Nagasaki University, Nagasaki, Japan, [2]PCCMB, NHLBI, NIH, Bethesda, MD

*Helicobacter pylori* vacuolating cytotoxin, VacA, induces multiple effects on epithelial cells, e.g., pore formation, vacuolation, mitochondrial damage, apoptosis, p38 activation, eventually leading to gastric injury. We reported that VacA interacts with target cells by binding to two types of receptor-like protein tyrosine phosphatases (RPTPs), i.e., RPTPα and RPTPβ, resulting in toxin internalization and vacuolation. Translocation of VacA with RPTPβ to lipid rafts and VacA-induced cellular alteration including vacuolation and p38 phosphorylation in AZ-521 cells, which mainly express RPTPβ, were inhibited by treatment with methyl-β-cyclodextrin (MCD). These results suggest that translocation of VacA with RPTPβ to lipid rafts is critical for internalization of the toxin following by vacuolation, and effects on signal transduction as well as p38 activation. In AZ-521 cells, 5-nitro-2-(3-phenylpropylamino)-benzoic acid (NPPB), which blocks anion channels, reduced internalization of VacA and subsequent vacuolation, but neither translocation of VacA to lipid rafts nor VacA-induced activation of p38 was inhibited. Similar to MCD treatment, however, incubation with phosphatidylinositol-specific phospholipase C (PI-PLC) inhibited these VacA-induced events. Neither NPPB nor PI-PLC did not affected VacA binding to cells and interaction with RPTPβ. Thus, VacA localization with RPTPβ to lipid rafts is critical for its internalization and cytotoxicities, such cellular vacuolation and p38 activation.

1182

**The LOX-1 Scavenger Receptor Recognises Phosphatidylserine and Apoptotic Cells in a Calcium-Dependent Manner**

J. E. Murphy, J. H. Walker, S. Ponnambalam; Faculty of Biological Sciences, University of Leeds, Leeds, United Kingdom

Lectin-like oxidized low-density lipoprotein receptor-1 (LOX-1) is a member of the scavenger receptor family (Murphy *et al.* (2005) *Atherosclerosis* In Press) that mediates vascular responses to pro-atherogenic oxidized low-density lipoprotein particles. The extracellular ligand-binding domain of LOX-1 is homologous to the natural killer cell C-type lectins that mediate calcium-independent recognition of MHC class I-related molecules. We find that human LOX-1 recognises a key cellular phospholipid, phosphatidylserine (PS), in a calcium-dependent manner both *in vitro* and *in vivo*. We have expressed a soluble, folded and glycosylated extracellular domain of human LOX-1 using a baculovirus expression system and investigated its ability to bind membrane ligands. Protein lipid overlay assays have revealed that this recombinant LOX-1 protein binds PS but not phosphatidylcholine, phosphatidylethanolamine or phosphatidylinositol. PS recognition by LOX-1 required physiological levels (>1 mM) of calcium ions, suggesting that native LOX-1 binds PS under extracellular conditions where millimolar calcium ion levels are present. Magnesium ions cannot substitute for calcium ions in LOX-1-mediated recognition of PS indicating that the divalent cation requirement is calcium-specific. Full-length LOX-1 protein was expressed in transfected human cells and was found to bind PS-containing apoptotic bodies. This binding was dependent on calcium ions and reduced to background levels by divalent cation chelation, LOX-1 blocking antibodies or PS-containing liposomes. The LOX-1 scavenger receptor is thus a calcium-dependent phospholipid-binding protein, indicating ligand recognition and calcium binding to the C-type lectin superfamily is more complex than predicted.

1183

**The Adaptor Protein RACK1 Associates with the Beta Isoform of the Thromboxane $A_2$ receptor**

A. Parent, G. Laroche, E. Hamelin, J. Parent; Rheumatology Division, University of Sherbrooke, Fleurimont, PQ, Canada

The thromboxane $A_2$ receptor is a G protein-coupled receptor which is implicated in the regulation of diverse pharmacological events such as platelet aggregation as well as constriction and proliferation of vascular and bronchiolar smooth muscle cells. This receptor is expressed as two alternatively spliced isoforms (TPα and TPβ) which share the first 328 amino acids. Our previous studies have shown that only TPβ, but not TPα, undergoes agonist-induced and constitutive internalization and that this specificity is conferred by the C-terminus of TPβ. In order to identify

putative proteins which are implicated in this specific regulation, we used the yeast two-hybrid system to screen for proteins that interact with the C-terminus of TPβ. One of the novel interactions identified occurs with the adaptor protein RACK1 (receptor of activated kinase 1). RACK1 is a WD-repeat protein which appears to serve as a scaffold for numerous proteins such as protein kinase C and Src kinase. The interaction between RACK1 and the C-terminus of TPβ was confirmed with purified proteins in vitro and co-immunoprecipitations in HEK293 cells. These experiments showed that RACK1 is constitutively associated with TPβ and that this association is not affected by stimulation with the TP agonist U46619. We also performed detailed mapping studies of the interaction sites of the C-terminus of TPβ and RACK1. The minimum site for RACK-1 binding was mapped to amino acids 328-337 of the TPβ C-terminus. On the other hand, the third and the seventh WD repeat domains of RACK1 were found to be involved in the interaction with TPβ. Taken together, our results suggest a novel interaction between a G protein-coupled receptor and the adaptor protein RACK1.

1184

**Interaction Between Rab3D and the Polymeric Immunoglobulin Receptor in Lacrimal Acinar Cells**

W. Zhang, G. Jerdeva, S. F. Hamm-Alvarez, C. T. Okamoto; Pharmaceutical Sciences, University of Southern California, Los Angeles, CA

Rab3D, a small molecular weight ras-like GTP-binding protein, is localized to secretory vesicles of various exocrine secretory cells, such as the acinar cells of the pancreas, parotid and lacrimal glands, and the chief cells of the stomach. Immunofluorescence studies indicated that rab3D, the secretory vesicle marker, and the polymeric immunoglobulin receptor (pIgR) are colocalized subjacent to the apical plasma membrane of lacrimal acinar cells. Therefore, we explored the interaction between rab3D and pIgR to determine the role of rab3D in the regulation of pIgR trafficking in primary cultured rabbit lacrimal acinar cells. Pull-down of pIgR from resting lacrimal acinar cell lysates with $(His)_6$-tagged wild-type rab3D (rab3DWT) showed that rab3DWT and dominant-negative rab3DT36N, a GDP-locked rab3D mutant, bind to pIgR; however, the constitutively-active rab3DQ81L, a GTP-locked rab3D mutant, does not bind to pIgR. Furthermore, when GTPγS or GTP is included in the pull-down assays with rab3DWT, binding of pIgR is significantly inhibited. The binding characteristics of pIgR to rab3D were reproduced when cell lysates of pIgR-tranfected MDCK cells were used in pull-down assays. Stimulation of lacrimal acinar cell secretion with 100 μM carbachol (CCh) for up to 2 hours prior to lysis, followed by incubation of lysates from stimulated acini with recombinant rab3DWT, resulted in a loss of pIgR binding to rab3DWT. A recovery of binding occurred after longer incubations of cells with CCh (4~24 hours). These data suggest that rab3D binds to pIgR when in the GDP-bound form, and GDP exchanging to GTP leads to the disruption of interaction between pIgR and rab3D. These changes may regulate pIgR trafficking in lacrimal acinar cells in a stimulation-dependent manner.

1185

**Structural Inhibition of Sema3A Effects by Synthetic Molecules**

L. Roth,[1] C. Nasarre,[1] S. Grosch,[1] D. Aunis,[1] P. Hubert,[2] D. Bagnard,[1] G. Crémel[1]; [1]U575, INSERM, Strasbourg, France, [2]CNRS, Marseille, France

Semaphorins are guidance molecules involved in neuronal connexions formation and in cellular migration. Among all known semaphorins, Sema3A is a secreted molecule whose particularity is to exert a functional duality for a unique cellular type. All studies performed highlighted that this functional diversity depends on the formation of a receptor complex. This receptor complex is composed of receptor units, namely neuropilins 1 and/or 2, and of transduction units, among them plexins. For a better comprehension of the receptor complex formation, we tried to disturb Sema3A signaling by preventing its receptor complex assembly. We synthesized a molecule A mimicking a specific neuropilin 1 domain. Interaction studies showed the high dimerization capacity of this domain. This capacity depends itself on the presence of small structural interaction motifs. We performed sucrose gradient analysis in presence or not of the semaphorin and showed that receptor complex evolution is highly dynamic. Molecule A induced complex disassembly. We next performed functional tests. In a collapsus assay, molecule A at 10-8M is able to specifically prevent the inhibitory effect induced by Sema3A on growth cone of cortical neurons. This effect has been confirmed on neuropilin 1/plexin A1 transfected COS-1 cells, whose shrinkage induced by Sema3A is totally inhibited by synthetic molecule A at 10-9M. We also synthesized an analog of molecule A (molecule B), carrying a mutation in neuropilin 1 interacting motifs. Molecule B is unable to reproduce these effects and shows molecule A specificity. As the dimerization motif found in neuropilin 1 is present in many other Sema3A coreceptors (neuropilin 2, L1-CAM, Vascular Endothelial Growth Factors), this type of synthetic molecule could allow in the future the understanding of the receptor complex formation and of its consequence in semaphorin signaling.

1186

**Antidepressants Bind to the Phencyclidine Locus in the Nicotinic Acetylcholine Receptor**

P. Bhumireddy, H. R. Arias; Pharmaceutical Sciences, Western University of Health Sciences, Pomona, CA

**ASCB DECEMBER 2005** **Objective:** To characterize the antidepressant (AD) binding sites in the resting and desensitized *Torpedo* AChRs. To demonstrate that ADs induce AChR desensitization. **Methods: (1)** [$^3$H]Doxepin equilibrium binding and Scathard-plot; **(2)** radioligand competition experiments using well known noncompetitive antagonists such as [$^3$H]TCP, [$^3$H]dizocilpine, and [$^{14}$C]amobarbital as well as Schild-type analyses; and **(3)** AD-induced [$^3$H]cytisine binding modulation. **Results:** These experiments yielded the following results: **(1)** there is one high-affinity binding site ([$^3$H]Doxepin $K_d$ = 2.7 ± 0.7 μM) for ADs in the *Torpedo* AChR; **(2)** the AD affinity for the [$^3$H]TCP or [$^3$H]dizocilpine locus in the desensitized state follows the sequence: imipramine (I) = amitriptyline (A) > fluoxetine (F) > doxepin (D) bupropion (B), whereas in the resting state it is: F = A > I > D = B; **(3)** Schild-type analyses suggest that ADs may sterically interact with both PCP and dizocilpine sites in the desensitized state; **(4)** the PCP locus partially overlaps the dizocilpine locus in the desensitized state; **(5)** I and F also inhibited [$^{14}$C]amobarbital binding in the resting state. However, the observed $K_d$s were higher than that for [$^3$H]TCP inhibition; and **(6)** [$^3$H]cytisine binding was enhanced by ADs when the AChR was in the resting but activatable state. However, this enhancement was not observed when the AChR was in the desensitized state. **Conclusions:** Considering these results we concluded that: **(a)** ADs bind to a site that overlaps both the PCP and dizocilpine loci in the desensitized state, as well as the PCP site in the resting state. **(b)** ADs, except bupropion, may inhibit the AChR by inducing the desensitization process; and **(c)** AD practically do not bind to the agonist sites.

1187

**TLR4 Is Expressed and Functions as LPS Receptor In Human Fetal Astrocytes**

S. J. Choi, H. S. Park, S. J. Park, K. Lee, S. Kim, J. Y. Park; Dept. Microbiology, Institute of Basic Medical Science, Yonsei University, Wonju College of Medicine, Wonju, Kangwondo, Republic of Korea

Although CNS is segregated from immune systems by BBB, bacterial challenges are able to induce inflammatory responses in the brain. There have been accumulating results that astrocytes actively participate in ongoing immune responses in the CNS. Toll like receptors have been known to participate in the recognition of microbial components such as LPS, peptidoglycan, and dsRNA. Until now, eleven TLR members have been identified in human. Among these receptors, TLR4 mediates LPS signaling along with CD14 and MD-2. To date, there have been conflicting results for the expression and its function of TLR4 in human astrocytes. In this study, we investigated the functional expression of TLR4 in human astrocytes. Using RT-PCR and Western blotting, TLR4 expression was demonstrated in unstimulated human astrocytes. To determine cellular responses induced by LPS, we used RT-PCR and ELISA for analyzing cytokine production and EMSA for NF-κB activation. The expression of TNF-α, IL-6, and IL-8 was increased by LPS treatment in serum containing condition, but not in serum free condition. NF-κB was activated by LPS treatment in serum containing media. The supplement of sCD14 molecules to the cultures restored the LPS effect. To determine whether TLR4 acts as LPS receptor, we used neutralizing anti-TLR4 antibody, HTA125. The cellular responses induced by LPS were abolished by HTA125 treatement. Taken together, we conclude that TLR4 is expressed in human astrocytes, allowing the cells to recognize G(-) bacterial infection.

1188

**Functional Expression of P2Y1 Receptor in Human Retinoblastoma**

D. Kim,[1] J. Park[2]; [1]Department of Basic Nursing Science, Keimyung Univ. College of Nursing, Daegu, Republic of Korea, [2]Institute for Nursing Science, Keimyung Univ., Daegu, Republic of Korea

Expression profiles of P2Y receptors vary according to the species and the cell types. It has been also known that P2Y2 receptor is the most prominent one among P2Y subfamilies in the many ocular tissues including retina. Therefore, we examined any changes in the subtypes of P2Y receptors along with malignant transformation in human retina. To achieve this goal, we used $Ca^{2+}$ imaging technique and Western blot analysis in WERI-Rb-1 cell, a human retinoblastoma cell. ATP (10 μM) elicited strong but transient increase in $[Ca^{2+}]i$ higher than 80% in the WERI-Rb-1 cells (n=46) in a concentration-dependent manner. This $[Ca^{2+}]i$ increase was well maintained by higher than 90.7±1.0 % after external $Ca^{2+}$-depletion (n=48). Phospholipase C inhibitor (U-73122, 1 μM) modestly suppressed the ATP-induced response eliciting 10.4±1.8% increase in $[Ca^{2+}]i$ (n=55), while its isoform (U-73343, 1 μM) had no suppression (n=69). $Ca^{2+}$-ATPase inhibitor (thapsigargin, 1 μM) also elicited a modest suppression on the ATP-induced response eliciting 8.1±0.9% increase in $[Ca^{2+}]i$ (n=52). And $IP_3$ receptor blocker (2-APB, 20 μM) suppressed the ATP-induced response by 92.5±1.3% (n=71). An order of potency of P2Y agonists to evoke $[Ca^{2+}]i$ transients was 2-MeATP>ATP>>UTP=α,β-meATP, which was compatible with the subclass of P2Y1 receptor. The $[Ca^{2+}]i$ transients by application of 2-MeATP and/or ATP was also greatly suppressed in the presence of $P2Y_1$ selective blocker (MRS 2179, 30 μM). $P2Y_1$ receptor protein was identified by using Western blot in WERI-Rb-1 cells. Taken together, P2Y1 receptor is mainly expressed in retinoblastoma cell, which activates $Ca^{2+}$ release from internal $Ca^{2+}$ storage sites via the PLC-mediated $IP_3$ pathway. P2Y1 receptor expressed in retinoblastoma may be worth as a novel target of therapeutic approach to this lethal cancer. The present research has been conducted by the Bisa Research Grant of Keimyung University in 2005.

**Regulation of Dopamine D5 Receptor Signaling in Lipid Rafts in HEK-293 Cells**

P. Yu, J. R. T. Altea, Y. Luo, R. A. Felder, P. A. Jose; Pediatrics, Georgetown Medical Center, Washington, DC

The D1-like dopamine receptors play an important role in the regulation of renal function and blood pressure. D1-like receptors are composed of D1 and D5 receptors. We have recently reported that human D1 receptors (hD1Rs) expressed in HEK cells are regulated in the low density sucrose gradient lipid raft fractions that contain caveolin-2. We now show that the human D5 receptor (hD5R) signaling is also regulated in lipid rafts. The hD5Rs, heterologously expressed in HEK-293 cells, range in size from 33 to 250 kDa. The majority of the hD5Rs are located in the lipid raft membrane (LRM). The D1-like agonist, fenoldopam (5μM) increased the adenylyl cyclase activity by 2.6± 0.2 fold (n=4) in LRM and 1.7± 0.6 fold in non-LRMs. The cholesterol depleting reagent, methyl-β-cyclodextrin (β-CD), decreased the stimulatory effect of fenoldopam on cAMP accumulation by 26% relative to cells not treated with β-CD. The hD5Rs co-fractionated with lipid raft marker proteins, flotillin-1 and flotillin-2 in low density fractions. The D5Rs also co-immunoprecipitated with caveolin-2β, and co-localized with caveolin-2 by confocal microscopy. In addition, caveolin-2β co-immunoprecipitated with flotillins 1 and 2 in HEK-hD5 cells. The results indicate that the hD5Rs, like hD1Rs, are regulated to a greater extent in LRM than in non-LRM.

**New Tools to Investigate Trail and Trail Receptors**

B. Bonnin,[1] E. Sergent,[1] M. O. Jauberteau,[2] O. Micheau,[3] J. M. Viart,[1] F. Bousquet,[1] J. Wijdenes[1]; [1]Diaclone, Besancon, France, [2]CNRS-UMR, Limoges, France, [3]Inserm U517, Dijon, France

Receptors of the TNF/NGF family have been shown to mediate a number of physiological functions including induction of apoptosis. Tumour necrosis factor-related apoptosis-inducing ligand (TRAIL) induces apoptosis in many tumour cells but only rarely in normal cells. Five distinct receptors have been described for TRAIL: TRAIL-R1 (DR4), TRAIL-R2 (DR5, TRICK), TRAIL-R3 (TRID, DcR1), TRAIL-R4 (TRUNDD, DcR2) and Osteoprotegerin (OPG). Monoclonal antibodies (mAbs) were raised against the different molecules to study their role in apoptosis. MAbs were generated against TRAIL (B-S23, B-T24), TRAIL-R1 (B-N28, B-N36, B-T35), TRAIL-R2 (B-D37, B-K29, B-L27), TRAIL-R3 (B-D44, B-E45, B-H47, B-N29) or TRAIL R4 (B-L34, B-R27, B-T32). These mAbs were evaluated in terms of their ability to detect by Western blot, immuno-precipitation or by flow Cytometry TRAIL and TRAIL receptors. Moreover, the mAbs were tested in bioassays and ELISAs were developed to quantify the soluble TRAIL and TRAIL receptors. Of the anti-TRAIL mAbs B-S23 is an agonistic mAb while the B-T24 is an antagonistic mAb. Within the anti-TRAIL-R1 mAb family only B-N36 is an antagonistic mAb. Among the mAb panel against anti-TRAIL-R2 the B-D37 behaves as an agonistic mAb whereas B-K29 reacts as an antagonist mAb. One mAb against the TRAIL-R3, B-D44, has antagonistic

activity. Antibodies against TRAIL-R1, R2 and R4 were found to precipitate the receptor with or without the DISC while none of the mAbs against TRAIL-R3 could precipitate the antigen. Only the mAbs against TRAIL-R3 and R4 could be used in Western blotting. For all four soluble TRAIL receptors an ELISA was set up with a range of 30 - 1000 pg/ml.

**Use of Complementary Peptides to Characterize Potential New Binding Sites for Thrombin and the Thrombin Peptide, TP508**

J. S. Bergmann,[1] G. M. Fuller,[2] D. H. Carney[1]; [1]Human Biological Chem & Genetics, Univ. Texas Medical Branch, Galveston, TX, [2]Dept. Cell Biology, Univ. Alabama, Birmingham, AL

The discovery that protein sequences encoded by complementary strands of nucleic acids can bind to one another is known as the molecular recognition theory. A number of laboratories have generated peptides with sequences derived from the complementary nucleic acid strand of the ligand and shown that the ligands bind the complementary peptides (CP). Antibodies to these CP have been used to identify specific receptors that have been difficult to purify. The 23 amino acid thrombin peptide, TP508, initiates a cascade of signals involved in tissue repair without the proteolytic activity required to activate previously cloned thrombin receptors, suggesting that this molecule activates a separate non-proteolytically activated thrombin receptor. To help identify the receptor molecule to which TP508 binds, we designed and synthesized peptides complementary to TP508 and regions within the molecule thought to interact with its receptor. Based on evidence that TP508 binds to a thrombin receptor, we chose to determine if thrombin could bind specifically to the CP adsorbed to ELISA plates. Specific thrombin binding was determined using biotinylated thrombin ([B]-thrombin) alone and with a 100-fold excess of unlabeled thrombin (define nonspecific binding). One of these peptides specifically binds [B]-thrombin while other sequences do not. In binding experiments in which increasing concentrations of [B]-thrombin are added, half maximal binding to this peptide was 4.8 ± 0.2 nM (n=2 ± SD). Interestingly, this value is similar to that reported for high affinity thrombin binding to fibroblasts. Addition of TP508 inhibits the specific binding of [B]-thrombin suggesting that the CP has a three-dimensional structure similar to the thrombin-TP508 receptor on cells. Antibodies to these peptides may therefore be useful in characterizing the thrombin binding site that is activated by TP508. (Supported by OrthoLogic Corp.)

**Transmembrane Segment Peptides Can Disrupt Cholecystokinin Receptor Oligomerization Without Affecting Function**

K. G. Harikumar, M. Dong, Z. J. Cheng, D. I. Pinon, L. J. Miller; Cancer Center, Mayo Clinic, Scottsdale, AZ

Oligomerization of the G protein-coupled cholecystokinin (CCK) receptor has been demonstrated to exist, but its molecular basis and functional importance are not yet clear. Here, we have explored the ability of peptides representing transmembrane (TM) segments of this receptor to competitively disrupt oligomerization of wild type CCK receptor expressed in COS cells. Precedent for this approach comes from $\beta_2$-adrenergic receptor studies (Heber, JBC 1996). We utilized bioluminescence resonance energy transfer (BRET) to monitor oligomerization of CCK receptor constructs tagged at the carboxy terminus with *Renilla* luciferase or yellow fluorescent protein. Synthetic peptides representing TM I, II, V, VI and VII were utilized. Of these, only TM VI and VII peptides disrupted CCK receptor BRET. Control studies established that the $\beta_2$-adrenergic receptor TM VI peptide that had disrupted oligomerization of that receptor had no effect on CCK receptor BRET. Of interest, disruption of CCK receptor oligomerization had no effect on agonist binding or biological activity. To gain further insight into the face of CCK receptor TM VI that was most relevant for the disruption of receptor oligomerization, we also utilized analogous peptides that replaced the natural residues in positions 315, 319, and 323 (interhelical face) or in positions 317, 321, and 325 (external face) with Ala residues. The Ala317,321,325 peptide eliminated the disruptive effect on CCK receptor BRET, while the other mutant peptide behaved like wild type TM VI peptide. This suggests that the basis of CCK receptor oligomerization reflects the external face of the helical confluence, with particular importance of TM VI. This is most consistent with external contact dimerization in which established seven-helix bundles associate, rather than crossed-domain dimerization that has been previously suggested. Receptor mutagenesis experiments are currently in progress to further extend these observations.

**Heterodimerization Alters the Functional Properties of G Protein-Coupled Receptors**

M. R. Tougas, K. K. Vincent, H. Radhakrishna, N. A. McCarty; School of Biology, Georgia Institute of Technology, Atlanta, GA

G protein-coupled receptors (GPCRs) play central roles in the responses of many cells to various chemical stimuli. Although GPCRs were formerly thought to exist only as monomers and homodimers, recent studies have shown that some may form heterodimers. The angiotensin II type I (ATR1) and bradykinin ($B_2$R1) receptors, and the $\beta_1$ and $\beta_2$ adrenergic receptors ($\beta_1$AR, $\beta_2$AR), are two receptor pairs that have been shown to heterodimerize through biochemical methods, although the functional consequences of heterodimerization in these receptors are not known. We used electrophysiological techniques to study whole-cell current in response to stimulation in *Xenopus* oocytes. Dose-response curves were obtained in oocytes expressing $\beta_1$AR or $\beta_2$AR, either alone or in combination, using the subtype-selective agonists dobutamine and terbutaline, respectively. The dose-response curve for terbutaline was right-shifted while the curve for dobutamine showed increase slope in cells expressing both receptors as compared to cells expressing only the cognate receptor. Cells co-expressing ATR1 and $B_2$R1 underwent heterologous desensitization upon exposure to either ligand, suggesting co-regulation upon heterodimerization. To determine whether heterodimerization also induced co-internalization of these receptors, we quantified surface receptor abundance as a function of ligand stimulation using a cell surface receptor ELISA. Kinetics of agonist-induced internalization were different when ATR1 and $B_2$R1 were co-expressed versus when expressed individually, supporting the notion that heterodimerization also altered receptor trafficking. Heterodimerization between the $G_\alpha$q-coupled $B_2$R1 and the $G_\alpha$s-coupled $\beta_2$AR altered both the internalization of $B_2$R1 and the agonist dose response of $\beta_2$ARs. Heterodimerization of $B_2$R1 and $\beta_2$AR also revealed a novel signaling cascade where activation of the $G_\alpha$q-coupled $B_2$R1 led to stimulation of $G_\alpha$s signaling through the heterodimerized $\beta_2$AR. Taken together, these data indicate that heterodimerization within and between different classes of GPCRs affects receptor function. Sponsor: PURA program at Georgia Tech

**Monitoring the Assembly of Hetero-Trimeric G-Proteins and $GABA_B$ Receptor Heterodimers by Multiplex Resonance Energy Transfer Approaches**

B. Breton,[1,2] M. Lagacé,[1,2] M. Bouvier[1,2]; [1]Biochemistry, Montreal University, Montreal, PQ, Canada, [2]Groupe de Recherche Universitaire sur le Médicament, Montreal, PQ, Canada

Seven transmembrane receptors are now known to interact with their cognate heterotrimeric G protreins as dimers or even higher oligomeric complexes. A particularly convincing example is provided by the metabotropic $GABA_B$ receptor (GBR) that requires the formation of a heterodimer between GBR1 and GBR2 to constitue a functional receptor. GBR1 harbors the only hormone binding site but, in the absence of GBR2, is retained intracellularly. Its interaction with GBR2, allows the targeting of the heterodimer to the cell surface and assures its functional coupling to the G protein. However, neither the exact stoechiometry nor the structural organization of the complex have been studied in living cells. Here we multiplexed two bioluminescence resonance energy transfer techniques ($BRET^1$ and $BRET^2$) along with fluorescence resonance energy transfer (FRET) to probe the formation of GBR/G protein complex. Individually, neither GBR1 nor GBR2 could interact with any of the G-protein subunits tested ($G\alpha i1$,$G\beta 1$, $G\gamma 2$). However, a truncated version of GBR1 that can be trafficked to the plasma membrane in the absence of GBR2 was found to interact with the G-protein subunits indicating that plasma membrane trafficking permits GBR1 pre-coupling to the G-protein. This contrasts with the lack of constitutive association between GBR2 and the G-protein indicating a different propensity of the two receptor subtypes to spontaneously engage the G-protein. Upon co-expression of the two receptors, interaction between each of them and the G-protein subunits could be readily observed confirming the formation of a pentameric complex that could lead to G protein activation. In addition to provide new insight on the nature of the GBR/G protein complex formation, our study provides a proof of principle that RET multiplexing allows to monitor the formation of multimeric protein complexes in living cells.

**Increased Insulin Signaling and Receptor Density in Calreticulin Deficient Cells**

S. Jalali, N. Mesaeli; Division of Stroke and Vascular Disease, Winnipeg, MB, Canada

Akt/PKB is one of the down stream signaling molecules of insulin receptor. Akt mediates many significant biological functions such as growth, survival and differentiation. Calreticulin is an endoplasmic reticulum resident calcium binding protein and chaperone. Recent studies show that calreticulin deficient cells (*crt-/-*) have a higher rate of cell proliferation and resistance to apoptosis. The aim of this study was to determine the change in the insulin signaling in the absence of calreticulin. Treatment of *crt-/-* cells with insulin resulted in more than 2 fold increase in the Akt kinase activity and a significant increase in both pAkt (S473) and pAkt (T308). Wortmannin and LY294002 inhibited insulin mediated activation of Akt, emphasizing a role for PI3 kinase activity. Furthermore, insulin treatment in the presence of AG1024 (IGF receptor blocker) did not alter Akt phosphorylation level. To determine if the observed changes in the phosphorylation was due to the changes in phosphatase activity we used fluorescent-based tyrosine phosphatase (PTP) and protein phosphatase 2A (PP2A) assays. There was no change in the PTP activity; however, PP2A was significantly higher in the *crt-/-* cells. Using western blot analysis we observed a significant increase in the insulin receptor β-subunit and phospho-GSK-3β level (up-stream and down-stream effectors of that Akt) in the *crt-/-* cells. Overall, our data show that insulin receptor signaling is up-regulated in the *crt-/-* cells which may partly account for the increased survival signal in the *crt-/-* cells. Furthermore, *crt-/-* cells show increased rate of serine/threonine phosphorylation and dephosphorylation.

**Vasopressin Up-Regulates Immediate-Early Gene Expression by Two Different Epidermical Growth Factor Receptor (EGFR) Transactivation Pathways in A-10 Cells**

L. Q. Fuentes,[1] G. Perdomo,[1] C. E. Reyes,[1] S. Troncoso,[1] C. D. Figueroa,[2] C. B. Gonzalez[1]; [1]Physiology, Universidad Austral de Chile, Valdivia, Chile, [2]Histology and Pathology, Universidad Austral de Chile, Valdivia, Chile

Vasopressin induces mitogenic responses via transactivation of EGFR. We studied the effect of vasopressin stimulus on the expression of the growth-related immediate-early genes (IEG); c-Fos and Egr-1, which are downstream targets of EGFR. In A 10 cells, derived from rat vascular smooth muscle cells, one hour of vasopressin treatment caused maximal response in the expression of these genes. This effect was completely abrogated by both the PKC inhibitor GF109203X and the EGFR inhibitor AG 1478. The MEK inhibitor PD98059 only blocked the Egr-1 AVP-induced up-regulation. Two wide-spectrum metalloproteinase inhibitors greatly reduced only the c-Fos AVP-induced up-regulation. In contrast, the PP1 Src inhibitor significantly diminished only the Egr1 transcriptional activation. These results suggest that the AVP simultaneously induces the EGFR transactivation by two different pathways, one of which involves a metalloproteinase and the generation of EGF from the heparin-binding EGF-like growth factor and the other the activation of Src/PYK2. Furthermore, the transactivated EGFR up-regulates these two IEG by two divergent pathways one of which is MEK/MAPK-dependent. Supported by grant 103261 from FONDECYT and DIUACH.

**Requirement of Transforming Growth Factor Beta Differs between Members of the Glial Cell Line-Derived Neurotrophic Factor Family**

H. Peterziel,[1] K. Unsicker,[1] K. Krieglstein[1,2]; [1]Neuroanatomy, University of Heidelberg, Heidelberg, Germany, [2]Department of Neuroanatomy,, DFG Center of Molecular Physiology of the Brain (CMPB), University of Göttingen, Göttingen, Germany

Glial cell line-derived neurotrophic factor (GDNF) and neurturin (NRTN) constitute target-derived factors with important roles in the development and maintenance of different parasympathetic neuron populations including ciliary ganglion (CG) neurons. Recently, we have shown that survival and signaling mediated by GDNF in CG neurons essentially requires transforming growth factor β (TGFβ). We have provided evidence that TGFβ regulates the availability of the glycosyl phosphatidylinositol (GPI)-anchored GDNF receptor alpha 1 (GFRα1) by promoting the recruitment of the receptor to the plasma membrane. We report now that in addition to GDNF, NRTN, but not persephin or artemin, is able to promote survival of CG neurons. Interestingly, in contrast to GDNF, NRTN is not dependent on cooperation with TGFβ, but efficiently promotes neuronal survival and intracellular signaling in the absence of TGFβ. Additional treatment with TGFβ does not further increase the NRTN response. Both NRTN and GDNF exclusively bind and activate their cognate receptors, GFRα2 and GFRα1, respectively, as shown by the use of receptor-specific neutralizing antibodies. Immunocytochemical staining for the two receptors on the surface of CG neurons reveal that, in contrast to the effect on

GFRα1, TGFβ is not required for recruitment of GFRα2 to the plasma membrane. Moreover, disruption of TGFβ signaling does interfere with GDNF-, but not NRTN-mediated signaling and survival. We propose a model taking into account data from GFRα1 crystallization and ontogenetic development of the CG that may explain the differences in TGFβ-dependence of GDNF and NRTN.

## ER to Golgi Transport (1198-1213)

1198

### Regulation of Glutamate Transporter Trafficking from the ER to Golgi Complex

Y. Liu,[1] A. M. Ruggiero,[2] S. Vidensky,[1] J. D. Rothstein[2]; [1]Neurology, Johns Hopkins University, Baltimore, MD, [2]Neurology and Neuroscience, Johns Hopkins University, Baltimore, MD

Excitatory amino acid transporters (EAATs) are the primary regulators of extracellular glutamate concentrations in the central nervous system. Their dysfunction may contribute to several neurological diseases. In spite of their importance in synaptic actions, little is known concerning the regulation of their trafficking from the ER to the cell surface. Here we show that the glutamate uptake activity and cell surface distribution of the transporters are regulated by two integral ER membrane proteins, GTRAP3-18 and RTN2.GRTAP3-18, a mammalian Yip6b is an inducible protein and able to reduce transporter activity both in-vitro and in-vivo. RTN2 is a member of reticulon family. Both proteins associated with transporters directly. Over-expression of GTRAP3-18 results in the ER retention of the transporters, whereas transporters exit out of the ER and reach the cell surface efficiently when expressed alone or co-expressed with RTN2. Moreover, GTRAP3-18 and RTN2 interact with each other, suggesting a crosstalk of their regulation on ER retention and export. Our data indicate that interaction of transporters with ER proteins can affect their ER to Golgi trafficking and surface composition of transporters may be adjusted by controlling their export from the ER.

1199

### A Cargo-dependent Variable Coat Assembly Mechanism Controls Organelle Homeostasis

Y. Guo, A. D. Linstedt; Department of Biological Sciences, Carnegie Mellon University, Pittsburgh, PA

The size and integrity of endomembrane compartments depends on balanced membrane flux, but the mechanism that determines this balance is unknown. Here, we tested the hypothesis that Golgi proteins regulate COPII assembly at the endoplasmic reticulum (ER) thereby determining the extent of membrane input to the Golgi and Golgi size. This hypothesis predicts that COPII assembly level correlates with availability of Golgi proteins in the ER, and that increased availability of Golgi proteins in the ER, if sustained, causes an imbalance favoring membrane input to the Golgi and Golgi growth. In support of the first prediction, a marked transient increase in assembly of the COPII component sec13p at ER exit sites was observed to coincide with the emergence of Golgi proteins from the ER during synchronous assembly of the Golgi apparatus. Increased COPII assembly was even maintained at steady-state under conditions in which Golgi proteins rapidly cycle through the ER. Remarkably, and in support of the second prediction, overexpression of a single Golgi protein induced both increased COPII assembly and an overall increase in the size of the Golgi apparatus. Although several Golgi proteins contain binding sites for the sar1 GTPase, increased membrane recruitment required the sec23/24 complex in addition to sar1. The outer coat components sec13/31 were not required and increased assembly occurred in the absence of GTP hydrolysis. Altogether, these results indicate that COPII assembly provides a variable exit rate mechanism underlying homeostasis of the Golgi such that the level of COPII assembly is determined, in part, by direct interactions between Golgi proteins and the COPII coat complex.

### Structural and Biochemical Characterization of the Self-assembled COPII Cage Mediating Cargo Export from the Endoplasmic Reticulum

C. Gurkan,[1] S. M. Stagg,[2,1] D. M. Fowler,[1,3] P. LaPointe,[1] C. S. Potter,[2,1] B. Carragher,[2,1] W. E. Balch[1,4]; [1]Department of Cell Biology, The Scripps Research Institute, La Jolla, CA, [2]National Resource for Automated Molecular Microscopy, The Scripps Research Institute, La Jolla, CA, [3]Department of Chemistry, The Scripps Research Institute, La Jolla, CA, [4]The Institute for Childhood and Neglected Disease, The Scripps Research Institute, La Jolla, CA

Coat protein complex II (COPII) machinery comprising the small Sar1 GTPase and the cytosolic protein complexes Sec23/24 and Sec13/31 mediates cargo export from the endoplasmic reticulum (ER). While the current models suggest concerted polymerization of the Sec23/24 and Sec13/31 complexes to drive ER membrane budding, elucidation of the actual mechanism of COPII cage assembly and structure has so far been elusive. We have now established that Sec13/31 can self-assemble to form a cage-like particle with ~60 nm diameter independent of the Sec23/24 complex. The size of these Sec13/31 cages is consistent with that previously observed for COPII vesicles *in vitro* and *in vivo*. Using cryo-electron microscopy (cryo-EM) and single particle analysis, we have reconstructed the Sec13/31 cages at 30 Å resolution to reveal a novel cuboctahedron geometry that is distinct from the icosahedral clathrin lattices involved in endocytosis. In the cuboctahedral Sec13/31 lattice, the asymmetric unit corresponding to each edge is composed of the Sec13/31 heterotetramer. We now propose a revised model for COPII assembly in which Sec23/24 plays a non-structural role as a multivalent ligand localizing the self-assembly of the Sec13/31 cage to specialized regions of the ER for cargo export. This new model is expected to stimulate further experiments to elucidate the dynamics of Sec13/31 cage assembly/disassembly requisite for understanding ER cargo export.

1201

### Analyzing the Role of Sec16 in Transitional ER Organization in *Pichia pastoris*

E. A. Montegna, M. Esaki, P. L. Connerly, B. S. Glick; Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL

In most organisms, COPII vesicles bud from specialized subdomains of the endoplasmic reticulum known as transitional ER (tER) sites. We have identified the peripheral membrane protein Sec16 as an important determinant of tER structure in the budding yeast *Pichia pastoris*. Sec16 had previously been shown to interact with several COPII components in *Saccharomyces cerevisiae* which lacks tER sites. We reasoned that comparing of the roles of Sec16 in these two yeasts will lead to a better understanding of the organizational properties of *P. pastoris* Sec16 (PpS16). In a simple model of tER organization, Sec16 could independently associate with the ER membrane, and then organize COPII components. To test this idea, we overexpressed PpS16 in both *P. pastoris* and *S. cerevisiae*. While the overexpressed PpS16 correctly localized to tER sites in *P. pastoris*,

PpS16 did not colocalize with COPII components in *S. cerevisiae*. Likewise, overexpressed *S. cerevisiae* Sec16 (ScS16) properly colocalized with COPII components in *S. cerevisiae*, but did not appear to associate with the ER in *P. pastoris*, suggesting that a species-specific interaction is important for proper localization of Sec16. We are now creating ScS16/PpS16 chimeric proteins to further test this hypothesis. Both PpS16 and ScS16 contain a large N-terminal unconserved region (NTU). We will use our chimeric proteins to test whether this region may be important for the organizational properties of PpS16. We are also overexpressing the NTU of both PpS16 and ScS16 in each yeast to determine the effects on COPII distribution. Additionally, preliminary evidence indicated PpS16NTU that may self-associate; we are testing this possibility by subjecting purified PpS16NTU and ScS16NTU to analytical ultracentrifugation. Ultimately, we hope to understand how the biochemical properties of Sec16 affect tER organization in diverse organisms.

1202

### A RNA-Protein Complex that is Required for Efficient TGF-α Secretion in *Drosophila*

J. E. Wilhelm, M. Buszczak, S. Sayles; Carnegie Institution of Washington, Baltimore, MD

Proper trafficking of proteins through the secretory pathway is critical for a number of signaling events that establish the primary body axes. It has become increasingly apparent that a number of signaling molecules require specialized chaperones or processing for proper transit through the secretory pathway. During *Drosophila* oogenesis, the dorsal-ventral axis is establishd by localized signaling between the oocyte and the follicle cells by *gurken* (*grk*), a TGF-α homolog. We have identified a novel gene, *trailer hitch*, that is required for proper secretion of Grk. Mutations in *trailer hitch* cause Grk protein to accumulate in large membrane vesicles that appear to be derived from the ER. Consistent with a role in ER-Golgi trafficking of Grk, we have found that Trailer Hitch localizes to regions that overlap and surround ER exit sites and that mutations in *trailer hitch* disrupt the normal organization of ER exit sites. Surprisingly, *trailer hitch* contains an atypical Sm domain and a FDF domain, suggesting that it regulates some aspect of mRNA metabolism. Biochemical purification of Trailer Hitch complexes has revealed that Trailer Hitch is part of a large RNA-protein complex that includes the RNA helicase, Me31B, and the eIF-4E binding protein, Cup. Me31B and Cup also colocalize with Trailer Hitch at ER exit sites, confirming the *in vivo* relevance of their biochemical association with Trailer Hitch. We propose that the normal secretion of Grk requires the local translation of proteins at ER exit sites and that *trailer hitch* is required for this process. Because *trailer hitch* is present in virtually all eukaryotes, these findings raise exciting new possibilities for how mRNA localization and translation could interface with the classical secretory pathway to promote efficient protein trafficking in the cell.

1203

### The Role of Sar1B in the Assembly of Chylomicrons

A. K. Townley,[1] B. Jones,[2] P. Williams,[2] P. D. Watson,[1] C. C. Shoulders,[2] D. J. Stephens[1]; [1]Biochemistry, University of Bristol, Bristol, United Kingdom, [2]Medical Research Council Clinical Sciences Centre, Hammersmith Hospital, London, United Kingdom

The transport of proteins from the ER to the Golgi apparatus requires the COPII protein complex. COPII is comprised of multiple subunits and its assembly on the ER membrane is initiated by GDP:GTP exchange on the small GTPase Sar1. Two isoforms of Sar1 are present in humans (A and B). Mutations in Sar1B cause chylomicron retention disease and Anderson's disease, both of which are characterised by defective assembly and/or secretion of chylomicrons. Notably there are also multiple isoforms of other COPII subunits (e.g. there are four human isoforms of Sec24). We are investigating the role of Sar1B in the assembly of the other subunits of the COPII complex and in secretion of chylomicrons. We show that Sar1A and Sar1B are functionally interchangeable for many aspects of COPII function but show specific differences in terms of the assembly and secretion of chylomicrons.

1204

### CAP-ER, a Late ER Compartment in Cartilage Cells for Aggrecan Trafficking and Quality Control

T. L. Chen, H. Li, B. M. Vertel; Cell Biology and Anatomy, Rosalind Franklin University of Medicine and Science, North Chicago, IL

We present a novel late ER compartment in chondrocytes that we name CAP-ER (Chondrocyte Aggrecan Precursor containing, late ER compartment), based on the relatively high concentration of aggrecan core protein observed within it. Link protein, which stabilizes aggrecan-hyaluronan associations in the cartilage ECM, is present in CAP-ER. In contrast, oligomerizing cartilage ECM molecules, such as types II and IX collagen and cartilage oligomeric matrix protein (COMP), are not detected in the compartment, but are prominent in broader regions of the rER. The membranes enclosing CAP-ER structures are ribophorin-negative, and smooth without associated ribosomes. The limited colocalization of ER chaperones BiP, GRP94 and calreticulin with aggrecan core protein in CAP-ER is a consistent observation. The association of ER exit sites (ERES) with CAP-ER and sensitivity of the compartment to brefeldin A suggest that one aspect of its function is as a source for aggrecan precursors trafficking to the Golgi complex. Dedifferentiation of the chondrocyte phenotype induced by treatment with retinoic acid or passage at low density is accompanied by a shift in the distribution of remaining aggrecan precursors to CAP-ER, suggesting a role for the compartment in the chondrocyte-specific, posttranslational regulation of aggrecan production. Expression studies, including live cell imaging of GFP aggrecan domain proteins, demonstrate that G1-containing versions enter the CAP-ER of chondrocytes but are not sequestered in corresponding ER structures in non-chondrocytic cells. We suggest that CAP-ER is a late ER compartment unique to chondrocytes that acts as a holding station or gateway for aggrecan precursors, which will either progress through the secretory pathway, be retained or be targeted for degradation. Chondrocytes, in producing high levels of aggrecan and modulating its production, utilize CAP-ER as a specialized posttranslational processing station for aggrecan precursors.

### Reconstitution of ER-stress Induced ATF6 Budding *in vitro*

A. Schindler,[1,2] R. Schekman[1,2]; [1]Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA, [2]Howard Hughes Medical Institute, Berkeley, CA

ATF6 is an ER-localized transcription factor precursor protein that traffics to the Golgi complex during ER stress. In the Golgi membrane, ATF6 is cleaved by proteases into a soluble transcription factor that induces gene expression in the unfolded protein response. We have reconstituted the budding of ATF6 using crude ER microsomes isolated from mammalian cells. Treatment of the lysate with DTT, a potent ER-stress inducer,

caused budding of ATF6 precursor into vesicles. The packaging of other cargo molecules was less strongly stimulated by treatment of the lysate with a reducing agent. Other requirements such as nucleotide and cytosol, and characteristics such as inhibition by nonhydrolyzable GTP analogs and dominant negative forms of the GTP-binding protein, Sar1, were similar for ATF6 and other cargo proteins. Experiments to identify proteins that interact with ATF6 indicated that it exists as a high-molecular weight complex stabilized in part by disulfide bond(s).

1206

**Segregation of CFTR from Conventional Cargo Proteins in the ER-Golgi Intermediate Compartments**

A. Niibori,[1] T. Okiyoneda,[1] T. Kouno,[1] I. Wada,[2] M. S. Suico,[1] T. Shuto,[1] H. Kai[1]; [1]Molecular Medicine, Faculty of Pharmaceutical Sciences, Kumamoto, Japan, [2]Cell Science, Fukushima Medical Univ, Fukushima, Japan

Cystic Fibrosis (CF) is the most common lethal genetic disease in Caucasians, which is caused by the mutation of the gene encoding cystic fibrosis transmembrane conductance regulator (CFTR). The most common mutant of CFTR in CF patient (~90%) is Delta F508 CFTR that has a trafficking defect from the endoplasmic reticulum (ER). Since Delta F508 CFTR functions as a regulated $Cl^-$ channel, it is very important to overcome the trafficking defect from the ER for the CF treatment. However, the trafficking pathway of CFTR remains unclear although previous reports indicated that trafficking pathway of CFTR in the early secretory pathway is non-conventional. To examine the differences in the trafficking pathway of CFTR and conventional cargo proteins, we compared the trafficking pathway of CFTR and vesicular stomatitis virus G protein (VSV-G), which utilizes the conventional trafficking pathway. Both proteins were retained in the ER by brefeldin A, which inhibits the ER-Golgi transport, and their trafficking pathways from the ER were examined by immunocytochemical analysis using dual color imaging. Our results showed that the trafficking pathway of CFTR was different from that of VSV-G. The temperature-mediated trafficking block revealed that CFTR is segregated from VSV-G in the ER-Golgi intermediate compartments (ERGIC). Inhibition of the retrograde transport from cis-Golgi to the ER induced the accumulation of CFTR in cis-Golgi, indicating that CFTR is retrieved from cis-Golgi to the ER. Moreover, we also observed that CFTR was further segregated from VSV-G in the post-Golgi vesicles. These data emphasize that CFTR utilizes the non-conventional pathway.

1207

**Export to and from the ERGIC is Mediated by Two Distinct Motifs in the GABA Transporter1 C-terminus**

H. Farhan,[1] V. Reiterer,[1] V. M. Korkhov,[1] H. Hauri,[2] E. Sztul,[3] H. H. Sitte,[1] M. Freissmuth[1]; [1]Center of Biomolecular Medicine and Pharmacology, Medical University of Vienna, Institute of Pharmacology, Vienna, Austria, [2]Department of Pharmacology and Neurobiology, Biozentrum, University of Basel, Basel, Switzerland, [3]Department of Cell Biology, University of Alabama at Birmingham, Birmingham, AL

Export from the ER is mediated by COPII coated vesicles. In mammalian cells these vesicles have been shown to homotypically fuse and generate the intermediate compartment (ERGIC). The nature of this compartment and the mechanism of ERGIC-to-Golgi transport have been intensely depated. According to the maturation hypothesis, ERGIC membranes fuse and generate the cis-Golgi network. Here cargo is transported passively from ERGIC to the Golgi. According to the stationary compartment hypothesis, the ERGIC is a real compartment. In this model COPI components were suggested to control ERGIC-to-Golgi transport. We show that the transmembrane protein GABA transporter 1 (GAT1) recruits the COPII component Sec24D via a motif in its cytosolic C-terminus. In the absence of this interaction, GAT1 leaves the ER in a non-concentrative manner. We also identified the binding site in Sec24D. After exit from the ER, GAT1 is transported to the ERGIC. Here, its export is controlled by a distinct, trihydrophobic motif in the C-terminus. Mutation of this motif to serines (GAT1-SSS) leads to retention in the ERGIC. This is supported by the finding the GAT1-SSS colocalizes with the dominant negative Rab1a (Rab1a-N124I). In addition this compartment is discontinuous with the ER because: (i) using fluorescence recovery after Photobleaching (FRAP) we found that GAT1-SSS doesn't recover 90 sec after bleaching. (ii) GAT1-SSS is capable of leaving the ER (determined by an in vitro budding assay). We propose a two-step model for the ER-to-Golgi transport of GAT1. First COPII mediates cargo concentration and export to the ERGIC. Then a motif in the C-terminus controls export from the ERGIC. These data strongly support the notion that ERGIC-to-Golgi transport is controlled by motifs in the cargo molecule itself and thus support the stationary compartment hypothesis.

1208

**A Role of ArfGAP1 in ER to Golgi Transport of the GABA Transporter1**

V. Reiterer, M. Freissmuth, H. Farhan; Center of Biomolecular Medicine and Pharmacology, Medical University of Vienna, Institute of Pharmacology, Vienna, Austria

We have found that the C-terminus of the GABA transporter1 (GAT1) interacts with the COPII component Sec24D. A mutant that is deficient in this interaction (GAT1-RL/AS) fails to be incorporated into vesicles (determined by an in vitro vesicle budding assay). Here we find that beside export in COPII coated vesicles, GAT1 also undergoes a concentration process in the ER after the COPII step. When we mutated a trihydrophobic motif in the C-terminus of GAT1 to serines (GAT1-SSS), this mutant was retained in the ERGIC as well as in vesicular tubular clusters (VTC) that were continuous with the ER. Formation of VTC was disrupted by co-expression of the dominant negative version of the Arf1 exchange factor GBF1. Rab1 has been shown to support COPI coat recruitment to the ER. In agreement with this, the dominant negative version, Rab1a-N124I, also inhibited VTC formation. These results point to a role of COPI in the concentration process. ArfGAP1 has been recently shown to mediate cargo concentration into COPI vesicles. The GST-tagged wild type GAT1 C-terminus (GST-wt) was able to pulldown ArfGAP1 from a cytosolic lysate. The C-terminus also interacted with purified ArfGAP1. While GST-SSS also interacted with ArfGAP1, GST-RL/AS failed to interact with ArfGAP1. Importantly, the level of beta-COP recruited by GST-SSS was 4-fold lower than that recruited by the wild type version. GST-RL/AS did not recruit any beta-COP. As the RL-motif mediates the interaction with Sec24D, we propose that coat exchange from COPII to COPI takes place on the same (RL-)motif. Additionally, we propose that the adjacent trihydrophobic motif stabilizes the interaction with coatomer which is recruited by ArfGAP1. As GAT1 is an anterograde cargo, our data show that ArfGAP1 is probably involved in ER-to-Golgi transport.

1209

**Role of EHD Proteins in Secretory Pathway**

J. J. Blume, M. Plomann; Centre of Biochemistry and CMMC, University Hospital of Cologne, Cologne, Germany

The EHD (Eps15 homology domain-containing) protein family consists of four members in mammals, which share a conserved modular

arrangement of an N-terminal potential GTPase domain (Pfam database), a non-conserved central linker region and a conserved C-terminal EH domain. All isoforms appear to participate in the regulation of the cargo transport via tubular structures in clathrin-mediated endocytosis as well as in a clathrin-independent pathway. Furthermore, EHD1 is essential for the release of transmembrane cargo proteins from the recycling endosome as dominant-negative mutations in the P-loop region or close to the EH domain of EHD1 significantly reduce their recycling to the plasma membrane. Purified recombinant EHD1 wildtype protein is able to hydrolyze GTP verifying that the EHD proteins represent a novel GTPase protein family. In addition, all family members bind to phospholipid-enriched liposomes with highest affinities for phosphoinositides in vivo predominantly found at Golgi-derived membranes. Furthermore, in case of EHD4 overexpression of an EH domain deletion mutant appears to abolish the correct targeting of the secretory pathway cargo molecules LDLR-GFP and GFP-GPI. Both are retained in EHD4deltaEH-positve compartments, which are resistent to Brefeldin A treatment and were identified as PDI-positive ER-derived compartments. These data suggest that EHD proteins are not only important for the regulation of endocytic processes but also participate in secretory trafficking events.

1210

**The Role of Mammalian GTRAP3-18 in the Early Secretory Pathway**

S. Maier,[1] V. M. Korkhov,[1] A. Ruggiero,[2] J. D. Rothstein,[3] H. H. Sitte,[1] H. Farhan[1]; [1]Center for Biomolecular Medicine and Pharmacology, Institute of Pharmacology, Vienna, Austria, [2]Department of Pharmacology, Vanderbilt University, Nashville, TN, [3]Departments of Neuroscience and Neurology, John Hopkins University School of Medicine, Baltimore, MD

GTRAP3-18 has originally been identified as a modulator of the neural glutamate-transporter excitatory amino acid carrier 1 (EAAC1). Co-localization studies using fluorescently labelled markers revealed its sub-cellular distribution to be predominantly in the endoplasmic reticulum (ER). Data from the literature showed that GTRAP3-18 leaves the ER and recycles back by means of its last four amino-acids (KARE). In contrast to these results we find that GTRAP3-18 is resident in the ER in an oligomeric form (determined by fluorescence resonance energy transfer). In addition, GTRAP3-18 failed to bind to Sec24, the COPII component required for cargo incorporation into COPII coated vesicles, supporting the notion that it is a resident protein. To determine the effect of GTRAP3-18 on ER-to-Golgi transport, we used the temperature-sensitive viral stomatitis virus glycoprotein (VSVG-tsO45). The rate of ER-to-Golgi transport was significantly slowed in the presence of GTRAP3-18. We next wanted to determine the mechanism by which GTRAP3-18 exerts its effect. As GTRAP3-18 is resident in the ER, we hypothesized that it might block cargo concentration in the ER. Concentration of EAAC1 was reduced by 50% in cells expressing GTRAP3-18. Recently, Rab1 has been shown to recruit COPI components to the ER and to mediate concentration of cargo into vesicular tubular clusters. Additionally, GTRAP3-18 shares conserved domains with the prenylated Rab acceptor proteins that regulate intracellular trafficking. Thus, we hypothesized that GTRAP3-18 might act by blocking the effect of Rab1. When we used cytosol that highly expressed Rab1 and added it to semi-intact cells expressing EAAC1 alone or together with GTRAP3-18, the effect of the latter on EAAC1 concentration was completely overcome. Therefore, we conclude that GTRAP3-18 slows the rate of ER-to-Golgi transport by blocking the action of Rab1 on the ER.

1211

**Regulation of the p115 Golgi Tethering Protein**

A. Satoh,[1] M. Beard,[2] J. Shorter,[3] G. Warren[1]; [1]Cell Biology, Yale University School of Medicine, New Haven, CT, [2]Physiology and Cellular Biophysics, Columbia University, New York, NY, [3]Whitehead Institute, Cambridge, MA

The p115 tethering protein (Uso1p in yeast) is essential for ER to Golgi and early Golgi transport. It comprises three domains: an N-terminal globular head, a coiled-coil tail, and a short, acidic C-terminus. The acidic domain has been implicated in binding to GM130 and Giantin, and by so doing was thought to help tether COPI vesicles to cis Golgi membranes. The coiled-coil domain has been shown to aid in the subsequent assembly of SNARE complexes containing syntaxin 5. We now show that the coiled-coil tail also binds to the small GTPase, Rab1, and this binding is inhibited by the acidic domain. Furthermore, the binding of GM130 and Giantin to the acidic domain stimulates p115 binding to Rab1, suggesting that this process is regulated. The data lead to a model in which GM130 and Giantin regulate the recruitment of p115 to cis Golgi membranes by opening up a rab1 binding site that can then catalyze downstream SNARE assembly events.

1212

**The Discovery of Novel Factors that Regulate the Intracellular Trafficking of Chs3 Using Yeast Functional Genomics**

K. K. Y. Lam, E. Conibear; Centre for Molecular Medicine and Therapeutics, Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada

The spatial distribution of many proteins within a cell is altered by stimulus from the external environment however, the connection between signal transduction and vesicle transport is only partially understood. We use the protein *chitin synthase 3* (Chs3) in the yeast *Saccharomyces cerevisiae* to model the process of stimulus-driven trafficking, as components of vesicle machinery and trafficking pathways are well conserved from yeast to mammals. Cell stress induces the translocation of Chs3 from stable intracellular pools to the plasma membrane. We have carried out a fluorescence-based screen on the collection of ~5000 yeast gene knockout mutants to discover genes required for the cell-surface transport of Chs3 under conditions of stress. This high-throughput screen identified, as expected, all genes currently known to be required for Chs3 surface translocation, as well as components of the stress-activated cell integrity Pkc1-Slt2 protein kinase cascade. Numerous uncharacterized genes were also identified. Many of these belong to known functional clusters, including cell wall biosynthesis, signaling, and lipid metabolism. We have further characterized one gene of unknown function, *DUC1*, which was found to be required for endoplasmic reticulum (ER) export of Chs3. Our data suggest that Duc1 may be acting in cooperation with a known Chs3 ER exit factor, Chs7. Elucidating the fundamental mechanisms of Chs3 transport may contribute to our understanding stimulus-driven trafficking in higher cells.

1213

**Antagonistic Functions of Ypt6 and Ypt31/32 in Transport through the Golgi**

A. A. Tokarev, N. Segev; Biological Sciences, University of Illinois, Chicago, IL

The Ypt/Rab GTPase family regulates all intracellular transport steps in eukarytic cells. Transport and recycling through the yeast Golgi involves at least three of the eleven Ypt GTPases: Ypt6 and the Ypt31/32 functional pair. However, it is not clear if these GTPases have discrete or

overlapping functions. Here, we used live fluorescent microscopy and genetic analysis to address this question. We found that the two GTPases co-localize in the Golgi. Specifically, while Ypt31/32 localize mainly to the trans-Golgi and also endosomes, Ypt6 mostly resides in the cis-Golgi and not in endosomes. Over-expression and double mutant analyses reveal that the two GTPases affect cell growth and transport through the exocytic pathway in an antagonistic way. While Ypt6 is required for Golgi-to-ER retrograde transport, Ypt31/32 is required for anterograde transport. Lastly, protein recycling to the trans-Golgi in ypt31/32 and ypt6 mutant cells cannot be suppressed by the over-expression of the other Ypt. In conclusion, we show that in endosome-to-Golgi transport Ypt6 and Ypt31/32 GTPases have parallel but discrete functions, while in exocytic transport and cell viability their functions are opposite.

## Endocytosis II (1214-1232)

1214

### Yeast Clathrin is Important for Normal Cortical Actin Dynamics and Progression of Sla2p Containing Patches during the Early Stage of Endocytosis

T. M. Newpher,[1,2] R. P. Smith,[3] V. Lemmon,[3] S. K. Lemmon[1]; [1]Molecular and Cellular Pharmacology, University of Miami, Miller School of Medicine, Miami, FL, [2]Molecular Biology and Microbiology, Case Western Reserve University, Cleveland, OH, [3]Miami Project to Cure Paralysis, University of Miami, Miller School of Medicine, Miami, FL

Clathrin is a major vesicle coat protein involved in receptor-mediated endocytosis. Previously we found clathrin on highly mobile internal *trans*-Golgi/endosomal structures and on smaller cortical patches in yeast. Total Internal Reflection Fluorescence Microscopy (TIRFM) showed cortical clathrin patches are likely endocytic sites, as clathrin is recruited prior to a burst of intensity of the actin patch/endocytic marker, Abp1. Clathrin is also present at the cortex with internalizing alpha-factor receptor, Ste2p, and with epsins Ent1/2p, AP180s and Sla2p. Here we show that the coiled-coil domain of Sla2p interacts directly with the N-terminal conserved sequence of clathrin LC, similar to what has been observed between mammalian LC and Hip1/R. TIRFM of Sla2p and clathrin shows that both proteins are early endocytic patch components that disappear at the onset of Abp1/actin recruitment; however, clathrin is recruited to patches prior to Sla2p. Deletion of the Sla2p coiled-coil domain ablates the interaction with clathrin LC and the lifespan of Sla2-Δcc-GFP in cortical patches doubles from 37s to 80s. Clathrin-deficient cells show a dramatic increase in Sla2-GFP lifespan at cortical patches, as well as aberrant actin comet tails, suggesting an important role for clathrin in endocytic patch organization/progression. To better define the importance of LC-Sla2 interactions, cells expressing LCs that no longer interact with Sla2p, but still bind clathrin HC, were generated. These cells still display normal growth, TGN sorting, and clathrin coated-vesicle formation. Therefore, Sla2p/LC interaction does not appear to be required for the TGN functions of yeast clathrin. Currently, we are investigating dynamics of the early and late stages of endocytosis in the Sla2p binding mutants, to determine the role of the LC/Sla2p interaction during endocytosis.

1215

### Sorting Nexin 9 Regulates Actin Polymerization Through Modulation of N-WASP Activity

D. Yarar, C. M. Waterman-Storer, S. L. Schmid; Cell Biology, The Scripps Research Institute, La Jolla, CA

We have previously established that F-actin dynamics are required for multiple steps of clathrin-coated vesicle formation. While numerous endocytic accessory proteins have been linked directly or indirectly to the actin cytoskeleton, the regulation of actin dynamics at sites of endocytosis is not understood. We have identified Sorting Nexin 9 (SNX9), a dynamin GTPase binding partner, as a regulator of actin dynamics in mammalian cells. We find that SNX9 binds directly to the neuronal Wiskott-Aldrich Syndrome protein (N-WASP) and enhances N-WASP/ Arp2/3-mediated actin nucleation. In contrast to other known SH3 domain-containing N-WASP activating proteins, SNX9 does not require its SH3 domain for this stimulatory activity, indicating that another region of SNX9 participates in activation of N-WASP/ Arp2/3 mediated nucleation. In living cells, GFP-SNX9 is transiently recruited to clathrin-coated pits late in endocytosis and localization at coated pits does not depend on an intact actin cytoskeleton. However, inhibition of actin assembly/ disassembly dynamics results in the accumulation of GFP-SNX9 at coated pits and loss of the transient association of GFP-SNX9 with coated pits. In addition, we find that RNAi-mediated depletion of SNX9 dramatically alters cellular morphology and actin architecture. Overall, these results suggest that SNX9 is a regulator of actin assembly in endocytosis and functions through the regulation of N-WASP.

1216

### Distinct Functions For Arp2/3 Activators During Endocytosis

Y. Sun, A. C. Martin, D. Drubin; Molecular and Cell Biology, UC Berkeley, Berkeley, CA

Nucleation of actin polymerization by the Arp2/3 complex plays an essential but poorly understood role during endocytic internalization. The Arp2/3 complex requires the binding of an activator to fully stimulate its nucleation activity. A fundamental question is why multiple Arp2/3 complex activators are needed to carry out endocytic internalization. Here, we use the budding yeast, S. cerevisiae, to determine how four Arp2/3 complex activators, Las17p (yeast WASP), Myo3/5p (type I Myosin), Pan1p (yeast Eps15), and Abp1p, cooperate during endocytic internalization. Because Myo3/5p has not been directly shown to activate the Arp2/3 complex in budding yeast, we first purified full-length Myo5p and demonstrated its ability to activate the Arp2/3 complex in vitro in a Vrp1p (yeast WIP)-dependent manner. Myo5p/Vrp1p Arp2/3 activation activity was higher than Pan1p and Abp1p, but lower than Las17p. These differences in the efficiency of Arp2/3 activation and the fact that Arp2/3 activators have been shown to localize to endocytic sites at different times suggested that these activators play distinct roles during endocytosis. We investigated the function of each Arp2/3 activator by analyzing the phenotypes of complete gene deletions and targeted mutations that prevent Arp2/3 binding. We found that while Las17p is important for initiating actin assembly at endocytic sites, Myo5p is most important for actin endocytic internalization. Together, these results provide new insights into how multiple Arp2/3 activators function together during force-generating processes such as endocytic internalization.

1217

### Negative Regulation of the Yeast Eps15-like Protein, Pan1p, an Arp2/3 Activator, by Sla2p, Related to Mammalian Hip1R

J. Toshima, J. Y. Toshima, Y. Sun, M. C. Duncan, J. T. V. Cope, D. G. Drubin; Molecular and Cell Biology, University of California, Berkeley,

Berkeley, CA
Endocytosis is important for receptor internalization, nutrient uptake, antigen presentation, pathogen internalization, and plasma membrane homeostasis. In both yeast and mammals, endocytic internalization is accompanied by a transient burst of actin polymerization. Pan1p, the yeast homologue of the mammalian endocytic protein Eps15, is an essential protein that is involved in both the internalization step of endocytosis and the organization of the actin cytoskeleton. Pan1p is a 160 kDa protein consisting of two Eps15 homology (EH) domains at the N-terminus, a central coiled-coil region, and acidic and proline-rich regions at the C-terminus. Pan1p physiologically interacts with several endocytic proteins implicated in actin cytoskeleton and endocytic function. Previously our group reported that Pan1p binds and activates the Arp2/3 complex through its C-terminal acidic region, and that the activity is negatively regulated by phosphorylation by the kinase Prk1p. In this study, we identified Sla2p, the yeast Hip1R-related protein, as a novel binding partner of Pan1p. We found that Sla2p binds to the coil-coil region of Pan1p and inhibits its Arp2/3 activation activity. We also found that the central coiled-coil region of Sla2p is important for the binding and the inhibitory activities. Furthermore, pan1 mutant defective in Arp2/3 activation partially suppresses the growth defect observed in sla2 deletion cells at the non-permissive temperature, providing evidence for the biological relevance of the Pan1p-Sla2p interaction. These results suggest that Pan1p activity is regulated by phosphorylation by Prk1p and binding to Sla2p.

1218

### A Putative Role for Phosphoinositides in the Subcellular Localization and Function of the E3 Ubiquitin Ligase, Neuralized

L. C. Skwarek,[1,2] M. K. Garroni,[1] G. L. Boulianne[1,2]; [1]Developmental Biology, Hospital for Sick Children, Toronto, ON, Canada, [2]Medical and Molecular Genetics, University of Toronto, Toronto, ON, Canada
Neuralized is a key regulator of the Notch signalling pathway which is required for the development of most tissues in all multi-cellular organisms. In *Drosophila*, the endocytosis of the Notch ligand Delta in the signalling cell is essential for the transmission of the signal to a neighbouring cell. Neuralized is an E3 ubiquitin ligase that is required for the endocytosis of Delta in a subset of Notch signalling contexts, and in the absence of Neuralized, signalling does not occur. The precise mechanism by which Neuralized initiates signal transmission through Delta endocytosis is unknown. Here we have examined the interaction between Neuralized and phosphoinositides and its potential role in Delta trafficking. Through *in vitro* binding assays we have determined that Neuralized binds a number of different phosphoinositides, particularly those that play a role in intracellular trafficking from the plasma membrane. We have mapped the region required for this interaction and show that mutation of this phosphoinositide binding motif mislocalizes the protein in S2 cell culture. In addition, we have studied the role of the mutated form of Neuralized *in vivo* using the GAL4/UAS system. Using flies expressing wild-type and mutant transgenic Neuralized we are currently assessing the functional consequences of disruption of phosphoinositide binding *in vivo* with the goal of understanding how this interaction is involved in Delta trafficking and signal initiation.

1219

### Functional Expression Cloning Identifies a MAP Kinase Phosphatase as Modulator of Dopamine Transporter Function

O. V. Mortensen,[1] B. M. Prasad,[2] M. B. Larsen,[1] S. G. Amara[1]; [1]Dept of Neurobiology, Univ of Pittsburgh, Pittsburgh, PA, [2]Dept of Pharmacology and Toxicology, Medical College of Georgia, Augusta, GA
The antidepressant sensitive monoamine transporters are the primary mechanism for clearance of their respective neurotransmitter from the extracellular space and pharmacological studies have established that the transporters serve a pivotal role in limiting monoamine-mediated neurotransmission and ultimately in determining behavior. We have found that modulation of transporter number by activating protein kinase C (PKC) and thereby stimulating trafficking of carriers to and from the cell surface is a process that seems to vary with the expression system used. To identify molecules responsible for these differences we have successfully used functional co-expression cloning in *Xenopus* oocytes. This led to the identification of a MAP kinase phosphatase, MKP3, as a modulator of PKC induced internalization of transporters and other membrane proteins. Surprisingly conventional MAP kinase families are not involved in the PMA-stimulated internalization, as MAP kinase inhibitors had no effect on internalization, nor did the activity state of different MAP kinases (ERK1/2, p38 and SAPK/JNK) correlate with the PMA-induced down regulation. These results suggest that MAP kinase phosphatases modulate a novel signaling transduction pathway involved in the regulation of clathrin mediated endocytosis. To identify other proteins involved in the trafficking of neurotransmitter transporters we are currently using substrate-trapping methods to isolate target substrates of MKP3.

1220

### Expression of Sorting Nexin-2 Enhances Lamellipodia Formation by the Neuronal Rac1 and RhoG Guanine Nucleotide Exchange Factor Kalirin-7

D. C. Prosser,[1,2] J. K. Ngsee[1,2]; [1]Ottawa Health Research Institute, Ottawa, ON, Canada, [2]Department of Neuroscience, University of Ottawa, Ottawa, ON, Canada
Sorting nexin 2 (SNX2) is a Phox-homology (PX) and Bin/Amphiphysin/Rvs (BAR) domain-containing protein involved in sorting of receptors within the endocytic pathway. Although previous studies have indicated that SNX2 plays a role in targeting of proteins to lysosomes, the precise cellular roles of SNX2 are not well understood. In order to identify SNX2-interacting proteins, we performed a yeast two-hybrid screen of a human brain cDNA library and identified Duo, a Rac1 and RhoG guanine nucleotide exchange factor (GEF), as a putative interactor. Binding of SNX2 to kalirin-7, the rat orthologue of Duo, was confirmed by co-precipitation from extracts of Chinese hamster ovary (CHO) cells co-expressing both proteins, and the C-terminal BAR domain of SNX2 was specifically required for binding to kalirin-7. Interestingly, CHO cells co-expressing SNX2 and kalirin-7 displayed a robust lamellipodia phenotype indicative of Rac1 or RhoG activation. Co-expression of SNX2 and kalirin-7 significantly increased the proportion of cells displaying lamellipodia compared to cells expressing kalirin-7 alone (89.7 ± 3.3% and 28.3 ± 1.7%, respectively) or SNX2 alone (0.7 ± 0.5%), and this phenotype was dependent on the GEF activity of kalirin-7. Truncation of SNX2 revealed that the PX and BAR domains are required for induction of lamellipodia, and mutations within these domains were able to inhibit lamellipodia formation compared to wild-type SNX2. Finally, co-expression of SNX2, kalirin-7 and dominant-negative forms of RhoG and Rac1 revealed that RhoG, but not Rac1, is required for SNX2-mediated induction of lamellipodia by kalirin-7. Overall, these results suggest a novel role for SNX2 in regulating actin dynamics by modulating the function of kalirin-7.

1221

**The Heterotrimeric Gq Protein Directly Interacts with Various ARF-GEFs**

E. Dupre, G. Laroche, J. Parent; Rheumatology Division, University of Sherbrooke, Fleurimont, PQ, Canada

G protein-coupled receptors are widely expressed seven transmembrane receptors with diverse pharmacological effects which are tightly regulated. In the present study, we report novel mechanistic aspects of their intracellular signaling by a direct molecular interaction between the heterotrimeric Gαq protein and various guanine nucleotide exchange factors (GEFs) for the small GTPases ARF1 and ARF6. The GEFs included in our study were cytohesin-1, GRP1, EFA6 and ARF-GEP$_{100}$. All of these GEFs co-immunoprecipitated with Gαq in experiments carried out in HEK293 cells, although the association between Gαq and EFA6 appeared to be the weakest. Interestingly, cytohesin-1 and its dominant negative mutant cytohesin-1(E157K) preferentially associated with a constitutively active mutant of Gαq compared to wild-type Gαq. Using GST-cytohesin-1 and Gαq proteins purified from bacterial and Sf9 cells respectively, we show that there is a direct interaction between these two proteins. We previously demonstrated that internalization of the G protein-coupled receptor for thromboxane $A_2$ required Gαq signaling through a phospholipase Cβ- and protein kinase C-independent mechanism. We then studied the role of cytohesin-1 in the internalization of this receptor. Noteworthy, over-expression of cytohesin-1 or cytohesin-1(E157K) respectively decreased and increased cell surface expression of the receptor in HEK293 cells. Our data also shows that co-expression of the cytohesin-1(E157K) mutant inhibited agonist-induced internalization of the thromboxane $A_2$ receptor by 40% after 60 min of stimulation in HEK293 cells. Together, our results demonstrate for the first time a direct interaction between Gαq and GEFs for ARF1 and ARF6. We also provide evidence that cytohesin-1 is positively involved in Gαq-mediated internalization of a G protein-coupled receptor.

1222

**The Arf6 GEF BRAG2 Regulates Cell Adhesion by Controlling Endocytosis of β1 Integrins**

J. L. Dunphy,[1] T. Lasell,[2] R. Moravec,[1] P. Melancon,[2] J. E. Casanova[1]; [1]Cell Biology, University of Virginia, Charlotesville, VA, [2]Cell Biology, University of Alberta, Edmonton, AB, Canada

Accumulating evidence indicates that Arf6 regulates post-endocytic trafficking of a subset of membrane proteins, including β1 integrins, that are thought to lack interactions with the clathrin-based endocytic machinery and are instead internalized by clathrin-independent mechanisms that remain poorly defined. In some cell types, these proteins enter an Arf6-positive endosomal compartment that is morphologically and functionally distinct from early endosomes containing cargoes internalized via the clathrin-dependent pathway. Importantly, dominant negative Arf6 mutants impair recycling of these proteins to the plasma membrane, suggesting that this process requires active Arf6. BRAG2 is a recently described guanine nucleotide exchange factor (GEF) with specificity for Arf6 in vitro. We have identified a second, longer isoform of BRAG2 (BRAG2b), which like BRAG2a is ubiquitously expressed. Both isoforms activate Arf6 in vivo, as determined using a pulldown assay for Arf6-GTP. To determine the role of BRAG2 in Arf6 function, we performed an RNAi analysis using β1 integrin trafficking as a readout. Knockdown of Arf6 itself led to a 30% reduction in surface expression of β1 integrin and impaired both attachment and spreading of cells on fibronectin. Surprisingly, knockdown of BRAG2a and BRAG2b resulted in a 41% increase in surface β1 and a corresponding enhancement of both attachment and spreading. This effect was specific for integrin, as surface levels of both transferrin receptor and EGF receptor remained unchanged, and was also specific for BRAG2, as knockdown of a different Arf6 GEF, ARNO, had no impact on adhesion. Together these results suggest that Arf6 regulates both integrin internalization and recycling and that BRAG2 selectively regulates the endocytic step.

**Probing Arf Guanine Nucleotide Exchange Factor (GEF) Specificity with Chimeric Proteins**

L. A. Cohen, J. G. Donaldson; Laboratory of Cell Biology, NHLBI, National Institutes of Health, Bethesda, MD

EFA6 and Arno are two Arf guanine nucleotide exchange factors (GEFs) which contain a sec7 domain that catalyzes nucleotide release from Arfs, allowing these proteins to cycle from an inactive GDP bound state to an active GTP bound conformation. How and whether this domain contributes towards specificity of the GEFs for particular Arf family members is not well understood. The EFA6 family of GEFs has been shown to be specific for Arf6, while the ARNO/cytohesin family of GEFs may act on both Arf1 and Arf6. To address whether the sec7 domain can determine specificity for particular Arf family members, and to address the significance of an exchange factor's specificity, we created chimeras replacing either the sec7 domain of ARNO with the sec7 domain of EFA6A (AEA) or replacing the sec7 domain of EFA6A with the sec7 domain of ARNO (EAE), and examined the function of these chimeras in cells. Co-expression of EFA6A and Arf6, but not Arf1, led to the formation of distinctive vacuolar structures, while co-expression of ARNO with either Arf6 or Arf1 did not. Co-expression of the AEA chimera with Arf6, but not Arf1, led to the accumulation, in some cells, of vacuoles similar to those formed in cells expressing EFA6A and Arf6. Interestingly, co-expression of the EAE chimera with either Arf6 or Arf1 led to an accumulation of these structures. These studies suggest that the sec7 domain itself dictates substrate specificity and that in some situations the backbone of the exchange factor, not the specificity of the exchange factor per se, is important in determining cellular outcome.

**Src-kinase Expression Inhibits Compensatory Endocytosis During Early Sea Urchin Development**

J. F. Covian-Nares, S. S. Vogel; National Institute of Alcohol Abuse and Alcoholism, National Institutes of Health (NIH), Rockville, MD

Tyrosine phosphorylation is an important regulatory mechanism for modulating the response of cells to external stimuli. In sea urchin embryos, Src family kinases (SFKs) regulate cell division (Hiriyanna et al., Exp. Cell Res. **216**: 21-29). In most cells, exocytotic activity is balanced by compensatory endocytosis to maintain cell surface area. Between the 8- and 32-cell stages of sea urchin development, endocytotic activity is down-regulated. This result in the net increase in embryonic cell surface area required for subsequent cell divisions (Frejtag et al., Dev Biol, 2003. **259**: 62-70). While the mechanism responsible for regulating this form of compensatory endocytosis is poorly understood, tyrosine-phosphatase inhibitors were found to block this form of endocytosis (unpublished results). The goal of the present study was to determine if over-expression of Src-kinase would also block compensatory endocytosis. We coinjected ***SpSK1*** (S*trongylocentrotus purpuratus* egg Src kinase) RNA (0.51 μg/μl), and fluorescent dextran (0.1 mg/ml, labeled with either tetramethylrhodamine or cascade blue) into single blastomeres of two-cell stage embryos of *L. variegatus* and compared subsequent cleavage patterns, and FM 1-43 uptake (4 μM), with that of their non-injected sister blastomeres (n=25).

Control embryos were injected with fluorescent dextrans only. As expected, SpSFK1 RNA injection inhibited cell division, while control blastomeres and uninjected sister blastomeres continued to divide. Two-Photon Microscopy revealed that SpSFK1 RNA injection arrested FM 1-43 uptake. Normal uptake was observed in non-injected sister blastomeres, and in control injected cells. These results suggest that the balance of tyrosine kinase and phosphatase activity during early development regulates compensatory endocytosis.

**A Confocal Microscopy Analysis of the Effect of Tyrphostin-8, a GTPase Inhibitor, on Transferrin Intracellular Pathways in Caco-2 Cells**

F. Norouziyan, W. C. Shen; Pharmaceutical Science, USC, Los Angeles, CA

The extent of transferrin receptor (TfR)-mediated transcytosis in cultured epithelial cell monolayers is usually very low due to the efficient recycling of TfR to the originated surface. However, transcytosis of transferrin (Tf) has been detected in several epithelial cell lines including Caco-2 cells. In this report, the effect of the GTPase inhibitor tyrphostin-8 (AG10), which has been shown previously to increase the transcytosis of Insulin-Tf conjugate in Caco-2 cells, was used to investigate the intracellular processing of endocytosed FITC-Tf in order to identify compartments involved in TfR-mediated transcytosis. Caco-2 cells grown on transparent filter membranes were pulsed with FITC-Tf, bound to the apical or basal cell membranes, in the presence and absence of AG10 at 37°C for 30 min. The cells were then fixed and labeled with an antibody against Rab11. The images were collected from different fields of the prepared slides by using a confocal laser scanning microscope. When FITC-Tf was bound to the apical surface of Caco-2 monolayers, a high level of perinuclear colocalization between FITC-Tf and Rab11 was observed. However, no significant colocalization between FITC-Tf and Rab11 was observed in cell monolayers that were pulsed with FITC-Tf bound to the basal surface. On the other hand, AG10 increased the colocalization of FITC-Tf and Rab11 with both apical and basal internalization. These results suggest that apically endocytosed Tf may reach an endosomal comopartment containing Rab11, which is not readily accessible from the basal endocytosis of Tf. However, AG10 can increase the transport of Tf to a Rab11-containing endosomal compartment from both the apical and the basal surface, suggesting the involvement of this compartment in transcytosis and slow-phase recycling of Tf in Caco-2 cells. **Intracellular Cholesterol Traffic in Macrophages upon Internalization of Aggregated LDL**

I. Grosheva,[1] F. R. Maxfield,[1] L. M. Pierini[2]; [1]Biochemistry, Weill Medical College, New York, NY, [2]Surgery, Weill Medical College, New York, NY

A critical event in the developing atherosclerotic lesion is accumulation of macrophages around sub-endothelial LDL deposits, which are typically large aggregates of LDL rather than monomeric LDL particles. Internalization and digestion of these lipoproteins by macrophages results in the transformation of macrophages into cholesterol overloaded “foam cells” that play a role in both early atherogenesis and late lesional events. In this study, the early events following contact between macrophages and aggregated LDL and the intracellular fate of LDL-derived free cholesterol were investigated. Two different model systems were used to study the interactions between macrophages and aggregated LDL: LDL-coated latex beads and LDL aggregates formed by vortexing of monomeric LDL. The use of LDL-coated latex beads allowed the quantification of free cholesterol specifically within the endocytic organelles containing the LDL-beads. Fluorescence imaging and digital image analysis of filipin-labeled samples was used to quantify the free cholesterol associated with LDL-bead-containing organelles. Using this approach, we determined the kinetics of free cholesterol association with the LDL-bead containing compartments both during and after LDL-bead internalization, and we evaluated the effects of various inhibitors on the trafficking of free cholesterol derived from the LDL-beads. These quantitative studies of cholesterol trafficking were conducted in parallel with EM visualization of phagosome ultrastructure, which revealed changes in LDL-containing compartments over time. The results obtained with LDL-beads were compared to those obtained with aggregates of LDL, and a model for the trafficking of free cholesterol derived from LDL aggregates is proposed. Our approaches to visualize and quantify cholesterol trafficking following LDL particle internalization will allow us to further elucidate the cellular processes involved in foam cell formation.

**Pyrene-labeled Sphingomyelins in Human Fibroblasts Exhibit Chain-length Specific Differences in Degradation, Recycling, Detergent Resistance and Lateral Distribution**

M. A. Koivusalo; Anatomy, Institute of Biomedicine, Helsinki, Finland

Sphingomyelin is an important structural component of mammalian cell membranes and the precursor for messenger molecules in a number of signalling pathways. In human fibroblasts the chain length of the *N*-linked acyl residue varies from 16 to 24 carbons but the significance of this structural variety is largely unknown. To address the significance of the SM acyl chain diversity we have here studied the behaviour of pyrene-labeled sphingomyelins ($Pyr_nSM$) of different pyrenylacyl chain lengths in living cells. Short-chain $Pyr_4SM$ and long-chain $Pyr_{12}SM$ were introduced into human fibroblasts as we have previously established their domain partitioning in model membranes. We found that the uptake of both lipids was rapid and that they were internalised into early sorting endosomes at a similar rate as assessed by fluorescence microscopy. After longer times, however, a larger fraction of $Pyr_{12}SM$ than of $Pyr_4SM$ resided intracellularly and was degraded into ceramide by lysosomal acid sphingomyelinase. These data suggest that $Pyr_4SM$ recycled preferentially to the plasma membrane while $Pyr_{12}SM$ was targeted to the late endosomal pathway. $Pyr_{12}SM$ associated with detergent resistant membranes more avidly than $Pyr_4SM$, in accordance with data from model membranes. The lateral organisation of $Pyr_nSM$ as well as the corresponding ceramides was investigated by monitoring their excimer to monomer fluorescence ratio (E/M) by microscopy in living cells. The data suggest that the E/M ratio of the long-chain probes was more sensitive to changes in membrane order than that of short-chain probes, presumably reflecting the difference in the transversal localisation of their pyrene moieties.

1228

**Cholesterol Mobilization By MLN64 START Domain**

M. Hölttä-Vuori, A. Mutka, E. Ikonen; Anatomy, University of Helsinki, Institute of Biomedicine, Helsinki, Finland

MLN64 is a late endosomal protein harboring a cholesterol-binding START domain. Here, we show that depletion of MLN64 results in the dispersion of late endosomes to the cell periphery. Overexpression of wild-type MLN64 is capable of rescuing the endosome dispersion in MLN64-

depleted cells while START domain mutants of MLN64 are not, suggesting a functional connection between MLN64 START-mediated sterol transfer and late endosome dynamics. Overexpression of MLN64 and especially the START domain alone has been shown to increase steroid hormone production in mitochondria (Watari et al. 1997, Proc. Natl. Acad. Sci. U.S.A. 94:8462-7). We provide evidence that in addition, overexpression of MLN64 increases the transfer of cholesterol to the ER for esterification. This effect is more pronounced upon expression of the START domain alone. The increase in cholesterol esterification is observed also in cells defective in NPC1 protein or incubated with the hydrophobic amine U18666A. These results suggest that when present in high amounts, MLN64 START domain is capable of transferring cholesterol between cellular pools, even bypassing low basal levels of cholesterol esterification characteristic to cells harboring late endosomal/lysosomal cholesterol accumulation.

**Differential Requirement of Sphingolipids for Various Clathrin-independent Endocytic Mechanisms**

Z. Cheng,[1] D. Sharma,[2] R. Singh,[1] E. Holicky,[1] K. Hanada,[3] D. Marks,[1] R. Pagano[1]; [1]Biochemistry and Molecular Biology, Mayo Clinic and Foundation, Rochester, MN, [2]Photometrics, Inc., Tucson, AZ, [3]Department of Biochemistry and Cell Biology, National Institute of Infectious Diseases, Tokyo, Japan

Sphingolipids (SLs) are plasma membrane constituents that are essential for membrane structure and organization. In the current study, the requirement of SLs for endocytosis was investigated. First, we showed that the uptake of cargo [lactosylceramide (LacCer), albumin, interleukin 2 receptors (IL-2R) and dextran] internalized by clathrin-independent endocytic mechanisms was inhibited by overall SL depletion in CHO cells using either a mutant cell line defective in SL biosynthesis or inhibitors of SL synthesis; however these treatments had no effect on clathrin-dependent endocytosis. Second, depletion of glycosphingolipids (GSLs), a subgroup of SLs, blocked caveolae-mediated endocytosis of LacCer, but had no effect on uptake of IL-2R or dextran, two markers internalized through non-caveolar mechanisms regulated respectively by RhoA and Cdc42. The inhibition of caveolar endocytosis by SL depletion could be overcome by acute treatment with GM3 ganglioside, but not by sphingomyelin. Additional experiments demonstrated that SL depletion inhibited the non-clathrin, non-caveolar endocytic mechanisms by inhibiting the targeting of RhoA and Cdc42 to the plasma membrane. This inhibition could be partially restored by incubating cells with sphingomyelin, but not GSLs or ceramide. These results provide the first evidence that SLs differentially regulate multiple mechanisms of clathrin-independent endocytosis. (Supported by USPHS Grant GM22942)

**Participation of Different Dynamin2 Spliced Variants in Distinct Endocytic Processes**

H. Cao, J. Henley, M. Awoniyi, M. A. McNiven; Center for Basic Research in Digestive Diseases and Department of Biochemistry and Molecular Biology, Mayo Clinic College of Medicine, Rochester, MN

The dynamin family of large GTPases has been implicated in a variety of different endocytic events, although its participation in the fluid phase endocytic process remains controversial. Multiple spliced-variants of the Dyn2 isoform have been identified in epithelial cells and predicted to participate in distinct membrane trafficking events. In this study, we test the role of Dyn2 in clathrin-mediated endocytosis (CME) as well as macropinocytosis and fluid-phase endocytosis in a variety of different mammalian epithelial cells. Inhibiting all forms of Dyn2 was first performed using microinjection of purified antibodies and siRNA knock-down of Dyn2. We find that microinjection of two different purified dynamin antibodies known to inhibit Dyn2 function, or siRNA knock-down of Dyn2, significantly reduces the internalization of transferrin in cells, as well as uptake of the fluid-phase marker dextran. In contrast, Dyn2 antibody-injected or Dyn2 knock-down epithelial cells, grown in high serum or treated with EGF to stimulate the macropinocytotic pathway, internalize substantial amounts of fluid dextran. Following these broad blocks of Dyn2 function, we tested if a specific Dyn2 variant form might selectively support fluid uptake in cells. Expression of four different Dyn2 variants (aa, ab, ba and bb) reveals distinct cytoplasmic localizations and, when mutated, differentially attenuate the internalization of dextran and transferrin. Interestingly, the wt Dyn2ba form accentuates fluid uptake by more than 20% compared to mock transfected cells, while the Dyn2baK44A GTPase mutant reduces dextran uptake by 60%. Other Dyn2 forms had little affect on fluid phase endocytosis. These findings suggest that Dyn2 function is required for the uptake of fluid dextran in a variety of epithelial cells by endocytic pathways distinct from the macropinocytotic process while implicating distinct spliced variants in specific endocytic functions.

1231

**Surface Downregulation of ErbB2 by Antibody Crosslinking Involves an Unusual Endocytic Pathway**

A. M. De Mazière,[1] C. D. Austin,[2] S. M. van Dijk,[1] J. Klumperman,[1] R. H. Scheller[2]; [1]Department of Cell Biology, University Medical Center Utrecht, Utrecht, The Netherlands, [2]Genentech Inc., South San Francisco, CA

ErbB2 is an oncogenic member of the EGFR family of receptor tyrosine kinases and is overexpressed in 20-30% of human breast cancers. ErbB2 heterodimerizes with EGFR to potentiate its mitogenic signaling, partly through diversion from EGF-induced surface receptor downregulation. Trastuzumab and pertuzumab are humanized monoclonal anti-ErbB2 antibodies that inhibit tumor cell growth in vitro and in vivo without downregulating surface ErbB2 (1). Our aim was next to establish the endocytic pathway involved in downregulation of ErbB2 by crosslinking. We find that antibody crosslinking of trastuzumab or pertuzumab triggers ErbB2 surface downregulation through both induced endocytosis and altered endosomal sorting. Immunogold labeling of ultrathin cryosections revealed clusters of crosslinked ErbB2 within unusual endocytic profiles, distinct from typical clathrin-coated pits or caveolae, after only a few minutes of incubation. These structures appeared as narrow, deep tubules or folds, occasionally with a clathrin-coated pit at the bottom. After longer incubations, similar tubules were clustered adjacent to and occasionally fused with early endosomal vacuoles, positive for Hrs and poor in LAMP-1. Ultimately, crosslinked complexes appeared to be sorted to internal vesicles of multivesicular bodies. Antibody uptake kinetics in cells expressing mutant forms of ErbB2 suggested that crosslinking-induced downregulation involves ErbB2 kinase-dependent acceleration of endocytosis as well as cytoplasmic domain-dependent, kinase-independent endosomal sorting. These results support the idea that ErbB2 has dormant trafficking determinants that mediate surface downregulation after antibody crosslinking through an unusual endocytic pathway. ### Transferrin Regulates the Trafficking of Transferrin Receptor 2 in Hepatoma Cells

M. B. Johnson, C. A. Enns; Cell & Developmental Biology, Oregon Health & Science University, Portland, OR

Transferrin receptor 2 (TfR2) is a homologue of the classical transferrin receptor (TfR1). TfR2 is predominantly expressed in the liver. Like TfR1, TfR2 binds diferric transferrin ($Fe_2Tf$), a serum protein that delivers iron to cells, but with 30-fold lower affinity. Interestingly, mutation or knockout of TfR2 results in the iron overload disease hereditary hemochromatosis (HH), suggesting that TfR2 functions in iron homeostasis rather than iron delivery. We have previously shown that $Fe_2Tf$ regulates TfR2 protein stability at physiologically relevant concentrations. The finding suggests that trafficking of TfR2 may be regulated by its ligand and important for its function. We have studied the localization and trafficking of TfR2 in HepG2 hepatoma cells that endogenously express TfR2 and in Hep3B hepatoma cells stably transfected with TfR2. Western blot analysis shows that treatment of HepG2 cells with bafilomycin, an inhibitor of lysosomal degradation, increases TfR2 levels, indicating that TfR2 is degraded by the lysosome, whereas treatment with proteosomal inhibitors does not effect TfR2 levels. Confocal microscopy studies show that TfR2 partially colocalizes with EEA1 and TfR1 in early and recycling endosomes. Treatment with $Fe_2Tf$ increases the fraction of TfR2 present in recycling endosomes. In nonpermeabilized Hep3B/TfR2 cells, TfR2 is also visible at the plasma membrane. Differential immunoprecipitation of cell surface and intracellular TfR2 from Hep3B/TfR2 cells 48 hours after seeding indicates that TfR2 distributes equally between intracellular compartments and the cell surface. The mutation Y23A in the cytoplasmic domain of TfR2 increases the proportion of TfR2 localizing to the cell surface, suggesting that the YQRV sequence in the cytoplasmic domain may serve as an endocytic motif. These results indicate that TfR2 most likely internalizes through a tyrosine-based motif and that Tf stabilizes TfR2 by altering its trafficking in hepatoma cells.

## Protein Targeting to the Cell Surface (1233-1246)

1233

### Utilizing the Power of Yeast Genetics to Search for Proteins that Regulate the Intracellular Fate of Secretory IgM μs Heavy Chains

G. Nadel, M. Mayrose, O. Burdelova, S. Bar-Nun; Biochemistry, Tel-Aviv University, Tel-Aviv, Israel

The mechanisms that control the developmentally regulated secretion and degradation of secretory IgM are not yet fully understood. The C-terminus of μs heavy chain and its penultimate Cys575, designated μstpCys, functions in B-cells as a *cis*-acting retention signal (Sitia et al. 1990 *Cell* **60,** 781-790). This motif is also sufficient to confer retention and degradation onto several reporter proteins in lymphoid and non-lymphoid mammalian cells. However, *trans*-acting cellular components that contribute to μs retention remain elusive. The remarkable conservation of the secretory pathway from yeast to man intrigued us to ask whether this μstpCys motif could confer retention also onto yeast secretory proteins. Hence, the μstpCys and its mutant inactive form μstpSer were grafted onto the C-terminus of invertase and secretion of this chimeric protein from *Saccharomyces cerevisiae* was followed by its enzymatic activity, or directly from spheroplasts using immunoblotting assays. Yeast neither synthesize immunoglobulins nor μstpCys is found in the yeast genome. Nonetheless, μstpCys, but not μstpSer, conferred cellular retention onto invertase. Although the retained invertase-μstpCys was not degraded, it was dislocated back to the cytosol. The crucial involvement of the penultimate cysteine, together with the stimulating effect of β-mercaptoethanol exclusively on the secretion of invertase-μstpCys, focused us on ER thiol-oxidoreductases. In *eug1Δ* strain, lacking the human protein disulfide isomerase homolog Eug1p, the increased secretion of invertase-μstpCys matched the unaffected secretion of invertase-μstpSer. It indicates that Eug1p contributes to μstpCys-mediated retention, although its mode of action remains to be elucidated. We conclude that the molecular mechanisms underlying secretory IgM secretion can be studied in yeast, exploiting its well characterized genetics.

1234

### Sar1 Regulates the Intracellular Transport of Kv111 Early in the Secretory Pathway

B. P. Delisle, J. K. Slind, J. A. Kilby, B. M. Moungey, H. A. S. Underkofler, J. D. Foell, R. C. Balijepalli, T. J. Kamp, C. T. January; Medicine and Physiology, University of Wisconsin-Madison, Madison, WI

Voltage-gated $K^+$ (Kv) channels are essential components of sarcolemmal excitability, and mutations in Kv genes that disrupt the transport of Kv channels in the secretory pathway are associated with several diseases. The molecular mechanisms that govern the intracellular transport (trafficking) of Kv channels in the secretory pathway are unknown. The Sar1-GTPase (Sar1) regulates the transport of proteins out of the Endoplamic Reticulum in coat protein II (COPII) vesicles. Sar1 was cloned using human heart cDNA and was used to generate the dominant negative Sar1[H79G] mutation. We determined the effect of co-expressing Sar1 or Sar1[H79G] and the *human Ether-a-go-go-Related Gene*-encoded $K^+$ channel (Kv11.1) in Human Embryonic Kidney (HEK) 293 cells. Western blot analyses of cells expressing Kv11.1 alone or co-expressing Sar1 demonstrated two distinct Kv11.1 protein bands, a 135kDa protein band that corresponds to the MW of core-glycosylated Kv11.1 and a 155kDa protein band that corresponds to complex-glycosylated Kv11.1. Western blot analyses of cells co-expressing Kv11.1 and Sar1[H79G] demonstrated only the 135kDa core-glycoyslated protein band. We modified the carboxy-terminal of Sar1 to contain a poly-histidine tag (Sar1-poly-his). In cells co-expressing Kv11.1 and Sar1-poly-his, anti-Kv11.1 and anti-poly-his antibodies co-immunoprecipitated Sar1-poly-his and core-glycosylated Kv11.1 respectively. To determine the effect of co-expressing Sar1 or Sar1[H79G] on the sarcolemmal expression of Kv11.1, the peak Kv11.1 current ($I_{Kv11.1}$) was measured in cells expressing Kv11.1 alone, Kv11.1 and Sar1, or Kv11.1 and Sar1[H79G]. Compared to cells expressing Kv11.1 alone, co-expression of Sar1 did not alter the mean peak $I_{Kv11.1}$ (126±29pA/pF and 161±49pA/pF respectively, n=4 each, $p>0.05$). Compared to cells expressing Sar1, co-expression of Sar1[H79G] reduced the mean peak $I_{Kv11.1}$ by 95% (8±4pA/pF, n=4, $p<0.05$). We conclude that Sar1 mediates the trafficking Kv11.1 in the early stages of the secretory pathway.

1235

### Surface Expression of Membrane Proteins Directed by a Novel Group of 14-3-3 Binding Motifs

B. Coblitz,[1] S. Shikano,[1] M. Wu,[1] S. B. Gabelli,[2] L. M. Cockrell,[3] Y. Hanyu,[4] H. Fu,[3] L. M. Amzel,[2] M. Li[1]; [1]Dept. of Neuroscience and HiT Center, Johns Hopkins University, Baltimore, MD, [2]Dept. of Biophysical Chemistry, Johns Hopkins University, Baltimore, MD, [3]Dept. of Pharmacology, Emory University School of Medicine, Atlanta, GA, [4]Institute for Biological Resources and Functions, National Institutes of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan

Dimeric 14-3-3 proteins usually recognize phosphate-specific peptide motifs. With more than two hundred reported interacting proteins, 14-3-3 has been implicated in a range of functions including regulation of subcellular localization. Using a genetic selection, we have identified a group of C-terminal 14-3-3 binding motifs, termed SWTY, which are capable of overriding the strong ER localization signal RXR and redirecting expression on the cell surface. Because the canonical consensus binding motifs of modes I and II are internal, a C-terminal binding consensus, mode III, represents an expansion of the repertoire of 14-3-3-targeted sequences. We report a series of biochemical and mutagenesis studies to investigate the mode III interaction and its function in plasma membrane localization. Because mode III sequences have been found in native proteins, these results support a broad significance of 14-3-3 interaction with protein C-termini.

1236

**Regulation of the RabGAP AS160 by Interaction with 14-3-3 and GLUT4 Vesicle Cargo**

G. Ramm, M. Larance, J. Stockli, D. James; Diabetes and Obesity, Garvan Institute of Medical Research, Sydney, Australia

Insulin stimulates the translocation of the glucose transporter GLUT4 from intracellular vesicles to the plasma membrane. Akt-dependent phosphorylation of AS160, a member of the RabGAP/TBC family, has been implicated in this process. Purification of intracellular GLUT4 vesicles and subsequent LC MS analysis revealed the association of AS160 with GLUT4 vesicles. Based on morphological and biochemical criteria, IRAP and Vamp2 are the only other membrane protein constituents in those vesicles. We find that AS160 directly associates with the cytosolic tail of IRAP with high affinity and this facilitates its interaction with GLUT4 vesicles, from which it is released into the cytosol upon phosphorylation. Insulin stimulation of AS160 phosphorylation resulted in binding of AS160 to 14-3-3 proteins. Co-expression of constitutively active Akt and AS160 in CHO cells caused insulin-independent association of AS160 and 14-3-3, implicating a role for Akt in this process. The interaction site was mapped to Thr 642, a known Akt phosphorylation site in AS160. In contrast to AS160WT, an AS160T642A mutant no longer bound 14-3-3 in the presence of insulin and overexpression of this mutant in adipocytes is known to inhibit insulin-stimulated GLUT4 translocation, but to a lesser extent than a mutant lacking three additional Akt phosphorylation sites AS1604P. Preliminary studies indicate that restoration of 14-3-3 binding to this AS160 mutant independently of phosphorylation reversed the inhibitory effect on GLUT4 translocation. Fractionation studies showed that the AS160T642A mutant, in contrast to the AS1604P mutant, underwent insulin-dependent translocation into the cytosol similar to wtAS160. These data suggest a mechanism whereby multiple phosphorylation sites regulate different aspects of AS160 function likely involving either its association with GLUT4 vesicles and/or its GAP activity. This could denote a novel mechanism for protein sorting in eukaryotes regulating cargo RabGAP interaction.

1237

**Akt-phosphorylation Is a Switch for Swty Signals to Direct Cell Surface Expression of Membrane Proteins**

J. L. Chung, S. Shikano, M. Li; Neuroscience and High Throughput Biology Center, Johns Hopkins School of Medicine, Baltimore, MD

Regulated trafficking of receptor proteins is important in controlling many biological processes. SWTY motif represents a novel class of C-terminal transport signals that are capable of overriding ER localization activity and directing protein expression to the cell surface. Phosphorylation-dependent recruitment of 14-3-3 proteins by the SWTY motif is required for SWTY-mediated potentiation of cell surface expression. However, the identity of kinase(s) that phosphorylate the SWTY sequence is unknown. In the present study, we characterize a role for Akt-mediated phosphorylation of SWTY to confer the interaction with 14-3-3. We also report a series of biochemical and cell biology studies to investigate Akt signaling pathway in regulating surface expression via the SWTY motif. Our data suggests that Akt serves as a phosphorylation switch for the SWTY signal to direct membrane proteins to cell surface.

1238

**Targeting Signals in Myelin P0 Protein are Interpreted Differently in MDCK Cells and Neurons**

P. Huang,[1] V. K. Yadav,[2] S. Low,[3] T. Weimbs,[3] B. D. Trapp,[1] G. J. Kidd[1]; [1]Neurosciences, Lerner Institute, Cleveland, OH, [2]Agricultural Research Station, Durgapura, India, [3]Molecular, Cellular, and Developmental Biology, University of California Santa Barbara, Santa Barbara, CA

In myelinating Schwann cells, P0 protein is specifically targeted to compact myelin membrane domains and is not detected in other Schwann cell membranes. To determine the molecular basis for P0 targeting we expressed truncated and mutated forms of P0 in MDCK cells. These experiments identified a region of the cytoplasmic C-terminal that was necessary and sufficient for targeting to the basolateral surface. Alanine substitutions identified the main targeting signal as a dual tyrosine-leucine based motif (YAML), in which the tyrosine was essential and the ML motif functional but not necessary. Experiments substituting EGFP for the P0 extracellular domain indicated that secondary apical targeting information was also present in the P0 extracellular domain. To determine whether the tyrosine-based motif predominated in P0 targeting in other polarized cells, we expressed P0 and EGFP-P0 mutated proteins in hippocampal neurons in culture. While many basolaterally targeted proteins in MDCK cells are restricted to the somatodendritic compartment of neurons, P0 was consistently detected in both dendrites and axonal membranes by confocal microscopy. Mutations to the tyrosine motif did not alter P0 distribution. EGFP-P0 chimeras were restricted to the neuronal ER. These data indicate that P0 contains a hierarchy of targeting signals that are utilized differently in different polarized cells.

1239

**The Cysteine-Rich Domain of the Secreted Proprotein Convertases PC5A and PACE4 Functions as a Cell Surface Anchor through Interaction with Tissue Inhibitors of Metalloproteinases**

G. Mayer,[1] N. Nour,[1] J. S. Mort,[2] C. M. Overall,[3] N. G. Seidah[1]; [1]Biochemical Neuroendocrinology, Montreal Clinical Research Institute, Montreal, PQ, Canada, [2]Joint Diseases Laboratory, Shriners Hospital for Children, Montreal, PQ, Canada, [3]Oral Biological and Medical Sciences, University of British Columbia, Vancouver, BC, Canada

The proprotein convertases PC5, PACE4 and furin contain a C-terminal cysteine-rich domain (CRD) of unknown function. We demonstrate that the CRD confers to PC5A and PACE4 properties of protein-protein interactions and cell surface tethering. Confocal microscopy and biochemical analysis revealed that the CRD is essential for cell surface localization of PC5A and PACE4 and that it co-localizes and co-immunoprecipitates with the full length and C-terminal domain of the tissue inhibitor of metalloproteinases-2 (TIMP-2). Moreover, in TIMP-2 null fibroblasts PC5A is not retained at the cell surface unless TIMP-2 is re-introduced by co-expression, indicating that the formation of a complex between both proteins

is requisite for plasma membrane anchorage of the convertase. Further analysis revealed that both PC5A and PACE4 can bind different sets of TIMP family members and that PC5A binds TIMP-3 in the extracellular matrix. In addition, to extend the relevance of proprotein convertases and TIMPs interaction towards the realm of a whole animal, PC5A and TIMP-2 are shown to be expressed in the small intestine and liver and to co-localize over the surface of enterocytes of the villi and crypts found in the duodenum and jejunum, as well as in liver sinusoids. In conclusion, the CRD of PC5A and PACE4 may represent a nucleation point favoring formation of complexes with TIMPs which could have a direct impact on the cell surface interaction of these convertases with their cognate substrates including lipoprotein and endothelial lipases and possibly matrix metalloproteases.

1240

**Interferon-gamma Promotes Membrane Retention of NHE1 and Associated Proteins Ezrin, Radixin and Moesin via STAT1 in HT-29 Cells**

F. Magro, S. Fraga, P. Soares-da-Silva; Inst. Pharmacol. Ther., Faculty of Medicine, Porto, Portugal

This study evaluated the effect of interferon-γ (IFN-γ) upon the function and expression of type 1 $Na^+/H^+$ exchanger (NHE1) in human intestinal epithelial HT-29 cells, namely that concerning the abundance of surface NHE1 and NHE1 binding to the ezrin, radixin, and moesin (ERM) family of proteins. HT-29 cells express endogenous NHE1 and the ERM family of proteins that retain the localization of NHE1 in the membrane. Long-term exposure (24 h) of HT-29 cells to IFN-γ resulted in a concentration dependent decrease in NHE1 activity. Inhibition of NHE1 activity by IFN-γ was absent after pretreatment with cariporide. The long-term exposure to IFN-γ was accompanied by increase in surface NHE1 and ERM abundance and no changes in total NHE1 and ERM abundance. Inhibition of STAT1 with epigallocatechin-3-gallate (EGCG) prevented the inhibitory effect of IFN-γ. Treatment with IFN-γ activated phospho-STAT1 was markedly attenuated by EGCG. The IFN-γ-induced increase in surface NHE1 and ERM abundance was prevented by EGCG. In conclusion, long-term inhibition of NHE1 activity by IFN-γ involves STAT1 phosphorylation and is accompanied by increased abundance of surface NHE1 and the NHE1 membrane anchoring ERM proteins.

1241

**Calcineurin Homologous Protein (CHP) Regulates $Na^+/H^+$ Exchanger-3 (NHE3) Apical Delivery in Epithelial Cells**

F. Di Sole,[1,2] V. Babich,[3,2] O. W. Moe[2]; [1]Cell and Molecular Biosciences, University of Newcastle upon Tyne, Newcastle upon Tyne, United Kingdom, [2]Internal Medicine, Nephrology Division, University of Texas Southwestern Medical Center, Dallas, TX, [3]Molecular Neuroendocrinology, National Institute for Medical Research, London, United Kingdom

Asymmetric membrane transporters delivery is an essential function in polarised cells. CHP is a widely expressed and evolutionary conserved $Ca^{2+}$-binding protein required for constitutive membrane traffic. CHP binds the apical transmembrane protein NHE3, a key mediator of net sodium and fluid balance in intestinal and renal epithelia. We have recently shown that this binding regulates NHE3 function in response to adenosine; here, we report a key role of CHP in NHE3 apical translocation. In opossum kidney (OK) cells, NHE3 is located in apical clusters where it associates with F-actin filaments. CHP co-localizes with NHE3 in the clusters (immunofluorescence). Overexpression of CHP increases both NHE3 activity (microfluorimetry) and apical surface NHE3 antigen (biotinylation assay) by 50%. Knockdown of CHP by siRNA inhibits NHE3 activity and reduces apical surface NHE3 antigen by 50%. CHP knockdown also decreases NHE3 cluster formation and F-actin polymerization. In order to examine the contribution of CHP-NHE3 binding to the process, GFP tagged NHE3 mutant lacking CHP binding region ($NHE3^{\Delta 462\text{-}552}$) was expressed in OK cells. $NHE3^{\Delta 462\text{-}552}$ does not show the typical apical membrane targeting seen in wild type NHE3 but localized uniformly in the cytoplasm, suggesting that lack of the CHP-NHE3 interaction induces mistargeting of NHE3 to the apical membrane. Consistent with a central role for ezrin-dependent NHE3 translocation, overexpression of CHP clearly induces a strong increase in phospho-ezrin (immunofluorescence and SDS-PAGE) without changes in total ezrin. CHP knockdown dramatically reduces phospho-ezrin (immunofluorescence and SDS-PAGE). In conclusion, CHP plays a critical role in NHE3 delivery to the apical membrane and its clustering organization. Ezrin phosphorylation may mediate the CHP-induced NHE3 apical translocation.

**Curcumin Increases the CFTR Expression by Down-Regulating Calreticulin, a Negative Regulator of CFTR**

K. Harada,[1] T. Okiyoneda,[1] Y. Hashimoto,[1] K. Ueno,[1] K. Nakamura,[2] K. Yamahira,[1] T. Sugahara,[1] T. Shuto,[1] I. Wada,[3] M. S. Suico,[1] H. Kai[1]; [1]Molecular Medicine, Faculty of Pharmaceutical Sciences, Kumamoto, Japan, [2]Pediatrics, Faculty of Medical and Pharmaceutical Sciences, Kumamoto, Japan, [3]Cell Science, Fukushima Medical University School of Medicine, Fukushima, Japan

Cystic fibrosis (CF), the most common lethal genetic disease in Caucasians, is caused by the mutation of CFTR, which functions as a cAMP-dependent $Cl^-$ channel at the plasma membrane of epithelial cells. The most common mutant of CFTR in CF patients, ΔF508 CFTR, has a trafficking defect from the ER although it can function as a $Cl^-$ channel, if expressed at the plasma membrane. Thus, rescue of ΔF508 CFTR from ER retention is a potential therapeutic strategy for CF. Recently, it was reported that curcumin corrects the defective trafficking of CFTR mutant (ΔF508). However, the effect of curcumin is under debate and its mechanism of action remains unknown. Here, we show that curcumin down-regulates an ER chaperone, calreticulin (CRT), which is a novel negative regulator of CFTR trafficking, leading to the increase of CFTR expression. Moreover, curcumin and CRT knockdown significantly enhanced the function of ΔF508 CFTR rescued by 26°C incubation. These results indicate that curcumin stimulates the trafficking of rescued ΔF508 CFTR to the plasma membrane by decreasing CRT, a negative regulator of CFTR. These findings have important implications in developing therapeutic approaches that target the trafficking of CFTR.

1243

**Hypotonicity Induces Actin Remodeling Associated with Aquaporin-2 Internalization and Cytosol to Membrane Translocation of ICln in Collecting Duct Renal Cells**

G. Tamma,[1] G. Procino,[1] A. Strafino,[1] M. Paulmichl,[2] M. Svelto,[1] G. Valenti[1]; [1]Department of General and Environmental Physiology, University of Bari, Bari, Italy, [2]Department of Biomolecular Science and Biotechnology, University of Milan, Milan, Italy

Kidney tubule cells are subjected to a significant transepithelial osmotic gradient and have a strong requirement for cell volume regulatory mechanisms. ICln is essential for the generation of ion currents activated during regulatory volume decrease after cell swelling (RVDC). Hypotonic

treatment (100 mOsm, 10 min) lead to a significant transposition of ICln to the cell membrane while increased the amount of AQP2 localized intracellularly. Interestingly, the total amount of AQP2 phosphorylated at ser-256, decreased significantly after hypotonic shock. Since the cAMP dependent protein kinase A (PKA), is committed to phosphorylate AQP2, we next examined the spatio-temporal intracellular dynamics of cAMP using fluorescence resonance energy transfer (FRET) technique in living cells. Interestingly we found that hypotonic stress caused decreased concentration of cAMP. Moreover, FRET analysis and co-immunoprecipitation experiments revealed that hypotonicity increased the interaction of ICln with actin, which might be important for its insertion into the membrane. Hypotonicity caused a deep actin reorganization, consisting in the loss of stress fibers and the formation of F-actin patches at the cell border. The expression of the dominant negative of Cdc42 (N17-Cdc42) suppressed the hypotonicity-induced microspikes formation at the cell border suggesting that Cdc42 principally regulates actin rearrangement. Hypotonic treatment activated LIMK1, a known downstream effectors of Cdc42, and increased the phosphorylation of the ADP-depolymerization factor cofilin, a known downstream effector of LIMK1. Phosphorylation inactivates cofilin, resulting in formation of F-actin patches at the cell border. Together these data demonstrate that hypotonicity causes a deep actin remodeling, increases the total amount of AQP2 localized intracellularly, and activates translocation of ICln to the plasma membrane. All these effects may contribute to regulatory volume decrease after hypotonicity induced cell swelling in renal medulla.

1244

**Kv21 K+ Channels Form Dynamic Cell Surface Microdomains That Are Sites For Membrane Insertion**

K. M. S. O'Connell, A. S. Rolig, M. M. Tamkun; Biomedical Sciences, Colorado State University, Fort Collins, CO

Voltage-gated $K^+$ (Kv) channels play a key role in establishing the resting membrane potential, shaping action potential repolarization and regulating spike frequency in nerve and muscle. These channels are often targeted to specific cell regions where they are assembled into signaling complexes. However, little is known about how these channels are transported to the membrane or about their behavior once they arrive. Using fluorescent protein tagged channels, FRAP and time lapse confocal microscopy, we show that the delayed rectifier Kv2.1 is preferentially inserted in specific regions of the HEK cell plasma membrane. These regions, which range in size from 0.1 $\mu m^2$ to > 7 $\mu m^2$ (avg = 0.86 ± 0.1 $\mu m^2$), are dynamic, often fusing and breaking apart over several minutes. Channels were delivered to these surface clusters via small intracellular transport vesicles that were observed fusing with preexisting cluster domains. Once inserted into a cluster, channel moved freely within that domain. The inability of channel to cross the cluster boundary is reminiscent of the “picket fence” model of membrane diffusion barriers. Kv2.1 containing surface clusters were similar in appearance to cholera toxin (Ctx) labeled GM1-ganglioside enriched lipid rafts, however the Kv2.1 clusters rarely internalized over the time course of Ctx internalization, nor was there any colocalization between the two domains. Cholesterol depletion with 2-hydroxypropyl-cyclodextrin decrease Kv2.1 mobility within the cluster ($\tau_{con}$ = 14.1 s vs. $\tau_{CD}$ = 53.1 s) and slowed cluster dynamics within the entire plasma membrane. However, Kv2.1 cluster domains were resistant to detergent solubilization under conditions expected to disrupt raft lipid (0.2% TX-100 + 7.5 mM octylglucoside at 30°C). Therefore, Kv2.1-containing surface clusters appear to be specialized microdomains for membrane insertion whose maintenance is likely a combination of protein-lipid and protein-protein interactions.

1245

**Plasma Membrane Association of K-ras4B is Dynamic**

J. R. Silvius, P. Bhagatji, R. Leventis, D. Terrone; Biochemistry, McGill University, Montréal, PQ, Canada

We have adapted the phenomenon of rapamycin-induced protein heterodimerization, originally exploited by Schreiber and colleagues as a ‘chemical switch,’ to investigate the kinetics of association of lipid-modified proteins with their target membranes in living cells. Lipidated fluorescent protein constructs that incorporate a rapamycin-dependent heterodimerization domain, and that are reversibly anchored to various cellular membranes, translocate from these membranes to mitochondria upon addition of rapamycin to cells coexpressing a mitochondrial outer membrane protein that incorporates a complementary heterodimerization domain. By quantitative image analysis the kinetics of the translocation process, and thereby the rates of dissociation of the fluorescent proteins from their normal target membranes, can be determined. Using this approach we show that singly-lipidated proteins lacking additional membrane targeting determinants can very rapidly redistribute between different cellular membranes, while analogous constructs bearing multiple lipid groups (S-prenyl or N-myristoyl plus S-acyl residues), show much slower rates of redistribution, with kinetics that appear to reflect the rates of turnover of the protein-linked S-acyl residues. Interestingly, we find that fluorescent fusion constructs incorporating full-length K-ras4B, constitutively activated or activation-resistant mutants of this protein or the prenylated/polybasic K-ras4B plasma membrane-targeting sequence alone are reversibly associated with the plasma membrane and can redistribute from the plasma membrane to mitochondria with halftimes of the order of a few minutes. The dynamic nature of the plasma membrane targeting of K-ras4B could in principle contribute additional versatility to the function of this protein, as does the acylation/deacylation-dependent redistribution of H- and N-ras between different cellular compartments. The novel method described here may offer a valuable alternative to fluorescence-photobleaching/photoactivation methods to investigate the dynamics of association of proteins with cellular membranes, particularly for proteins that are reversibly but very strongly associated with their target membranes. (Supported by the Canadian Institutes of Health Research).

**Subcellular Localization and Signaling Roles of Human Ras Superfamily Small Gtpases**

W. D. Heo, T. Meyer; Molecular Pharmacology, Stanford, Palo Alto, CA

The proteome of mammalian cells is largely built from protein families with individual members carrying out specific cellular tasks. Here we focus on the question of how the Ras superfamily regulate different signaling processes by cloning 142 human small GTPases and generating constitutively active and dominant forms for each of them. We first analyzed the subcellular localization of the wild-type and constitutively active forms of each small GTPases in HeLa and NIH3T3 and identified 48 small GTPases that are at least partially localized to plasma membrane (PM). Based on their PM localization and localization motifs, we classified them into four groups and characterized the localization mechanisms for each of the groups. Three of the groups included polybasic regions and we focused therefore on the role of these C- and N-terminal polybasic motifs as the most common mediators of the PM localization. Our initial studies suggest that electrostatic interaction with the PM, presumably by binding to phosphatidylserine, and not binding to $PI(4,5)P_2$ lipids is responsible for the PM targeting. In addition to the localization study, we also investigated the activation of PI3kinase by co-expressing a $PIP_3$ biosensor (Akt-PH domain) with each of the constitutively active human small GTPase. We

identified over 30 small GTPases that activate the PI3K pathway and explored whether some of them may participate in a positive feedback loop as has been suggested for Rac and CDC42. Using experiments in which we used dominant negative small GTPases and the PI3K inhibitor LY294002, we now identified a number of additional small GTPases that may participate up-stream and within such a positive feedback loop. Together, both these projects provide us with a better understanding of how functional specificity has evolved within a large family of signaling proteins.

## Protein Folding & Assembly in the Endoplasmic Reticulum I (1247-1259)

1247

### The Recognition of a Dibasic Degradation Motif at the Endoplasmic Reticulum

A. Ray, S. High; Faculty of Life Sciences, University of Manchester, Manchester, United Kingdom

Misfolded proteins that fail to pass the Endoplasmic Reticulum (ER) Quality Control system are ultimately delivered to cytosolic proteasomes for degradation by the ER-associated degradation (ERAD) pathway. Key events during ERAD include: substrate selection, retro-translocation and proteolysis of the misfolded proteins. The degron is a dibasic amino acid motif located within the hydrophobic transmembrane domain of some membrane proteins, such as TCR-α, and has been shown to target so called 'orphan' subunits and mis-assembled complexes for cellular degradation. The degron is masked when the subunits are correctly assembled into authentic oligomeric complexes at the ER. The ability of the degron to promote degradation is well documented, but the molecular basis for its recognition, and the route by which this substrate is delivered to the degradation pathway are unknown. The aim of this study is to investigate in detail the molecular mechanism underlying degron function. In this study, we have used both *in vivo* and *in vitro* techniques to investigate the effects of the degron when it is introduced into a model polytopic membrane protein, bovine opsin. Electron microscopy and immunofluorescence data indicates that wild type opsin is correctly sorted to the cell surface, whilst a degron mutant is retained within the ER, consistent with its targeting for degradation. Pulse Chase analysis indicates that the opsin degron mutant is degraded and that this process is mediated by proteasomes. Therefore the insertion of a degron into a polytopic membrane protein leads it to its specific ER retention and degradation via a route that closely resembles that used by the TCR-α subunit. The use of cross-linking has begun to reveal differences in the membrane environment resulting from the introduction of the degron.

### Retro-translocation of a Fluorescent-labeled ERAD Substrate through the ER Membrane *in vitro* Requires ATP and both Lumenal and Cytosolic Proteins

J. Wahlman,[1] W. R. Skach,[2] J. L. Brodsky,[3] A. E. Johnson[4]; [1]Department of Biochemistry and Biophysics, Texas A&M University, College Station, TX, [2]Division of Molecular Medicine,, Oregon Health Sciences University, Portland, OR, [3]Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA, [4]Department of Biochemistry and Biophysics, Chemistry, Medical Biochemistry & Genetics, Texas A&M University, College Station, TX

Endoplasmic reticulum-associated degradation (ERAD) involves the recognition of misfolded proteins in the endoplasmic reticulum (ER) lumen and their transport back to the cytosol for degradation. A number of proteins have been proposed to participate in this process, but the exact role of each has been difficult to establish. We have therefore created an *in vitro* system to assess the contributions of individual components to retro-translocation. After canine pancreatic microsomes were treated with high pH to release their lumenal contents, the extracted microsomes were reconstituted with a fluorescent-labeled ERAD substrate, the non-glycosylated yeast mating pheromone (Δgpαf), and either total lumenal proteins or some combination of individual purified lumenal proteins (e.g. BiP, PDI, etc.). The reconstituted microsomes containing encapsulated BODIPY-Δgpαf were then incubated in the presence of BODIPY-specific antibodies, and in the presence or absence of reticulocyte lysate, nucleotides, or various purified cytosolic components. Since the BODIPY fluorescence intensity is quenched about 80% by its binding to the antibody, the release of the encapsulated BODIPY-Δgpαf from the interior of the microsomes can be followed as a function of time by monitoring the reduction of BODIPY emission. In the presence of reticulocyte lysate, ATP, and total lumenal proteins more than 60% of the BODIPY-Δgpαf is retro-translocated within 30 minutes at 30 $^{\circ}$C under our *in vitro* conditions. In the absence of any of these components, only background exposure of encapsulated BODIPY-Δgpαf to the cytosolic antibody is observed. This novel spectroscopic approach therefore reveals the real-time rate of retro-translocation and its dependence upon molecules on both sides of the mammalian ER membrane. The importance of various lumenal and cytosolic components is now being determined. (Supported by NIH grant GM26494 and the Welch Foundation).

1249

### Monitoring the ER Luminal and the Cytosolic Face of the ERAD Substrate CD3delta

H. Lorenz, J. Lippincott-Schwartz; CBMB, NIH, NICHD, Bethesda, MD

Proteins of the secretory pathway, which fail to pass quality control are retrotranslocated from the endoplasmic reticulum into the cytosol and eventually degraded by the proteasome. This process is called ER-associated degradation (ERAD). Here, we examined the fate of both the luminal and cytosolic domains of the well-described ERAD substrate CD3delta using a new live cell imaging strategy. Different fluorescent proteins were placed simultaneously at the N- and C-terminus of CD3delta. By doing so, the protein's fate on both sides of the ER membrane can be observed in live cells. Furthermore, because a fluorescent protein's ability to fluoresce depends upon its proper fold, information about the folding state on either side of the membrane can be obtained. Using this chimera, we were able to demonstrate that CD3delta accumulates not only in the cytosol, but also significantly within the ER membrane upon proteasomal inhibition. Interestingly, while accumulated CD3delta remained fully folded along the membrane, its fluorescence was completely abolished in the cytosol, indicating a mere unfolded cytosolic pool of CD3delta. The application of drugs compromising sugar processing severely affected the fate and folding of CD3delta on either side, which could be detected and quantified. The strategy of doubly labeled transmembrane proteins expands significantly the use of fluorescent fusion proteins and helps understanding the steps proteins undergo while crossing membranes.

1250

### ERAD Substrates Traffic from the ER Due to ER Export Signals: ER Retention of Misfolded Proteins Is Due to a Failure to Exit

M. M. Kincaid, A. A. Cooper; School of Biological Sciences, University of Missouri-Kansas City, Kansas City, MO

The endoplasmic reticulum (ER) is the site of entry for soluble and transmembrane proteins into the secretory pathway of all eukaryotic cells. Proteins are translocated into the ER where they fold, are modified by carbohydrate addition and disulfide bond formation, and assemble into complexes. Misfolded proteins in the ER are retained and degraded by ER-associated degradation (ERAD). However, a subset of ERAD substrates fails to be retained in the ER and instead traffics to the Golgi prior to degradation. Our study in *Saccharomyces cerevisiae* of model ERAD substrates, with or without defined ER exit signals, demonstrates that misfolded proteins depart the ER by presenting functional exit signals in the same manner as the corresponding correctly folded proteins. Conversely, ERAD substrates that remain in the ER likely lack ER exit signals or are unable to functionally present them. These data indicate that ER retention of misfolded proteins is unlikely an active process but instead reflects a failure to exit the ER. These findings are contrary to the prevailing view of stringent and active ER quality control (ERQC) mechanisms preventing misfolded and potentially toxic proteins from traversing the secretory pathway. In addition, these data highlight the dynamic interplay between ERAD and ER exit in which both processes compete for binding of misfolded proteins that contain ER export signals. Inhibition of ERAD results in greater ER export of such misfolded proteins while blocking ER exit results in enhanced degradation of these proteins by ERAD.

1251

### A Screening System for Compounds to Protect Cells against Endoplasmic Reticulum (ER) Stress

Y. Tabata, O. Hori, K. Takano, Y. Kitao, S. Ogawa; Neuroanatomy, Kanazawa University Graduate School of Medicine, Kanazawa City, Japan

Once cells are exposed to stresses such as glucose starvation, inhibition of protein modification, disturbance of $Ca^{2+}$ homeostasis and oxygen deprivation, unfolded proteins accumulate in the endoplasmic reticulum (ER stress). If protein loads in the ER exceed its folding capacity, or dome defects in the ER stress response exist, cells tend to die, typically, with apoptotic features (ER stress-induced cell death). The crucial roles of the ER stress response/ER stress-induced cell death have been reported in many pathological conditions including diabetes, arteriosclerosis, ischemia and neurodegenerative diseases. Herp is a membrane bound, ubiquitin-like protein that is located in the endoplasmic reticulum (ER). Although Herp is strongly induced by ER stress, it decays rapidly consequent to proteasome-mediated degradation, suggesting the possible contribution of Herp in the ERAD. We recently reported that targeting disruption of the Herp gene caused F9 embryonic carcinoma cells vulnerable to ER stress, and the ER stress-induced death in F9 Herp null cells was associated with the aberrant ER stress signaling, structural changes in the ER and caspase activation (Genes Cells 2004, 9, 457-469). Using these cell lines and MIN6 cells, mouse insulinoma cell lines, we developed a screening system to obtain molecules that suppress ER stress/ER stress-induced cell death. Among approximately 20 well-known compounds, Dantrolene and some anti-oxidants had protecting effects against ER stress. We speculate that this system could provide novel therapeutic targets to the ER stress-related diseases.

1252

### The Putative Protein Determinant for ER-Associated Degradation

K. Kanehara, A. Sayeed, E. D. Spear, D. T. W. Ng; Temasek Life Sciences Laboratory and Department of Biological Sciences, National University of Singapore, Singapore, Singapore

The maturation of new synthesized proteins entering the secretory pathway is monitored by ER quality control (ERQC) mechanisms. ERQC retains newly proteins as they are folding. Proteins that are irreversibly misfolded are sorted and degraded by the ER-associated protein degradation (ERAD) pathway. To understand the relationship between quality control and ERAD, we analyzed a misfolded variant of carboxypeptidase Y (CPY) termed CPYΔ1. CPYΔ1 lacks the C-terminal 154 amino acids of CPY. CPYΔ1 was recognized and retained by ER quality control but failed to enter the ERAD pathway. The observation suggested that the deletion disrupted an ERAD-specific targeting signal. We showed that a single context-specific N-linked glycan is a required determinant of the signal. An analogous signal was found in misfolded proteinase A (PrA*), but in a different position. We hypothesized from these data that substrates utilize a bipartite signal comprised of carbohydrate and peptide elements. To test our hypothesis, systematic deletion analysis was performed on CPY* with the aim of disrupting the peptide determinant. Deletions spanning most of the protein had no effect on degradation. However, a small protein domain was determined to be required for ERAD, even with the signal carbohydrate intact. Interestingly, the determinant is functional when moved to another part of the molecule suggesting that it is not positionally constrained. These data indicate that specifically embedded signals in glycoproteins are used for targeting to the ERAD pathway if misfolded.

1253

### How UPR Regulation of the BiP/Kar2p Chaperone Contributes to ER Stress Tolerance

C. Hsu, D. T. W. Ng; Temasek Life Sciences Laboratory, Singapore, Singapore

The endoplasmic reticulum (ER) provides a tightly regulated environment for the folding and maturation of proteins destined to enter the secretory pathway. The homeostasis of the ER can be perturbed under various stress conditions, leading to the accumulation of misfolded and unfolded protein in the ER (termed ER stress). Consequently, a stress-inducible pathway known as unfolded protein response (UPR) is activated to alleviate stress. The UPR is an ER-to-nucleus signal transduction pathway that regulates a wide variety of genes to restore cellular homeostasis. However, how the induction of individual UPR targets contributes to stress tolerance has not been determined. In this study, we analyzed the role of *KAR2* gene activation. *KAR2*, a major UPR target gene, encodes the *Saccharomyces cerevisiae* ortholog of BiP, an ER chaperone of the Hsp70 family. We constructed a strain by which the *KAR2* gene is expressed at basal levels but unresponsive to the UPR (called *UPRE$^d$-KAR2*). The strain (CHY220) showed growth sensitivity to ER stress caused by the glycosylation inhibitor tunicamycin and overexpression of the misfolded protein CPY*. Interestingly, the strain tolerated a challenge by dithiothreitol (DTT), a reducing agent that disrupts disulfide bonds in the ER. These data show that *KAR2* upregulation is required for some forms of ER stress and not others. Kar2p plays a variety of essential functions including protein folding, translocation, and the turnover of misfolded proteins. Using this system, we are currently determining the specific role that *KAR2* upregulation plays in ER stress tolerance.

1254

### Overexpression of Megsin Induces Neuronal Degeneration: Role of the Endoplasmic Reticulum Stress Response

K. Takano,[1] Y. Kitao,[1] R. Inagi,[2] T. Miyata,[2] O. Hori,[1] S. Ogawa[1]; [1]Department of Neuroanatomy, Kanazawa University Graduate School of Medicine, Kanazawa, Japan, [2]Molecular and Cellular Nephrology, Institute of Medical Sciences, Tokai University, Isehara City, Japan

Serpinopathies are caused by intracellular accumulation/polymerization of mutant serine protease inhibitors. Transgenic rats overexpressing megsin (Tg meg), a newly identified serine protease inhibitor (serpin), unexpectedly demonstrated impaired memory by the water maze test. Hippocampal neurons cultured from Tg meg rats displayed enhanced sensitivity to glutamate. Consistently, immunoblotting of hippocampal extracts from Tg meg rats showed enhanced levels of ER stress proteins along with the activation of caspase-12 and caspse-3, which peaked 4-6 months after birth, which was associated with decreased neuronal density in the CA1 region of Tg meg animals. Immunohistochemical analysis of the hippocampus revealed increased expression of ER stress proteins, as well as activated caspase-3 and caspase-12. Similar findings of ER stress, activation of caspases and decreased neuronal density were also observed in tyrosine hydroxylase-positive nigro-striatal neurons, accompanied with the impairement of motor coordination. These data suggest that overexpression of megsin results in ER stress, which eventuates in selective cellular dysfunction and death, providing a novel model; increased levels of a wild-type serpin induce dysfunction of vulnerable neuronal populations.

1255

**Regulation of Endoplasmic Reticulum (ER) Stress at Translocational Site into the ER**

O. Hori,[1] M. Miyazaki,[1] E. Hartmann,[2] P. Mai,[2] S. Ogawa[1]; [1]Department of Neuroanatomy, Kanazawa University, Graduate School of Medicine, Kanazawa City, Japan, [2]Universität Lübeck, Lübeck, Germany

Stress-associated ER protein 1 (SERP1), also known as Ribosome-associated membrane protein 4 (RAMP4), is a Sec61-assocaited polypeptide that is induced by endoplasmic reticulum (ER) stress. $SERP1^{-/-}$ mice, made by targeted gene disruption, demonstrated growth retardation, increased mortality and impaired glucose tolerance. Consistent with high levels of SERP1 expression in pancreas, pancreatic islets from $SERP1^{-/-}$ mice failed to rapidly synthesize proinsulin in response to a glucose load. Unexpected was strong expression of SERP1 in the anterior pituitary. Reduced size and enhanced ER stress were observed in the anterior pituitary of $SERP1^{-/-}$ mice, and growth hormone production was slowed in $SERP1^{-/-}$ pituitary after insulin stimulation. Experiments using pancreatic microsomes from $SERP1^{+/+}$ and $SERP1^{-/-}$ mice revealed aberrant association of ribosome and Sec61 complex, and enhanced ER stress in $SERP1^{-/-}$ pancreas. In basal condition, Sec61 complex in $SERP1^{-/-}$ microsomes were more co-fractionated with ribosomes, compared with $SERP1^{+/+}$ counterparts, in high-salt condition. After glucose stimulation, in contrast, they showed less co-fractionation at early periods (45min), but more at late periods (120min). Although intracellular insulin/proinsulin levels were not significantly changed in both genotypes, these results suggest that subtle changes in translocation efficiency play an important role in the control of ER stress and rapid polypeptide synthesis.

1256

**Analysis of UPR Genes in Antibody Secretion: Chop Downregulation Enhances Antibody Specific Productivity**

G. Bannish, M. Rycyzyn, W. Cornwell, T. Petley, K. Stark, B. Pikounis, J. Giles-Komar; Cellular Biology, Centocor, Radnor, PA

The homeostasis of the ER is regulated in part by the unfolded protein response (UPR). By analyzing a panel of antibody secreting myelomas, a correlation was made between higher specific productivities and increased steady state levels of RNA for the UPR genes Bip, CHOP, and activated Xbp-1 (X54). This correlation was sustained when cells underwent stress, either by pharmacologic induction or the end static phase of their growth curve. Since increased levels of CHOP have previously been reported to inhibit protein production and induce apoptosis, we sought to ascertain if decreasing CHOP levels in cells could increase specific productivities. To that end, a representative cell line, cell line A, was stably transfected with shRNA vectors to target CHOP, Bip, or vector controls. Of the stable cell lines generated, 92% of the ones with the highest levels of secreted antibody were derived from the CHOP shRNA transfectants. Upon further analysis, these clones were found to express reduced amounts of CHOP RNA as assessed by Taqman analysis and had specific productivity values 2.5 fold higher than vector controls. This finding is consistent with the alternative UPR induction found to occur in plasma B cells and suggests a non-apoptotic mechanism for CHOP-mediated reduction of protein secretion.

1257

**Differential Accumulation of Derlin RNAs and Proteins during Prolonged ER Stress**

M. E. Kirst,[1] R. Jung,[2] R. S. Boston[1]; [1]Botany, NCSU, Raleigh, NC, [2]Pioneer Hi-Bred, A DuPont Company, Johnston, IA

Maintenance of a functional protein secretory pathway is facilitated by removal of terminally misfolded proteins through an ER-associated degradation pathway (ERAD). We have identified four maize genes (ZmDerlin1-1, 1-2, 2-1, 2-2) that encode proteins conserved in sequence and core function with the yeast ERAD protein, Der1p. Both ZmDerlin1 and ZmDerlin2 proteins are present in ER of the endosperm and are also associated with protein bodies, the ER derived protein storage organelles of the seed. Quantitative RT-PCR analysis showed that ZmDerlin1-1, 1-2 and 2-1 were up-regulated by ER stress while ZmDerlin2-2 expression appeared to be unaffected. During prolonged ER stress, we observed a reduction in the accumulation of ZmDerlin1 protein, but not ZmDerlin2 or the molecular chaperone BiP. RT-PCR analysis indicated that this reduction was not reflected in the polysomal RNA population. Thus, ZmDerlin1 itself may be an ERAD substrate.

**Human Homologs of Ubc6p Ubiquitin-conjugating Enzyme and Phosphorylation of Hsubc6e in Response to ER Stress**

R. Oh,[1,2] X. Bai,[1] J. Rommens[1,2]; [1]The Hospital for Sick Children, Toronto, ON, Canada, [2]Department of Medical Genetics and Microbiology, University of Toronto, Toronto, ON, Canada

Ubiquitin-conjugating enzyme Ubc6p is a tail-anchored protein that is localized to the cytoplasmic face of the ER membrane and has been implicated in the degradation of many misfolded membrane proteins in yeast. We have undertaken characterization studies of two human homologs, hsUbc6 and hsUbc6e. Both possess a tail-anchored protein motif, display high conservation in their catalytic domain, and are functional ubiquitin-conjugating enzymes as determined by *in vitro* thiol-ester assay. Both also display induction by the unfolded protein response, a feature of many endoplasmic reticulum associated degradation (ERAD) components. Post-translational modification of hsUbc6e was identified as phosphorylation and observed to be ER stress related. Under stress by thapsigargin and dithiothreitol, phosphorylation was diminished in mouse embryonic fibroblasts deficient for the ER stress regulated kinase PERK, suggesting that Ubc6e is regulated by this kinase. The phosphorylation site was mapped to Ser184, which resides within the uncharacterized region linking the highly conserved catalytic core and the carboxyl terminal transmembrane domain. Phosphorylation of hsUbc6e was dynamic and did not alter stability or subcellular localization. Parkin, a known Ubc6e

interacting E3 ligase, was found by co-immunoprecipitation experiments to associate with either phosphorylated or unphosphorylated forms of hsUbc6e. Assays of hsUbc6e$^{S184D}$ and hsUbc6e$^{S184E}$, which mimic the phosphorylated state, suggest that phosphorylation may reduce capacity for forming ubiquitin-enzyme thiol-esters. The occurrence of two distinct Ubc6p homologs in vertebrates, including one with phosphorylation modification in response to ER stress, emphasizes diversity in function between these E2s during ERAD processes.

1259

### Calnexin Is Important for Inhibition of the ERAD of Incompletely Folded CFTR but Not for the ER Retention

T. Okiyoneda,[1] A. Niibori,[1] K. Harada,[1] I. Wada,[2] M. Ikawa,[3] T. Kouno,[1] T. Shuto,[1] M. S. Suico,[1] H. Kai[1]; [1]Molecular Medicine, Kumamoto Univ, Kumamoto, Japan, [2]Cell Science, Fukushima Medical Univ, Fukushima, Japan, [3]Genome Information Research Center, Osaka Univ, Osaka, Japan

DeltaF508 CFTR, which is the most common mutant of CFTR in Cystic fibrosis (CF) patients, is retained in the ER by the ER quality control system, leading to ER-associated degradation (ERAD). Since DeltaF508 CFTR is functional as a regulated $Cl^-$ channel when expressed at the plasma membrane, rescue of DeltaF508 CFTR from ER retention may be useful for CF therapy. However, the molecular mechanism of the ER retention remains unclear although an ER chaperone, calnexin is thought to participate in the ER retention of DeltaF508 CFTR. To clarify whether calnexin retains DeltaF508 CFTR in the ER, we analyzed the effect of calnexin mutant, which is exported from the ER. Our results indicate that DeltaF508 CFTR is retained in the ER even if calnexin is exported from the ER. In calnexin-deficient cells, DeltaF508 CFTR was still retained in the ER and quickly degraded by the ERAD pathway. However, the introduction of calnexin into these cells inhibited the ERAD of DeltaF508 CFTR. These results demonstrate that calnexin is required for inhibition of the ERAD of DeltaF508 CFTR but not for the ER retention.

## Mechanisms of Nuclear Transcription (1260-1278)

1260

### NF-*k*B/RelA Transcription Factor Interacts with *a*-Actinin Isoforms

V. Babakov,[1] O. Petukhova,[1] L. Turoverova,[1] I. Kropacheva,[1] D. Tentler,[1] E. Podolskaya,[2] K. I. Magnusson,[3] G. Pinaev[1]; [1]Cell Cultures, Institute of Cytology, St. Petersburg, Russian Federation, [2]Environmental Biomedical Mass Spectrometry, Analytical Instrumentation, St. Petersburg, Russian Federation, [3]Medical Microbiology, Linkoping University, Linkoping, Sweden

The NF-kB/RelA family of transcription factors regulates inducible transcription of a large number of genes in response to diverse stimuli. Little is known, however, about location of NF-κB in cytoplasm and transport mechanism to the nucleus. We have found that NF-κB is associated with actin-binding protein α-actinin-4 by several criteria. First, NF-κB and α-actinin-4 co-localized along actin stress fibers and in focal adhesions in A431 cells. EGF- and TNF-α-stimulation of A431 cells for 5 min lead to a dramatic actin cytoskeleton reorganization, dorsal ruffling formation and accumulation of F-actin, α-actinin and p65/RelA subunit of NF-κB in this area. After 30-min stimulation, α-actinin-4 and p65 were found in the nucleus. Pretreatment of the cells with cytochalasin D and wortmannin prior to EGF or TNF-α treatment lead to increased p65 and α-actinin-4 translocation. Co-localization of α-actinin-4 with p65 was confirmed in isolated nuclei of stimulated cells. To determine which α-actinin isoform interacts with NF-κB complex, we used A431 cells stably transfected by GFP- α-actinin-1 and GFP- α-actinin-4. Both α-actinin isoforms co-localized with p65, but only α-actinin-4 migrated together with p65 to the nucleus after EGF or TNF-α stimulation. Second, antibodies to different NF-κB subunits co-immunoprecipitated α-actinin-4 from A431 cell lysates and nuclear extracts. Actinin-4 was identified using immunoblotting and MALDI-TOF mass-spectrometry. Third, affinity chromatography indicates that p65 and p50 subunits of NF-κB can bind to matrix-bound chicken gizzard α-actinin. With a blot overlay assay, p65, p50 and IκB-α of cell lysates recognized immobilized α-actinin; and only p65 bound to the 53 kDa fragment of α-actinin. We propose a crucial function of α-actinin-4 isoform in NF-κB nuclear translocation and nuclear events.The work was supported by RFBR grant 03-04-48251 and Visby program of the Swedish Institute. GFP- α-actinin constructs were kindly provided by Dr. Carol Otey.

### Bifurcated Converging Pathways for High Ca++- and TGFb-induced Inhibition of Growth of Normal Human Keratinocytes

M. Sakaguchi,[1] H. Sonegawa,[1] T. Nukui,[1] M. Miyazaki,[1] M. Namba,[2] N. Huh[1]; [1]Cell Biology, Okayama University Graduate School of Medicine and Dentistry, Okayama, Japan, [2]Niimi College, Okayama, Japan

Growth suppression of normal human keratinocytes by high Ca++ or transforming growth factor b (TGFb) was shown to be mediated by p21WAF1/CIP1 and Sp1. We previously demonstrated that S100C/A11 is a key mediator for growth inhibition of normal human epidermal keratinocytes (NHK) triggered by high Ca++ or TGFb (J. Cell Biol. 163:825-835, 2003; 164:979-984, 2004). On exposure of NHK cells to either agent, S100C/A11 is transferred to nuclei, where it induces p21WAF1/CIP1 through activation of Sp1/Sp3. In the present study, we found that high Ca++ activated NFAT1 through calcineurin-dependent dephosphorylation. In growing NHK cells, KLF16, a member of the Sp/KLF family, bound to the p21WAF1/CIP1 promoter and thereby inhibited the transcription of p21WAF1/CIP1. Sp1 complexed with NFAT1 in high Ca++-treated cells or with Smad3 in TGFb1-treated cells, but not Sp1 alone, replaced KLF16 from the p21WAF1/CIP1 promoter and transcriptionally activated the p21WAF1/CIP1 gene. Thus, high Ca++ and TGFb1 have a common S100C/A11-mediated pathway in addition to a unique pathway (NFAT1-mediated pathway for high Ca++ and Smad-mediated pathway for TGFb1) for exhibiting a growth inhibitory effect on NHK cells, and both pathways were shown to be indispensable for growth inhibition.

1262

### Molecular Chaperones Involved in Vitamin D Receptor Mediated Transcription in Keratinocytes

Y. Oda,[1] N. P. Hawker,[1] S. H. Meijsing,[2] R. J. Chalkley,[3] A. L. Burlingame,[3] D. D. Bikle[1]; [1]Endocrine Research, VA Medical Center San Francisco, San Francisco, CA, [2]Cellular Molecular Pharmacology, University of California San Francisco, San Francisco, CA, [3]Pharmaceutical Chemistry, University of California San Francisco, San Francisco, CA

Vitamin D, via its active metabolite 1,25(OH)2D3, controls the proliferation and differentiation of keratinocytes through the vitamin D receptor (VDR) by directly regulating gene transcription. Using GST-VDR affinity beads, VDR binding protein (DRIP) complexes were purified from keratinocytes and identified by mass spectrometry. Within the DRIP complex, we also identified chaperone heat shock proteins (Hsp). Chaperone

proteins are known to maintain the stability of nuclear receptors, although their role in transcription has not been fully elucidated. Recently chaperones have been suggested to be involved in nuclear receptor mediated transcription. Therefore, we evaluated the role of Hsp proteins in VDR stimulated transcription. Direct binding of Hsp 90 and the co-chaperone p23 to the VDRE complex within the 24 hydroxylase and keratin 1 promoters was detected using chromatin immunoprecipitation. When Hsp90 and the co-chaperone p23 were co-localized to a vitamin D response element (VDRE) site using GAL4, they inhibited VDR mediated transcription. Overexpression of p23 promoted removal of VDR from promoter sites. Blockage of chaperone function by geldanamycin induced keratinocyte differentiation shown by increased expression of the early differentiation markers keratin 1 and 10 with no effect on the expression of the basal keratins 5 and 14. These results suggest that chaperone proteins are directly involved in VDR mediated transcription through disassembly of the VDR complex from promoter sites. Inhibition of this function facilitates the transition from a proliferating keratinocyte to a differentiating one.

**The Peptidyl-prolyl Isomerase Pin1 Binds and Regulates the Transcription Factor Nur77**

B. Kim, H. Youn; Biochemistry & Molecular Biology, Seoul National University, Seoul, Republic of Korea

A peptidyl-prolyl isomerase (PPIase), Pin1 specifically recognizes pS(pT)P-motif containing proteins and induces their conformational changes, which ultimately leads to regulating their biological functions. Nur77, an orphan nuclear receptor, plays an important role in apoptosis in immature T cell and cancer cell. Nur77 was originally found as a multiphosphorylated protein. On later, the biological function of Nur77 has been known to be regulated by phosphorylation: DNA-binding ability, transcriptional activity, and translocation from nucleus to cytosol. In this study, we found that Pin1 strongly associates with Nur77 through pS(pT)-P motifs in the N-terminal transactivation domain(N-TAD) of Nur77. In particular, the mutations of three serine residues (S196, S202, S240) in N-TAD completely abrogated the Pin1-Nur77 interaction, indicating that Pin1 specifically binds to Nur77 through pS-P motifs in N-TAD. Ectopically expressing Pin1 decreased Nur77 transcriptional activity. Moreover, a Nur77 mutant [Nur77(S196A/S202A/S240A)] that cannot interact with Pin1 has a higher transcriptional activity than Nur77(WT). Taken together, we suggest that Pin1 may negatively regulate Nur77 transcriptional activity under the certain conditions that Nur77 is phosphorylated at three pS-P motifs.

1264

**A Novel Krüppel Related Factor Consisting of Only a KRAB-A Domain is Expressed in the Murine Trigeminal Ganglion**

K. Nikulina, M. Bodeker, J. Warren, A. Ellison, T. P. Margolis; F. I. Proctor Foundation, University of California San Francisco, San Francisco, CA

Productive infection with herpes simplex virus (HSV) type 1 requires activation of the promoter of the viral IE110 gene, which codes for the protein ICP4. A functional screen for possible repressors of the IE110 promoter led to the cloning of a rat gene, If1, encoding a Krüppel -associated box-A (KRAB-A) protein, whose expression had an inhibitory effect on HSV replication in vitro. Screening a murine cDNA library with a probe based on the If1 sequence resulted in the isolation of a mouse If1 homologue (Mif1) encoding a small 8.2 kDA protein comprised largely of a single KRAB-A domain. Northern and Western blot analysis of extracts of murine trigeminal ganglion revealed KRAB-A containing transcripts about 600 bps in size and small KRAB-A containing proteins. These data demonstrate the existence of a subset of Krüppel related factors which are comprised of only a KRAB-A box and no additional downstream domains, such as zinc fingers, normally seen in typical KRAB-domain proteins. Yeast two-hybrid analysis showed that Mif1 interacts with co-repressor TIF1β suggesting the same mechanism of regulation as typical KRAB-domain proteins. In a GAL4 fusion repressor assay Mif1 demonstrated significant downregulation of the herpes IE110 promoter. These results contribute to the discussion of the evolutionary and functional relationship of non-zinc finger KRAB-proteins and typical Krüppel zinc finger genes and there role and relevance to viral infection.

1265

**Translocation of Membrane EGF Receptor to Nucleus: Function and Mechanism**

M. Hung, S. Wang, H. Lo, S. Hsu, W. Xia, Y. Wei; Molecular and Cellular Oncology, The University of Texas M.D. Anderson Cancer Center, Houston, TX

Previously, we have found that the rat neu, a member of epidermal growth factor receptor (EGFR) family, was localized in the nucleus and could act as a transcriptional activator. Later, we demonstrated that the carboxyl terminus of EGFR contains a strong transactivation activity and EGFR complex recognizes an AT-rich consensus-sequence on cyclin D1 promoter. By using ChIP assays, we showed that nuclear EGFR associated with promoter region of cyclin D1 *in vivo*. EGFR may function as a transcription factor in the nucleus. Recently, using the ChIP cloning strategy, we identify that human HER-2/ ErbB-2 was associated with multiple genomic targets *in vivo*, including the *COX-2* gene promoter. We have shown that ErbB-2 forms a complex at a specific nucleotide sequence of the *COX-2* promoter and is able to stimulate its transcription. This study strengthens the functionality of ErbB-2 as a transcriptional regulator in the nucleus. Moreover, we demonstrate that EGFR physically interacts with signal transducers and activators of transcription 3 (STAT3) in the nucleus leading to transcriptional activation of inducible nitric oxide synthase (iNOS). In breast carcinomas, nuclear EGFR positively correlates with iNOS expression. The study describes a mode of transcriptional control involving cooperated efforts of STAT3 and nuclear EGFR. Our work suggests de-regulated iNOS/NO pathway may partly contribute to the malignant biology of tumor cells with high levels of nuclear EGFR and STAT3. In addition, we have analyzed 130 breast carcinomas via immunohistochemical analyses for the nuclear and non-nuclear EGFR. Kaplan-Meier survival analysis and log-rank test revealed a significant inverse correlation between high nuclear EGFR and overall survival ($P = 0.009$). Thus, our findings indicate pathological significance of nuclear EGFR and may have important clinical implication.

1266

**Phosphorylation of Ser1834 by Akt Enhances the HAT and Transcriptional Activities of p300**

C. Chen, W. Huang; Department of Pharmacology, College of Medicine, National Taiwan University, Taipei, Taiwan Republic of China

The PI3K/Akt pathway plays a critical role in the regulation of gene expression induced by numerous stimuli. p300, a transcriptional co-activator, acts in concert with transcription factors to facilitate gene expressions. Here we showed that Akt is activated and translocated to the nucleus in response to TNF-α. Nuclear Akt associates with p300 and phosphorylates its Ser-1834 both *in vivo* and *in vitro.* The phosphorylation induces

recruitment of p300 to the *ICAM-1* promoter, leading to the acetylation of histones in chromatin and association with basal transcriptional machinery RNA polymerase II. These two events, abolished by the p300 S1834A mutant, inhibitors of PI3K/Akt or siRNA of Akt, facilitate the ICAM-1 gene expression. Histone acetylation is attributed to the Akt-enhanced intrinsic HAT activity of p300 and its association with other HAT, p/CAF. Our study provides a new insight into the molecular mechanism by which Akt promotes the transcriptional potential of p300.

1267

**Nuclear Speckle-associated Protein Pnn/DRS Forms a Complex With RNA Polymerase II and Impacts E-cadherin mRNA Processing**

R. Alpatov, G. C. Munguba, S. P. Sugrue; Anatomy and Cell Biology, University of Florida, Gainesville, FL

Pnn/DRS (Pnn) is a "nuclear speckle"-associated multifunctional protein known to participate in mRNA processing in the nucleus. It is also directly involved in transcriptional regulation of the E-cadherin gene via its binding to CtBP, a multifunctional transcriptional repressor that targets the E-cadherin promoter. In light of recent reports of Pnn's presence in complexes associated with basal transcriptional machinery, we wished to address the possible interaction of Pnn with RNA polymerase II, which might imply Pnn-dependent coordination of transcription and mRNA splicing events. *In vivo* binding assays, using HeLa nuclear extracts, showed that endogenous Pnn and Pol II can interact. In addition, we demonstrated that Pnn preferentially associates with the transcriptionally active forms of Pol II: initiation-specific Pol II (phosphorylated on Ser5), elongation-specific Pol II (phosphorylated on Ser2), but not with pre-initiation Pol II (unphosphorylated). Immunofluoresence studies using NIH3T3hPnnGFP cells, which stably express epitope-tagged Pnn also demonstrated higher degree of overlap between Pnn and transcriptionally active forms of Pol as compared to pre-initiation Pol II. In addition, as an indication of their potential functional coupling, Pnn and active forms of Pol II exhibited similar redistribution dynamics in response to the actinomycin D-mediated transcriptional block, accumulating as enlarged, round speckles. Furthermore, using splicing reporter assay, utilizing E-cadherin exon4-intron-exon5 cassette driven by E-cadherin or SV-40 promoter, we demonstrated that Pnn can positively impact E-cadherin mRNA splicing efficiency in the promoter-specific manner. These data contribute to our understanding of Pnn's role in regulation of transcription as a coupling factor that can bridge components of basal transcriptional machinery and mRNA processing events. Supported by NIH grant EY07883

**Role of Phospholipase C and Inositol Polyphosphates in Transcriptional Regulation in Budding Yeast**

A. Demczuk, N. Guha, J. Chang, A. Vancura; Biological Sciences, St. John's University, Jamaica, NY

Phosphatidylinositol phosphates (PtdInsPs) are involved in signal transduction, cytoskeletal organization, and membrane trafficking. Inositol polyphosphates (InsPs), produced from PtdInsPs by the phospholipase C-dependent pathway, regulate chromatin remodeling. We used genome-wide expression analysis to further investigate the role of Plc1p (phosphoinositide-specific phospholipase C) and InsPs in transcriptional regulation. Plc1p regulates the expression of approximately 3% of yeast genes in cells grown in rich medium. Most of the genes are repressed by Plc1p. Surprisingly, genes regulated by Plc1p do not correlate with gene sets regulated by Swi/Snf or RSC chromatin remodeling complexes. In addition, the patterns of genetic interactions displayed by *plc1*Δ and *swi2*Δ mutations are distinct, however partly overlapping. Genes repressed by Plc1p show correlation with genes induced by diauxic shift and gene sets controlled by Msn2p/Msn4p, Srb10p, Mot1p, and NC2. The Plc1p-dependent repression of Srb10p-regulated genes does not involve regulation of Srb10p level or activity by Plc1p. Plc1p does not regulate nucleocytoplasmic distribution of Msn2p; however, *plc1*Δ cells display increased recruitment of Msn2p to the promoters of Msn2p-regulated genes. Taken together, the results indicate that in addition to chromatin remodeling, InsPs produced by the Plc1p-dependent pathway affect transcriptional regulation by yet another mechanism, possibly involving recruitment of Msn2p/Msn4p and formation of the preinitiation complex.

1269

**Expression of ABC Transporter *FLR1* Requires Phospholipase C and is Repressed by Mediator**

P. Desai, C. Romero; Biological Sciences, St. John's University, Jamaica, NY

In budding yeast, phosphoinositide - specific phospholipase C (Plc1p encoded by *PLC1* gene) is important for function of kinetochores. Deletion of *PLC1* results in benomyl sensitivity, alterations in chromatin structure of centromeres, mitotic delay, and a higher frequency of chromosome loss. In this study, we intended to utilize benomyl sensitivity as a phenotype that would allow us to identify genes that are important for kinetochore function and are downstream of Plc1p. However, our screen identified *SIN4*, encoding a component of the Mediator complex of RNA polymerase II. Deletion of *SIN4* gene does not suppress benomyl sensitivity of *plc1*Δ cells by improving the function of kinetochores. Instead, benomyl sensitivity of *plc1*Δ cells is caused by a defect in expression of *FLR1* and the suppression of benomyl sensitivity in *plc1*Δ *sin4*Δ cells occurs by derepression of *FLR1* transcription. *FLR1* encodes a plasma membrane transporter that mediates resistance to benomyl. Several other mutations in the Mediator complex also result in significant derepression of *FLR1* and greatly increased resistance to benomyl. Thus, benomyl sensitivity is not a phenotype exclusively associated with mitotic spindle defect. These results demonstrate that in addition to promoter-specific transcription factors that are components of the pleiotropic drug resistance network, expression of the membrane transporters can be regulated by Plc1p, a component of a signal transduction pathway, and by Mediator, a general transcription factor. The results thus suggest another layer of complexity in regulation of the pleiotropic drug resistance.

1270

**Elucidating the Function of the Truncated Hoxa1 Protein**

C. C. Fernandez, L. J. Gudas; Department of Pharmacology, Weill Medical College of Cornell University, New York, NY

Retinoic acid (RA), the natural acidic metabolite of vitamin A, has been shown to influence the proliferation and differentiation of a wide variety of different cell types. More specifically, RA plays an important role in cellular differentiation by transcriptionally up-regulating the expression of *Hox* genes. *Hox* genes are involved in establishing anterior to posterior pattern formation during vertebrate development. They act as transcription factors that characteristically bind to DNA through a helix-turn-helix motif termed the homeodomain. Previously, our lab has shown that RA transcriptionally regulates the expression of *Hoxa1* in F9 teratocarcinoma cells. The *Hoxa1* gene encodes two alternatively spliced mRNAs that can direct the synthesis of two distinct proteins, one that contains the homeobox, Hoxa1-993, and another truncated protein that lacks the DNA binding domain, Hoxa1-399. The function of the truncated protein is not known. I have used both wild type F9 and EW-F9 mutant embryonic stem cells,

which overexpress the Hoxa1-399 transcript in the presence of zinc, to examine the effects of the shorter Hoxa1 protein on the expression of Hoxa1 target genes. Overexpression of Hoxa1-399 in EW-F9 cells enhances the expression of endogenous *Hoxa1*, *Hoxb1* (a known Hoxa1 target), and various Hox cofactors. Results of GST pull-down assays show that Hoxa1-399 and Hoxa1-993 dimerize *in vitro*. Therefore, these results indicate that one function of the truncated Hoxa-1 protein is to up-regulate the expression of Hoxa-1 target genes. However, reporter assays using a small region of the *Hoxb1* promoter to drive luciferase expression implicate Hoxa1-399 as a negative regulator of the transcriptional activation of the Hoxa1 target gene, *Hoxb1.*

1272

**Modulation of Human SIM1 and SIM2 Transcription Factors**

Y. Shimizu,[1] A. Yamaki,[1] M. Okui,[2] A. Takayanagi,[2] J. Kudoh,[2] N. Shimizu[2]; [1]Medical Genetics, Kyorin University School of Health Sciences, Hachioji-shi Tokyo, Japan, [2]Molecular Biology, Keio University School of Medicine, Shinjuku-ku Tokyo, Japan

Human SIM1 and SIM2 proteins are members of the basic helix-loop-helix/Per-ARNT-Sim (bHLH/PAS) family of transcription factors. Previously, we identified the nuclear localization signal (NLS) at the aa 367-388 region of SIM1 and the aa 367-388 region of SIM2 (Biochem. Biophys. Res. Commun. 313:482-488, 2004). Here, we examined the modulation of the cellular localization of SIM1 and SIM2 proteins by ARNT or ARNT2. The NLS deficient mutants of SIM1 or SIM2 remain in the cytoplasm but cotransfection with ARNT or ARNT2 resulted in the nuclear localization of these SIM mutants, indicating the direct association of SIM and ARNT proteins. Interestingly, we found that SIM1 and SIM2 were poly-ubiquitinated in transiently transfected cells, and the poly-ubiquitinated proteins were more accumulated in the presence of a proteasome inhibitor MG132 in the stable transfectants. Furthermore, SIM1 and SIM2 were immunoprecipitated with the RING-IBR-RING-type E3 ubiquitin ligases, such as Parkin and HHAR1, but they were not immunoprecipitated with other E3 ligases, such as one RING type Siah-1 and the PHD type AIRE. Using the deletion constructs and mutants of SIM2, the poly-ubiquitination sites were identified at multiple Lys residues in the aa141-289 region. Poly-ubiquitinated SIM1 and SIM2 were immunoprecipitated with ARNT or ARNT2. These findings indicate that SIM1 and SIM2, form a complex with ARNT and their function may be regulated through poly-ubiquitination during the brain development.

1273

**Multiple Mechanisms Regulate Methionine Biosynthetic Gene Network Transcription in the Yeast *Saccharomyces cerevisiae***

S. Chandrasekaran,[1] A. Deffenbaugh,[2] D. Skowyra,[2] N. Mathias[1]; [1]Biochemistry and Molecular Biology, Louisiana State University Health Sciences Center, Shreveport, LA, [2]Biochemistry and Molecular Biology, St. Louis University, St. Louis, MO

When depleted of sulfur-containing amino acids, yeast cells remodel their transcription profile allowing expression of the methionine biosynthetic (*MET*) gene network. This network encodes transporters and enzymes required for the uptake and assimilation of extra-cellular sulfate to methionine, S-adenosyl methionine, and cysteine. A single transcription activator, Met4p, mediates the expression of the entire *MET* network and binds *MET* promoters through its association with four auxiliary proteins. Met4p activity is regulated by a negative feedback mechanism; however, different *MET* genes are repressed to different extents. Our objective is to understand how the abundance of methionine and cysteine are sensed and the mechanisms used to regulate Met4p activity. The $SCF^{Met30p}$ ubiquitin ligase is critical for *MET* gene repression. We have shown that overproduction of Met30p (the substrate recognition component of the ligase) increases the poly-ubiquitinated state of Met4p and represses *MET* gene expression. Thus, poly-ubiquitination of Met4p is sufficient to reduce its activity. By reconstituting the ubiquitination and proteasome-dependent degradation of Met4p, we have revealed that Met4p may be ubiquitinated in both - met and + met growth conditions but is only degraded in + met conditions. Thus, proteolysis of Met4p is important for repressing *MET* gene activity. The rate-limiting step of Met4p proteolysis is its release from its auxiliary proteins, which can be stimulated by the addition of exogenous cysteine and methionine. Thus, these amino acids evict Met4p from its transcriptional complexes and likely do so directly. Hence, we propose that multiple mechanisms regulate Met4p including its ubiquitination, interaction with auxiliary proteins, and degradation. Furthermore, we speculate that these mechanisms are not equally employed at each *MET* promoter, explaining how different *MET* genes are repressed to different extents.

1274

**Silencing of Retinoic Acid Receptors: An Epigenetic Domino Effect?**

S. Pozzi, G. Bistulfi, S. Rossetti, R. MingQiang, N. Sacchi; Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY

Resistance to the growth inhibitory action of retinoic acid (RA), the bioactive derivative of Vitamin A is common in human tumors. One form of RA resistance has been associated with aberrant DNA methylation and silencing of the retinoic acid receptor beta 2 (*RARβ2*) gene, whose transcription is regulated by RA. Understanding why *RARβ2* is prone to aberrant epigenetic silencing in human cells is critical for both prevention and early treatment of RA-resistance in human carcinoma cells. Here we show that an exacerbation of *RARβ2* transcriptional inactivity in human cells leads to heritable *RARβ2* DNA methylation and silencing. Further, we show that *RARβ2* epigenetic silencing leads to the development of RA-resistance and distinct features of tumor progression. This study serves as the proof of principle that epigenetic silencing can be consequent to an exacerbated transcriptional inactivity. Notably, *RARβ2* silencing is related to the silencing of other nuclear receptors.

1275

**Activation of the PI3K/Akt (PKB)/Bad Cascade by 1α,25-dihydroxy Vitamin $D_3$ in Osteoblasts**

X. Zhang, L. P. Zanello; Biochemistry, University of California-Riverside, Riverside, CA

1α,25-dihydroxy vitamin $D_3$ [1,25D], the biologically most active form of vitamin D, elicits cellular responses by means of two different mechanisms. On one hand, a genomic pathway involves regulation of gene transcription via a nuclear vitamin D receptor. On the other, a non-genomic pathway, which initiates at the plasma membrane level, comprises activation of specific cytoplasmic kinase cascades in different cell types. In osteoblasts, 1,25D promotes bone anabolic actions through both genomic and non-genomic pathways. However, the precise molecular mechanisms of membrane-initiated 1,25D actions are only partially understood. We report here 1,25D-activation of Akt phosphorylation in osteoblastic ROS 17/2.8 cells. Akt (protein kinase B), a PI3K downstream molecule, has been implicated in several cellular responses, including cell survival. Using a specific anti-phospho-serine 473 Akt antibody, we detected a dose dependent significant increase in Akt phosphorylation by 1,25D, with maximal response achieved with 10 nM of hormone. Time course experiments showed that hormone-stimulated Akt phosphorylation

can be measured as early as 5 min after treatment, and reached its maximum at around 10 min. In addition, we found that 1,25D induces phosphorylation of Bad, a downstream molecule of Akt implicated in cell survival. We show here that 10 nM 1,25D significantly reduces staurosporine-induced apoptosis in ROS17/2.8. Apoptotic cells were detected with propidium iodide stain and flow cytometry analysis. We conclude that rapid responses to 1,25D leading to cell survival occur via the PI3K/Akt/Bad pathway in osteoblasts. Anti-apoptotic effects of 1,25D may contribute to enhanced bone formation by osteoblasts treated with the steroid hormone. [Funded by NIH DK071115-01]

**Gene Expression Profiling of the Estrogen Responsive Genes by the Treatment With Alkylphenols, Chlorinated Phenols, Parabens, or Bis- and Benzoylphenols for Evaluation of Estrogen Activity**

M. Tanji,[1] S. Terasaka,[2,1] A. Inoue,[1] R. Kiyama[3,1]; [1]InfoGenes Co., Ltd., Tsukuba, Ibaraki, Japan, [2]SciMedia Ltd., Taito-ku, Tokyo, Japan, [3]National Institute of Advanced Industrial Science and Technology, Tsukuba, Ibaraki, Japan

We examined expression profiles of the estrogen responsive genes after the treatment with alkylphenols (p-cresol, 4-n-ethylphenol, 4-n-heptylphenol, 4-t-octylphenol and nonylphenol), chlorinated phenols (4-chlorophenol, 4-chloro-3,5-dimethylphenol, 2,4-dichlorophenol and pentachlorophenol), parabens (methylparaben, ethylparaben propylparaben and butylparaben), or bis- and benzoylphenols (bisphenols A and B, and p-hydroxybenzophenone) by means of DNA microarray assay for evaluation of estrogen activity of these chemicals. By selecting a set of 120 genes showing greater statistical reliability for estrogen, a greater reliability of the assays for the chemicals shown above was achieved and, for the chemicals whose data were available, the results were consistent with those by the previously reported ER-binding and yeast two-hybrid assays. Evaluation of the chemicals by gene functions indicated that the genes related to proliferation, transcription and transport were mostly up-regulated while significant numbers of genes related to enzymes and signaling showed down-regulation. The genes related to transcription showed the highest degree of variations among six categorized gene functions for the chemicals with relatively high estrogen activities. These results indicate that the variations of chemicals and their biological effects can be monitored by appropriate grouping of the estrogen responsive genes.

1277

**Protein Phosphatase 2A (PP2A) Transfer onto the Androgen Receptor (AR) Requires Specific HEAT Repeats in PP2A and the Agonist Conformation of AR**

C. Yang,[1] D. L. Brautigan,[2] B. M. Paschal[3]; [1]Center for Cell Signaling, University of Virginia, Charlottesville, VA, [2]Center for Cell Signaling, Department of Microbiology, University of Virginia, Charlottesville, VA, [3]Center for Cell Signaling, Department of Biochemistry & Molecular Genetics, University of Virginia, Charlottesville, VA

Nuclear receptor transcriptional activity is regulated by mechanisms including ligand binding and phosphorylation. In the course of characterizing phospho-regulation of AR, we found that SV40 small t antigen (ST) mediates selective transfer of the PP2A A/C heterodimer onto AR (MCB 25: 1298, 2005). Using deletion analysis, protein-interaction assays, and the published crystal structure of PP2A, we determined that AR contacts HEAT repeat 14 in the A-subunit of PP2A. Since ST binding is centered on HEAT repeat 4, ST apparently causes a conformational change that is transduced ~76 angstroms to HEAT repeat 14. Induced-conformation represents a novel form of PP2A targeting, which normally relies on a B-subunit to target PP2A to its substrates. Because PP2A binds exclusively to the agonist-bound form of AR, we hypothesized that PP2A dissociation would be driven by androgen dissociation. We demonstrated this by correlating androgen and PP2A dissociation rates in vivo (R2=0.9859). Non-androgenic compounds can activate AR and may explain how prostate cancer cells escape androgen deprivation therapy. We tested a variety of compounds (androgen agonists, antagonists, and estradiol) to determine whether non-androgenic compounds can induce a conformation of AR that is suitable for accepting PP2A. Only R1881, dihydrotestosterone and the adrenal androgen androstenedione induced an AR conformation that bound PP2A in the ST transfer reaction. Because non-androgenic compounds induce an AR conformation that is functional for transcription but not for PP2A transfer, we conclude that at least two different conformations of AR can promote transcription. The PP2A-bound form of AR binds androgen response element DNA in gel shift assays, leading us to suggest that AR might target PP2A to the promoters of androgen-regulated genes.

1278

**Progesterone and Estrogen Receptor Profiles in the Human Corneal and Conjunctival Tissues, Cells and Cell Lines**

J. Shankardas,[1] V. V. Mootha,[2] S. D. Dimitrijevich[1]; [1]Integrative Physiology, UNT Health Science Center, Fort Worth, TX, [2]Ophthalmology, UT Southwestern Medical School, Dallas, TX

**Background**: There is increasing evidence for the role of age and gender in some pathologies. Thus dry eye syndromes and Fuchs endothelial dystrophy are prevalent amongst post-menopausal women. The effect of changing hormonal levels on the human anterior ocular compartment requires a clear profile of the relevant hormone receptors in these tissues and their cellular components. **Purpose**: The objectives of this study were to determine: a. the profile of estrogen and progesterone receptors in the corneal and conjunctival tissue, b. the profile of these receptors in the primary keratocytes, epithelial and endothelial cells c. the presence of these receptors in the epithelial and endothelial cell lines. Method: The lysates of the corneal and conjunctival epithelia were obtained after isolation from donor tissue with dispase. The primary cells were subcultured on glass coverslips, fixed-permeabilized and examined by indirect immunoflurescence. The hTERT transformed epithelial cells and E6/E7 transformed endothelial cells were also examined by indirect immunofluorescence. The deparaffinized cross-sections of the donor corneas and conjunctivas were examined by indirect immunofluorescence. The receptor profiles were confirmed by western analysis of cell and tissue lysates. **Results**: Indirect immunofluorescence showed a variable intracellular localization of the estrogen receptors (ERa, ERb) in all the cells, cell lines and tissues from male donors. The presence of progesterone receptors (PRA, PRB) was only detected in the corneal epithelial cells, the cell line, the endothelial cells, and the corneal sections. The western analysis confirmed the presence of PRA and PRB and ERa and ERb. **Conclusions**: Indirect immunofluorescence and western blot analysis show the presence of progesterone (A and B) and estrogen (a, b) receptors in the cellular components of the cornea and conjunctiva, and tissue cross- sections from male donors.

### Instability of Foreign DNA Integrated into the Genome of Transformed Cells

A. V. Ivanov; Cell Biology Laboratory, Petersburg Nuclear Physics Institute RAS, Gatchina, Russian Federation

This study describes the faith of foreign DNA integrated into the cultured mammalian cell genome. The apposite model system was created. It contains in Chinese hamster cell line A23 TK-, a plasmid vector p16 with two selective genes NEO (G418 resistance) and TK (thymidinkinase) of human herpes simple virus type 1 (HSV). Presence of TK HSV makes cells sensible to the herpes drug ganciclovir and resistant for HAT medium (hypoxanthine, aminoptherine, thymidine). The collection of 64 independent clones was created. Four types of transgene behavior are found reflecting different rates of plasmid DNA instability. The real deleting of transfected DNA from genome was demonstrated using the PCR technology. This data fully check with the selection features losses pattern. In majority it is seems the both integrated plasmid selective genes are lost, but in several cases just one gene is lost and another is steel present. The possibility of homological recombination increase by means RecA - like bacterial recombinases is tested. To check the supposition of high instability sites near integrated foreign DNA presence into the genome (has been existed or formatted during the integrative process) the work of cloning flank sequences of exogenic DNA was carried out. 10 k.b.p. plasmid containing both the fragments of primary plasmid p16 and sequences flanking regions of integration to the cell genome was cloned. Transfection of this plasmid to A23 cells made out resulting of 100 % unstable integration in 18 clones. Such data confirm the presence of defensive mechanisms, which prevent integration and preservation of exogene DNA in the eukaryotic cell genome. Main suggestions of molecular mechanisms are homologous recombination and integration to freak sites of chromosomes.

1280

### Ultrastructure of Euchromatin Contact Points between the Closed Loops of Adjacent Interphase Chromosomes

J. H. Frenster, J. A. Hovsepian; RNA Research, Physicians' Educational Series, Atherton, CA

Recent fluorescence microscopy studies (Parada LA, McQueen PG, and Misteli T, Genome Biology, vol. 5, no. 7, r44 (June 21, 2004), involving a systematic analysis of the spatial positioning of a subset of mouse chromosomes in several tissues, have suggested the possibility of an associative clustering of particular chromosomes in particular tissues during nuclear interphase. We have noted a similar phenomenon in isolated lymphocyte nuclei of calf thymus (Frenster JH, Nature 205: 1341 (1965), and have further analyzed our electron micrographs in order to define the ultrastructure of the phenomena. In the course of the isolation of repressed and active chromatin from interphase calf thymus lymphocytes, a stage is reached in which the nuclei swell to twice their normal size, offering a favorable material for the examination of the structural relations between the active euchromatin microfibrils and the repressed heterochromatin masses. Such swollen nuclei were gently prepared in cation-free isotonic sucrose, and examined for the location, number, shape, caliber, and length of continuous, closed loops of the 10 nm caliber active euchromatin microfibrils. The closed loops appear to be tethered at intervals of 50-100 nm to single masses of repressed heterochromatin chromocenters. The loops extend out into the interior of the nucleus for up to 1 um, forming elongated lariats that contact similar loops from adjacent chromocenters. At the point of close apposition between opposing loops from distinct chromocenters, dense microcylinders of 20-30 nm caliber are formed, appearing to represent equal contributions from each chromocenter. The microcylinders range up to 100 nm in length before separating into their original calibers of 10 nm each. The fields of such chromosomal apposition range up to 3 um in diameter, and are often elliptical in outline.

1281

### Probing the Chromatin Assembly Factor 1 Proteome

M. Hoek, M. Myers, B. Stillman; Cold Spring Harbor Laboratory, Cold Spring Harbor, NY

The chromatin assembly complex CAF-1 couples chromatin assembly to DNA replication and is essential for passage through S-phase in human cell lines. Recent evidence also suggests that CAF-1 may coordinate other activities on chromatin in a replication and DNA repair dependent manner. To gain insight into the multiple functions of CAF-1, we have begun to systematically analyze the set of CAF-1 interacting proteins. Cell lines expressing a FLAG-HA tagged p150 subunit of CAF-1 were established in RKO cells and the tagged protein was shown to be functional by RNAi rescue experiments. When the tagged protein complex was purified under standard conditions from nuclear extracts few novel CAF-1 interacting proteins were identified. However, when the stringency of the immunoprecipitation conditions was reduced, many more putative CAF-1 interacting proteins as well as previously identified CAF-1 partners such as PCNA and HP1 were recovered. cDNAs encoding these proteins were cloned and screened for interaction with recombinant CAF-1 using in vitro translation. To date, one strong interaction with the Ku86/Ku70 complex and several weaker interactions with other proteins have been recapitulated in this secondary screen. The interaction between CAF-1 and Ku requires both subunits of the Ku complex, emphasizing the utility of this approach in identifying interactions that are not binary. Protein phosphatase inhibitors and ATP are both required for the stable interaction between these complexes, suggesting that phosphorylation of one or both components is required. We are currently attempting to identify kinases important in regulating this interaction and are testing whether CAF-1 may be recruited to double-strand breaks that are bound by Ku.

1282

### A Temperature-Sensitive Mutation in the WD Repeat-Containing Protein Smu1 Is Related to Maintenance of Chromosome Integrity

K. Sugaya,[1] E. Hongo,[1] Y. Ishihara,[1] H. Tsuji[2]; [1]Radiation Hazards Research Group, National Institute of Radiological Sciences, Chiba, Japan, [2]Low Dose Radiation Effects Research Project, National Institute of Radiological Sciences, Chiba, Japan

Temperature-sensitive CHO-K1 mutant cell line tsTM18 exhibits chromosomal instability and cell cycle arrest at S and $G_2$ phases with decreased DNA synthesis at the nonpermissive temperature, 39°C. To identify the causative mutation, we fused tsTM18 cells with normal human cells to generate hybrids carrying fragments of human chromosomes. Analysis of chromosome content of temperature-resistant transformants and introduction of a bacterial artificial chromosome containing part of human chromosome 9 led to isolation of the human *SMU1* gene. Comparison of sequences of the *Smu1* gene from wild-type and mutant cells revealed that the mutant phenotype is caused by a G-to-A transition that yields a gly-to-arg substitution at position 489 in hamster Smu1. The substituted glycine is located in the WD-repeat domain of Smu1. Single-stranded DNA accumulated in the nuclei of mutant cells at 39°C. Furthermore, cdc2 kinase was not activated during $G_2$ phase, and there was no chromosome

segregation due to incomplete assembly of the spindle during M phase. Thus, Smu1 appears to be involved directly or indirectly in DNA replication, activation of cdc2 kinase, spindle assembly, and maintenance of chromosome integrity, reflecting the important roles of Smu1 in cellular function.

1283

**Changes in Chromatin Structure and Mobility in Living Cells at Sites of DNA Double-strand Breaks**

M. J. Kruhlak,[1] A. Celeste,[1] O. Fernandez-Capetillo,[1] G. Dellaire,[2] W. Muller,[1] J. G. McNally,[1] D. P. Bazett-Jones,[2] A. Nussenzweig[1]; [1]National Cancer Institute, National Institutes of Health, Bethesda, MD, [2]Programme in Cell Biology, The Hospital for Sick Children, Toronto, ON, Canada

The repair of DNA double strand breaks (DSBs) is facilitated by the phosphorylation of H2AX which organizes DNA damage signaling and chromatin-remodeling complexes in the vicinity of the lesion. Large-scale relaxation of chromatin has been proposed to activate the DNA damage transducer ATM at a distance, and may also increase the mobility of DSB-containing chromatin domains, whereas damage-mediated condensation may facilitate faithful repair by limiting the diffusion of broken ends. Although indirect evidence supports the idea that disruption of DNA integrity induces an alteration of chromatin architecture, little is known about the physical properties of damaged chromatin. Here we use a photoactivatable version of GFP-tagged histone H2B to examine the mobility and structure of chromatin containing experimentally induced DSBs in living cells. We find that bulk chromatin containing DSBs exhibits limited mobility but undergoes an energy-dependent local expansion immediately following DNA damage. To determine the ultrastructure of irradiation induced foci (IRIF) and the chromatin changes associated with the activation of ATM, we employed a correlative fluorescence and energy-filtering transmission electron microscopy imaging method. We find that the localized expansion observed in real-time constitutes a relaxation in higher order chromatin structure, corresponding to a 30-40% reduction in the density of chromatin fibers in the vicinity of DSBs. The observed opening of chromatin occurs independently of H2AX and restricts the initial activation of ATM to the locally damaged region. We propose that localized ATP dependent decondensation of chromatin at DSBs increases the accessibility of regions of damaged DNA to protein complexes, thereby establishing a sub-nuclear environment that facilitates DNA damage signaling and repair.

1284

**Calcium-Mediated Proteolytic Processing and Cellular Locations of DNA Topoisomerases**

S. Chou, H. Chen, T. Huang, T. Li; Department and Graduate Institute of Microbiology, Scholl of Medicine, National Taiwan University, Taipei, Taiwan Republic of China

DNA topoisomerases perform their functions by catalyzing the transient breakage and rejoining of DNA strands. Substantial evidences have shown that many cations participate in the catalytic process and/or the regulation of enzymatic activity of this class of enzymes. Here we observed that, within 15min of treatment, calcium ($Ca^{2+}$) ionophores, ionomycin and A23187, efficiently triggered proteolytic cleavage of human DNA topoisomerase I (hTOP1) and topoisomerase II beta (hTOP2β), but not hTOP2α. The ionomycin-induced proteolytic processing of topoisomerases can be blocked by pre- or co-treatment of $Ca^{2+}$ chelators supports the involvement of $Ca^{2+}$ in this process. In addition, addition of $Ca^{2+}$ into culture medium can also efficiently activate the proteolytic processing of DNA topoisomerases with identical patterns to those exhibited by cells treated with ionomycin. The caspase (Z-VAD-fmk) and 26S proteasome (MG132, lactacystin) inhibitors were found to have only minimal effects on $Ca^{2+}$-activated proteolytic events. Nevertheless, pretreatment of HCT116 cells with calpain inhibitor I or II can efficiently repress the $Ca^{2+}$-activated processing of topoisomerases. Thus, the calpain proteases are most likely to be critically involved in the ionomycin-induced, $Ca^{2+}$-activated proteolytic processing of DNA topoisomerases. In agreement with this notion, transient expression of calpastatin, a natural calpain inhibitor, can reduce the ability of ionomycin to activate the proteolytic processing of topoisomerases. Based on the epitope recognitions of the antibodies used, we conclude that both cleavages of DNA TOP1 and TOP2β occur on C'-terminus. The biological implication of our discovery remains unclear. However, the nuclear distributions of hTOP1 and hTOP2β are delocalized and further concentrated in the nucleolus upon ionomycin treatment, possibly through regulating the SUMOylation status of topoisomerases. The relationship between $Ca^{2+}$, SUMOylation states and cellular locations of DNA topoisomerases are discussed.

1285

**Condensin I is Essential for the Structural Integrity of Centromeric Heterochromatin During Mitosis**

R. A. Oliveira, P. A. Coelho, C. E. Sunkel; Molecular Genetics of Mitosis, Institute for Molecular and Cell Biology, Porto, Portugal

During cell division chromatin undergoes structural changes essential to ensure faithful segregation of the genome. Condensins are abundant components of mitotic chromosomes and are known to form two different complexes, condensin I and II. To further examine the role of condensin I in chromosome structure and in particular in centromere organization, we depleted from S2 cells the *Drosophila* CAP-H homologue (Barren), a subunit exclusively associated with condensin I. Immunofluorescence and *in vivo* analysis of Barren/CAP-H depleted cells showed that mitotic chromosomes are able to condense but fail to resolve sister chromatids. Additionally, Barren/CAP-H depleted cells show chromosome congression defects that do not appear to be due to abnormal kinetochore-microtubule interaction. Instead, the centromeric and pericentromeric heterochromatin of Barren/CAP-H depleted chromosomes shows structural problems. After bipolar attachment, the centromeric heterochromatin organized in the absence of Barren/CAP-H cannot withstand the forces exerted by the mitotic spindle and undergoes irreversible distortion. Taken together, our data suggests that the condensin I complex is required not only to promote sister chromatid resolution but also to maintain the structural integrity of centromeric heterochromatin during mitosis.

1286

**Long-range Directional Movement of Interphase Chromosome Site Dependent on Actin and Nuclear Myosin**

C. Chuang; Dept. of Cell and Developmental Biology, University of Illinois at Urbana-Champaign, Urbana, IL

Increasing evidence suggests functional compartmentalization of interphase nuclei. This includes preferential interior localization of gene rich and early replicating chromosome regions versus peripheral localization of gene poor and late replicating chromosome regions, association of some active genes with nuclear speckles, and association of transcriptionally repressed genes with heterochromatic regions. How is this differential chromosome positioning established? Does interphase chromosome motion occur passively, through regulating attachment and detachment from nuclear substructures but with random diffusion between nuclear compartments, or is it actively driven, through long-range, directed motion? Here

we demonstrate migration of an interphase, mammalian chromosome site from the nuclear periphery to interior 1-2 hours after targeting a transcriptional activator to this site. Migration is perturbed by specific actin or nuclear myosin I mutants. Extended periods of chromosome immobility are interspersed with several minute periods in which chromosomes move unidirectionally along curvilinear paths oriented roughly perpendicular to the nuclear envelope at velocities of 0.1-0.9 mm/min over distances of 1-5 mm. Our results reveal an active mechanism for fast and directed long-range interphase chromosome movements.

1287

**Visualization of Chromosome Structure and Localization of Chromosomal Proteins in Human Metaphase Chromosomes**

L. Lin,[1] M. Yanagisawa,[1] S. Uchiyama,[1] S. Inaga,[2] S. Matsunaga,[1] A. Takaoka,[1] K. Fukui[1]; [1]Osaka University, Suita, Japan, [2]Tottri University, Yonago, Japan

Genomic DNA of higher eukaryote highly condenses and forms chromosomes during mitosis. Chromosome condensation is indispensable for precise and homogeneous segregation of daughter cells. The model of chromosome organization has not been definitively determined, even though several models were proposed to date. To elucidate the chromosome higher order structure, metaphase chromosomes isolated by a polyamine-percoll method from HeLa S3 cells synchronized with colcemid, were treated with various salt concentrations. Changes in chromosomal morphology were observed by SEM. Chromosomes basically maintained X-shaped structure in each salt concentration, but their surface structure changed from granular to fibrous structure along with increasing salt concentration. Chromatid segregation and chromosome decondensation were both considerably changed when chromosomes were treated with 0.4 M NaCl. Chromosome structural alteration with salt treatment suggested that specific proteins dissociated from chromosomes contribute to the higher-order chromosome structure. hCAP-G, a non-SMC subunit of condensin I, TopoII α and Ki-67 are identified as chromosomal proteins: hCAP-G and TopoII α are localized at chromosome axis and are required for mitotic chromosome assembly; Ki-67 is localized at nucleoli in interphase and periphery of chromosomes during mitotic phase. The localization of these proteins in chromosomes was further confirmed by an immunoelectron microscopy using gold labeled antibodies. However, chromosome morphological alteration was supposed to occur during or after immunogold staining in our initial studies. Optimization conditions for immunogold staining revealed that chromosomal morphology was well-preserved and chromosomes were more compact in PBS buffer containing $Mg^{2+}$. Localization analyses of Ki-67 using immunogold-labeling were consistent with immunofluorescent staining revealed that Ki-67 is localized at chromosomal periphery and centromeric region. To elucidatie higher-order chromosome structure localization and interaction analyses of chromosomal proteins would give further insight.

1288

**Targeting Heterochromatin Formation on the Dot Chromosome of D melanogaster**

S. C. R. Elgin,[1] A. Caudy,[2] W. Leung,[1] K. A. Haynes[1]; [1]Biology, Washington University, St. Louis, MO, [2]Lewis-Sigler Institute for Integrative Genomics, Princeton University, Princeton, NJ

The small fourth chromosome of *Drosophila melanogaster* is unusual; while it has a normal gene density in its short distal arm (1.2 Mb), this domain has a ca. 10-fold higher density of repetitious sequences than the euchromatic arms, and is largely packaged as heterochromatin. Using a *P* element reporter containing an *hsp70*-driven copy of the *white* gene to map the region on the fourth chromosome around *Hcf*, we observe that when the reporter lies within ca. 10 kb of a *1360* repetitious element, it shows a variegating phenotype, indicative of heterochromatin packaging; however, when the reporter lies further away, it shows a red eye phenotype, indicative of euchromatic packaging (Sun et al., 2004, Mol. Cell. Biol. 24, 8210). In a direct test, a single copy of *1360* in a *P* element construct did not by itself lead to a variegating phenotype, but did make a critical contribution to silencing when the *P* element was inserted into a pericentric region, as shown by a loss of silencing on FLP-medicated excision of *1360*. Silencing via heterochromatin formation has been shown to be dependent on the RNAi system in Drosophila (Pal-Bhadra et al., 2004, Science 303, 669). Northerns done using the *1360* from our *P* construct to probe total RNA from embryos, Kc or S2 cells show dsRNA of ca. 22 bp; the amount of *1360* products in cells is impacted by *Dicer* knockdown. An inverted arrangement of adjacent *1360* fragments within an intron of *Caps* is predicted to form a stable hairpin, a possible source of siRNA's. We infer that effective silencing depends on the presence of an appropriate *cis*-acting RNAi target sequence and on the local density of repetitious sequences in the genome. [Supported by NIH grant GM 068388.}

1289

**Human Transcriptional Coactivator PC4, a Chromatin Associate Protein Induces Chromatin Compaction**

C. Das,[1] K. Hizume,[2] K. Batta,[1] K. Takeyasu,[2] T. K. Kundu[1]; [1]Molecular Biology and Genetics Unit, J N Centre for Advanced Scientific Research, Bangalore, India, [2]Graduate School of Biostudies, Kyoto University, Kyoto, Japan

Human transcriptional coactivator PC4 is a highly abundant multifunctional protein, which plays diverse important roles in cellular processes including transcription, replication and repair. It is a unique activator of p53 function. Here we report that it is a bonafide component of chromatin with distinct chromatin organization ability. By direct cell imaging we show that PC4 is predominantly associated with the chromatin through all the stages of cell cycle and is broadly distributed on the mitotic chromosome arms in a punctate manner except the centromere. PC4 selectively interacts with core histones H3 and H2B (in vitro and in vivo) which is essential for PC4-mediated chromatin condensation as shown by micrococcal nuclease (MNase) accessibility assay, circular dichorism spectroscopy assay and atomic force microscopy. The AFM images show that PC4 compact the 100 kb reconstituted chromatin very distinctly as compared to the liker histone H1. Silencing of PC4 expression in HeLa cells results in chromatin decompaction as evidenced by the increased MNase accessibility. Global gene expression analysis reveals that knocking down of PC4 up-regulates several genes, suggesting its physiological role as a chromatin compacting protein. These results establish PC4 as a new member of chromatin associated protein (CAP) family, which plays an important role in chromatin organization.

1290

**Regulation of Genome Architecture in *Escherichia Coli*: The Expression of Topoisomerase-i is Essential for the Dps-dependent Nucleoid Compaction**

R. L. Ohniwa,[1] K. Morikawa,[2] J. Kim,[1] T. Ohta,[2] C. Wada,[1] A. Ishihama,[3] K. Takeyasu[1]; [1]Graduate School of Biostudies, Kyoto University, Kyoto, Japan, [2]Institute of Basic Medical Sciences, Tsukuba University, Tsukuba, Japan, [3]Nippon Institute of Biological Science, Tokyo, Japan

Atomic force microscopy (AFM) of *Escherichia coli*, *Staphylococcus aureus* and *Clostridium perfringens* nucleoids has revealed that the hierarchy of the bacterial genome organization is achieved via several steps of DNA folding using fundamental 40 and 80 nm fibers (Kim et al., 2004; Takeyasu et al., 2004). A nucleoid protein, Dps, plays a critical role to build up a tightly compacted nucleoid under specific environmental conditions in certain species. We report here the mechanisms of Dps/MrgA-dependent nucleotide compaction in bacteria. In *S. aureus*, an overexpression of exogenous MrgA (homologue of *E. coli* Dps) in the log phase led to a nucleotide compaction, whereas, in *E. coli*, such an overexpression of Dps did not induce nucleoid compaction. This was because Dps/MrgA-dependent nucleoid compaction required the expression of topoisomerase-I, and because the topoisomerase expression was repressed in the *E. coli* log phase, but not in the S. sureus log phase, due to the high-level expression of *E. coli* Fis that inhibited the topoisomerase-I gene expression. (Note that S. aureus does not possess the *fis* gene.) This molecular mechanism can be generally applicable to other types of nucleoid compaction; e.g., oxidative stress-induced nucleoid compaction. The expression of both endogenous *dps* and *mrgA* genes was up-regulated in the presence of 2mM $H_2O_2$. However, only the *S. aureus* nucleoid was compacted in this condition. When the *fis* gene was deleted and the topoisomerase-I expression was up-regulated in *E. coli*, such an oxdative stress successfully led to the nucleoid compaction. These results suggest that the regulation of DNA topology is critical for the Dps-induced nucleoid compaction.

1291

**Distinct Three Steps of Apoptotic Nuclear Condensation: Analysis of Cell-free Apoptosis by Time-lapse Imaging, Biochemical Technique and Electron Microscopy**

S. Tone,[1] K. Sugimoto,[2] K. Tanda,[1] H. Kanouchi,[1] Y. Minatogawa[1]; [1]Biochemistry, Kawasaki Medical School, Kurashiki, Japan, [2]Graduate School of Life and Environmental Sciences, Osaka Prefecture University, Sakai, Osaka, Japan

Dynamic changes of nuclear chromatin are a one of most essential phenomena in apoptotic execution. In healthy cells, genomic DNA, ~2m in size, are functionally packaged into nuclei, several micrometers in diameter. At mitosis, chromatin is more condensed and transformed into chromosomes. In apoptosis, giant complex of DNA and nuclear proteins are faithfully and efficiently unpackaged and chromatin goes condensation. Therefore, it is tempting to speculate that cells would have an apoptosis-specific system by which cells efficiently induce chromatin condensation. We have been studying molecular mechanisms on apoptotic chromatin condensation using cell-free system, which has been developed (Lazebnik et al., '93, Samejima et al '98) and made us possible to reveal critical roles of each molecules in apoptotic execution. In this presentation, at first we will show the nuclear dynamic changes in cell-free apoptotic system and make a definition of each steps (Ring--Slits/Necklace--Final). Next, we will show the time-lapse imaging of DNA and centromeric protein during cell-free apoptosis. In our hands, total time of cell-free apoptosis was ~30-40 min. Duration time of step to Ring and to final condensation step was both estimated within 4 mins. Chromatin and centromeres behaved together. Interestingly, EM revealed that neither chromatin nor subnuclear structures were present inside the "ring". DNase activity was not essential for the ring formation, because apoptotic extracts devoid of DNases could make ring structure. But DNase(s) are necessary to proceed to next Step, Slits/Necklace. Finally, if ATP will be omitted in the reaction of cell-free system, nuclear condensation arrested before Step of Final. It suggested that ATP-binding proteins acted in the final step. We will discuss the cell-biological significance of these findings in nuclear condensation.

1292

**Genetic and Biochemical Analysis of Chicken Smc5**

A. K. Stephan, C. Morrison; Biochemistry and NCBS, NUIG, Galway, Ireland

The Structural Maintenance of Chromosomes (SMC) proteins are highly conserved V-shaped molecules with long coiled-coil arms, existing as heterodimers in eukaryotes in complex with several non-Smc subunits. Three essential SMC- containing complexes have been identified to date: cohesin (containing Smc1 and Smc3), condensin (containing Smc2 and Smc4), and an as-yet unnamed complex containing Smc5 and Smc6 proteins. Like cohesin and condensin, the Smc5-6 complex is essential for viability and seems to control chromatin structure. Studies on mutants of the Smc5-6 complex in fission yeast have demonstrated that it plays a role in repairing double-strand breaks (DSBs) by homologous recombination. It is also suggested that the Smc5-6 complex is involved in checkpoint maintenance, by coordinating the checkpoint arrest of the cells until the completion of DNA repair. Nevertheless, the essential function of this complex remains unclear. To generate a model system for defining the roles of the Smc5 protein in DSB repair and mitosis we are using the hyper-recombinogenic chicken DT40 cell line. Initial results of targeting the *Smc5* locus indicate that disruption of the *Smc5* gene is lethal. In order to develop a conditionally null cell line with *Smc5* expressed from a tetracycline repressible promoter, *Smc5* cDNA and 5'untranslated region (5'UTR) were cloned and sequenced. Sequencing analysis showed 63% identity between chicken and human at the aminoacid level. We have also generated anti-chicken Smc1 and Smc5 antibodies, which will be used for characterizing Smc5 and investigating any direct or indirect interactions between the Smc5 protein and the cohesin complex that may control chromosome behaviour.

1293

**Live Imaging of the Amphibian Lampbrush Chromosomes**

N. Novikova, C. Austin, B. Beenders, S. Patel, M. Bellini; Cell & Developmental Biology, University of Illinois at Urbana-Champaign, Urbana, IL

While the amphibian oocyte provides a high spatial resolution to investigate nuclear structures, live imaging of its nuclear compartment requires the nucleus to be hand-isolated in mineral oil and directly mounted under a cover glass. In this *in vivo*-like condition, the nucleus maintains all its activities for more than 24h, and non-chromosomal organelles such as nucleoli, Cajal bodies, ICGs as well as a heterogeneous population of large RNP granules are readily observable by light microscopy. The chromosomes remain elusive however. When oocytes were microinjected with DNA fluorescent dyes such as DAPI or Picogreen prior to isolating nuclei, two different structures were labeled: nucleoli and several thin and long fibers. Surprisingly, these fibers changed shape overtime and in some rare instances resumed the aspect of chromosomes. We concluded that these fibers were stretched chromatin fibers and that the apparent absence of chromosomes in oil-isolated nuclei resulted from their extensive damage (stretching and numerous breakages) during sample preparations. We recently modified the preparation procedure to minimize the stress imposed on chromomes and we obtained the very first live images of the oocyte lampbrush chromosomes. As a result, it is now possible to investigate the dynamics of nuclear proteins involved in chromatin organization with an unprecedented resolution.

**The Use of miRNA and siRNA Libraries to Identify Genes Involved in the Regulation of hTERT Transcription**

D. Ovcharenko, K. Kelnar, A. Cheng, D. Wang, L. P. Ford; R&D, Ambion, Austin, TX

Human telomerase is composed of a catalytic reverse transcriptase, hTERT and an RNA component, hTR. The telomerase reverse transcriptase adds the telomeric repeat sequences found on the terminus of each human chromosome using hTR as the template. While most normal cells lack telomerase activity, more than 90% of all cancer cells are telomerase positive. In addition, induction of telomerase activity is strongly associated with the cellular transformation process. Although transcription of the hTERT gene is known to be the critical event in creating active telomerase in cells, it is not well understood how hTERT transcription is regulated. Therefore, we performed a screen using siRNA and miRNA libraries to identify genes that up regulate transcription of hTERT in a telomerase negative normal diploid human fibroblast cell line using a real time PCR assay. Using this approach we identified genes and miRNAs that induced hTERT transcription. The genes identified in the siRNA portion of the screen can be grouped into gene classes associated with cancer and aging. The miRNAs that were identified in the screen are predicted to regulate the expression of some of the genes identified in the siRNA screening. This suggests that these miRNAs are causing the induction of hTERT by regulating those predicted targets. This is the first account of combining siRNA and miRNA library screens to identify gene pathways and functions.

**An Analysis of the in vivo Mechanism of the Bacterial Condensin MukBEF**

R. B. Case,[1] N. R. Cozzarelli,[1] C. Bustamante[2]; [1]Molecular & Cell Biology, UC Berkeley, Berkeley, CA, [2]Physics, U.C. Berkeley, Berkeley, CA

MukBEF, the condensin in Escherichia coli, is a member of a protein family broadly conserved from bacteria to man that organizes and compacts DNA in a mechanism essential for faithful chromosome partitioning. While progress has been made through genetic analyses of mutants and through in vitro assays of purified components, critical details of the biological mechanism remain undiscovered. For example, the role of ATP in MukBEF-DNA association and compaction is unknown; and the presence of other protein interacting partners and the biological compact structures that are formed are both still undescribed. I will present my progress on a set of in vivo experiments that directly address each of these shortfalls. Specifically, I am making a collection of point mutations that are each predicted to block the MukBEF ATPase cycle in a different step (ATP binding, ATP hydrolysis, etc.). Each mutant or mutant protein will be analyzed with flow cytometry, single-cell fluorescence microscopy, mass spectrometry and AFM to reveal how each mutation affects the in vivo mechanism. Once completed, the results should provide sufficient insight for an initial model of the biological mechanism of MukBEF-dependent DNA compaction and organization.

**The JIL-1 Histone H3S10 Kinase Regulates Dimethyl Histone H3K9 Modifications and Heterochromatic Spreading in *Drosophila***

K. M. Johansen, W. Zhang, X. Bao, H. Deng, S. Lerach, J. Girton, J. Johansen; Biochemistry, Biophysics & Molecular Biology, Iowa State University, Ames, IA

In *Drosophila* euchromatic genes can be transcriptionally silenced as a result of their placement in or near heterochromatin, a phenomenon known as position effect variegation (PEV). Repression typically occurs in only a subset of cells and can be heritable leading to mosaic patterns of gene expression. PEV in *Drosophila* has served as a major paradigm for the identification and genetic analysis of evolutionarily conserved determinants of epigenetic regulation of chromatin structure. In this study we present evidence that the JIL-1 histone H3S10 chromosomal kinase functions in a novel pathway to establish or maintain euchromatic regions by antagonizing heterochromatization and gene silencing. In the absence of JIL-1 the overall levels of histone H3K9 dimethylation and HP1 are unchanged; however, these major markers for heterochromatin formation spread to ectopic locations with a pronounced increase on the male and the female X chromosomes. Genetic interaction assays demonstrated that JIL-1 functions antagonistically to Su(var)3-9 which is the major catalyst for dimethylation of the histone H3K9 residue. On the basis of these findings we propose a model where JIL-1 functions to mark euchromatic domains and counteract heterochromatization and gene silencing at ectopic locations by Su(var)3-9-mediated histone H3K9 dimethylation and HP1 recruitment. In support of this model we demonstrate that the lethality of a severely hypomorphic *JIL-1* heteroallelic combination could be almost completely rescued by a reduction in *Su(var)3-9* dosage that prevented ectopic dimethylation of histone H3K9. This indicates that the lethality of *JIL-1* null mutants may be largely due to repression of essential genes at ectopic sites as a consequence of the spreading of Su(var)3-9 activity. (Supported by NIH grant GM62916).

**Distinct Roles for Cysteines in the Structure and Nuclear Transport of the Chromatin Protein Hmgb1**

G. Hoppe, K. E. Talcott, S. K. Bhattacharya, J. W. Crabb, J. Sears; Cole Eye Institute, Cleveland Clinic, Cleveland, OH

Reversible modification of sulfhydryls by glutathione represents an efficient mechanism for regulation of protein activity in response to oxidative stress. Removal of glutathione adducts is catalyzed by a small oxidoreductase glutaredoxin. We sought to identify nuclear proteins that undergo redox-dependent S-glutathionylation and enzymatic de-glutathionylation in the retinal pigment epithelium (RPE). Selective oxidation of sulfhydryls was induced in cultured RPE cell lines diamide. Nuclear proteins were isolated, treated with recombinant glutaredoxin, labeled with biotin-maleimide, purified, and identified by mass spectrometry. Cellular localization and mobility of EGFP-fusion proteins were monitored using live fluorescent microscopy and fluorescence recovery after photobleaching. High mobility group protein B1 (Hmgb1), a DNA-binding structural chromosomal protein and transcriptional co-activator was identified as a substrate of glutaredoxin. Hmgb1 contains 3 cysteines, Cys23, 45, and 106 and their irreversible alkylation reduces Hmgb1 DNA binding. After oxidative stress, Cys23 and Cys45 readily form intramolecular disulfide bridge, whereas Cys106 remains in the reduced form. EGFP-tagged wild type Hmgb1 and endogenous Hmgb1 co-localized in the nucleus. Replacement of Cys23 and/or 45 with serines did not affect the nuclear distribution of the mutant proteins, while C106S and triple cysteine mutations impaired nuclear localization of Hmgb1. Intracellular mobility of Hmgb1 was severely impaired by the mutation of Cys106, but not of Cys23 or 45. Hmgb1 and its homologue Hmgb2 are the only HMG-box proteins that contain cysteines that may be targets of reversible protein S-glutathionylation. Cys23 and 45 confer redox-sensitivity by inducing conformational and functional changes in response to oxidative stress, while Cys106 governs nucleocytoplasmic shuttling of Hmgb1.

## Nuclear Import and Export Signals (1298-1311)

1298

### Nuclear Import of the HIV-1 Integrase

A. Armon-Omer, A. Loyter; Biological Chemistry, Hebrew University of Jerusalem, Jerusalem, Israel

The HIV-1 integrase (IN), have been implicated in mediating nuclear import of the viral pre-integration-complex. Previously we have shown that a synthetic peptides bearing residues 161-173 of the HIV-1 IN was able to mediate active import into nuclei of permeabilized cells, as well as binding to importin α, and therefore was designated as the nuclear localization signal NLS(IN). Subsequently we have study the karyophilic properties of a recombinant IN proteins lacking the NLS(IN) domain. This truncated protein designated as IN-152, exhibited partial nuclear import when incubated with permeabilized cells or when microinjected into intact cultured cells. Receptor-mediated nuclear import is evident from experiments showing that translocation of the IN-152 was competitively inhibited by it self. The IN-152 interacted with importin α, but to a lesser extent than that of the full-length IN. Thus it appears that in addition to the NLS(IN) region, additional domains may be involved in active nuclear transport of the IN. In-vivo studies of IN interaction with importin α were performed using the srp1-31 yeast mutant strain, whose importin α is not functional at non-permissive temperature. Cells were transfected with an inducible expression vector bearing the coding sequence of a yEGFP-IN. In mutant strain incubated at the permissive temperature nuclei, was highly fluorescence, while in those incubated at the non-permissive temperature a large part of the fluorescence was located in the cytosol. These findings strongly support the view that nuclear import of the IN occurs via the importin α pathway.

1299

### The Cellular Localizations of SR-Related Proteins in *Schizosaccharomyces pombe* Fission Yeast Are Affected by SR-Protein Specific Kinase Dsk1

Z. Tang, S. Alaei, C. Wilson, C. Chiu, J. Oya, J. Shin, H. Buitron, S. Hardy; W.M. Keck Science Center, Claremont Colleges, Claremont, CA

Prp2, Srp1, and Srp2 are SR-related proteins in *Schizosaccharomyces pombe*. Prp2 protein is the orthologue of U2AF large subunit that genetically interacts with Dis1-suppressing kinase (Dsk1), the orthologues of human SR-specific protein kinase1 (SRPK1). All three proteins are specifically phosphorylated *in vitro* by Dsk1 kinase. Srp1 and Srp2 form a complex and their association is inhibited by Dsk1-mediated phosphorylation. To investigate the regulatory role of Dsk1 *in vivo*, we determined the cellular localizations of Prp2, Srp1, and Srp2 by ectopical expression of the corresponding GFP fusion proteins in wild-type and *dsk1*-deletion fission yeast strains. Consistent with its role in pre-mRNA splicing, GFP-Prp2 was localized in the nucleus of wild-type cells, but it was diffused throughout the *dsk1*-null mutant cells. A similar distribution pattern was also observed for GFP-Srp2. Opposite to Prp2 and Srp2, GFP-Srp1 was normally spread out in the cell, while it became retained in the nucleus of the cell with $dsk1^+$ deleted. The cellular localization of these proteins were also investigated in a strain with another SRPK gene $kic1^+$ deleted. Although the localization pattern of Srp1 was partially changed in the *kic1*-null strain, the distributions of Srp2 and Prp2 remained the same in the mutant as in the wild-type cells. Therefore, the cellular localizations of the SR-related proteins are specifically affected by Dsk1 kinase. Our studies provide the first genetic evidence for the important role of Dsk1 in modulating the cellular localizations of the SR-related proteins, revealing an *in vivo* function of SRPKs. Together with the effect of the phosphorylation on the Srp complex, the results suggest a potential mechanism to govern the activities of the SR-related proteins by Dsk1 through regulating their interactions and localizations in fission yeast cells.

### Pushing the Envelope on Nuclear Import of Parvovirus

S. Cohen, A. Behzad, J. Carroll, N. Pante; Department of Zoology, University of British Columbia, Vancouver, BC, Canada

Parvoviruses are small DNA viruses that replicate in the nucleus of their host cells. After entering the cell by receptor-mediate endocytosis, the virus is released into the cytoplasm and enters the nucleus. Cell-entry of parvoviruses has been studied in some detail. However very little is known about trafficking of parvoviruses from late endosomes on. In particular, the mechanisms underlying parvovirus' nuclear import remain largely undefined. Nevertheless, it has been assumed that parvovirus enters the nucleus through the nuclear pore complex (NPC). In order to study this problem we microinjected the parvovirus minute virus of mice (MVM) into the cytoplasm of Xenopus oocytes and used electron microscopy (EM) to visualize its nuclear import. In contrast to oocytes microinjected with other import substrates that have shown the substrate crossing the NPC, MVM was not seen in transit through NPCs. Instead, we found that MVM caused damage to the nuclear envelope (NE) in a time- and concentration-dependent manner. Our findings suggest that MVM is imported into the nucleus using a unique mechanism that is independent of the NPC, and involves disruption of the NE. To demonstrate that this mechanism is used by MVM during infection, we then infected mouse fibroblast cells with MVM and examined the cells by fluorescent microscopy after performing double immuno-labeling with anti-lamin A/C and anti-MVM antibodies. Consistent with our results on Xenopus oocytes we found abnormal gaps in the lamin A/C immuno-staining. To further characterize these NE perturbations at the ultrastuctural level, MVM infected cells were also analyzed by EM. We found that MVM infection was associated with dramatic alterations in the nuclear shape and NE morphology. Our findings are consistent with a mechanism of nuclear entry of MVM that involves disruption of the NE and import through the resulting breaks.

### Apoptin Nuclear Accumulation is Modulated by a CRM1-Recognised Nuclear Export Signal that is Active in Normal but not Tumor Cells

I. K. H. Poon, C. Oro, M. M. Dias, D. A. Jans; Dept. of Biochem. & Mol. Biol., Monash University, Clayton, Australia

Cancer is a growing problem for human health world-wide, with a dearth of efficient and above all specific anti-cancer treatments. Viral protein 3 (VP3/apoptin) from Chicken Anaemia Virus (CAV), represents a potential, novel anti-cancer tool, as it appears to possess tumor-specific p53-independent, Bcl-2-enhanced pro-apoptotic activity (1). Intriguingly, the anti-tumour cell activity of VP3 is integrally linked to its ability to localise in the nucleus of transformed cells, but not in primary or non-transformed cells (1). We have characterised the signals responsible for VP3's novel nucleocytoplasmic trafficking properties in detail for the first time by performing transfection studies and quantitative confocal microscopic analysis in two isogenic tumor/non-tumor cell pairs. Additional to identifying the tumor cell-specific nuclear targeting signal (tNTS), comprising two stretches of basic amino acids in the VP3 C-terminus which are more efficient in tumor than normal cells, we define the CRM1-recognised

nuclear export sequence (NES; amino acids 97-105) within the VP3 tNTS which, intriguingly, is functional in normal but not tumor cells. The basis for lack of functionality in tumor cells appears to be through the threonine 108 phosphorylation site adjacent to NES which inhibits its action. We also characterize an N-terminal leucine-rich sequence within VP3 (amino acids 33-46) that contributes to VP3 nuclear accumulation by functioning as a nuclear retention sequence, conferring association with promyelocytic leukemia (PML) nuclear bodies. This unique combination of signals, and in particular the phosphorylation regulated NES, is the basis of VP3's tumor cell-specific nuclear targeting abilities, and may have important possible application in targeting drugs efficiently to the nucleus of tumor cells. **(1) Oro C, Jans DA.** *Curr. Drug Targ*ets **5**, 179, 2004 **(2) Poon IKH *et al.*** *J. Virol*. **79**, 1339, 2005

**Identification of a Novel Nuclear Export Sequence of OREBP/TonEBP/NFAT5 that Controls Cytoplasmic Localization**

B. Ko,[1] E. H. Tong,[1] S. S. Chung[2]; [1]Department of Chemistry, The University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China, [2]Department of Physiology, The University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China

The Osmotic-Response Element-Binding Protein (OREBP), also known as the Tonicity Enhancer-Binding Protein (TonEBP) or NFAT5, regulates the hypertonicity- induced expression of a battery of genes crucial for the adaptation of mammalian cells to extracellular hypertonic stress. Recently, it has been suggested that OREBP may play a role in metastasis. The nucleocytoplasmic trafficking of OREBP plays an important role in regulating its function. Here we show that, by immunocytochemistry and GFP fusion, the transactivation domain of OREBP is not necessary for the nucleocytoplasmic trafficking. Nuclear export of OREBP can be blocked by leptomycin B, suggesting that it is a Crm1-dependent process. However, two leucine-rich motifs located in the N-terminal of OREBP do not function as nuclear export signals (NES). In contrast, a protein domain N-terminal to the DNA-binding domain functions as NES and directs the localization to the cytoplasm. Recombinant OREBP devoid of the NES constitutively resides in the nucleus despite of extracellular hypotonicity.

1303

**Cse1: Exporting Importin-α**

A. G. Cook,[1] G. Schlenstedt,[2] E. Conti[1]; [1]Structural and Computational Biology, EMBL, Heidelberg, Germany, [2]Medizinische Biochemie und Molekularbiologie, Univeritaet des Saarlandes, Homburg, Germany

During interphase thousands of molecules of RNA and protein must cross the nuclear membrane to move from the site of synthesis to the site of function. Cse1 is a nuclear exportin of the karyopherin-β family that is required for RanGTP-dependent recycling of importin-α to the cytoplasm. Importin-α acts as an adaptor for importin-β by recognizing proteins with a classical nuclear localization signal (NLS). The structure of the cytoplasmic, cargo-free structure of Cse1 has been solved to 3.1 Å revealing a HEAT repeat protein consisting of an N-terminal and a C-terminal arch (Cook *et al* 2005 Mol. Cell 18:355). Comparison with the structure of the cargo-bound, nuclear form of Cse1 reveals a large conformational change. The cytoplasmic, cargo-free Cse1 forms a ring-like structure created by an intramolecular interaction between the N-terminal 3 HEAT repeats and part of the C-terminal arch. This interaction is disrupted in the nuclear form when RanGTP and importin-α are bound. The conformational changes are localized to a hinge region between the N- and C-terminal halves of Cse1. Isothermal calorimetry (ITC) analysis indicates that both RanGTP and importin-α are able to independently interact with Cse1. They form relatively low affinity complexes compared with the heterotrimer complex that has a binding constant in the low nanomolar range. Mutations in the intramolecular interface uncouple importin-α binding from RanGTP whereas mutations to a conserved insertion in the hinge region prevent complex formation. These data point to a mechanism of binding that involves initial recruitment of RanGTP and importin-α through low affinity interactions followed by a larger structural rearrangement to form a tight complex.

1304

**Nucleocytoplasmic Shuttling of Hsc70s Is Inhibited in Stressed Cells**

M. Kodiha, R. Zhang, X. Quan, V. Illanganathan, J. Yu, N. Matusiewicz, U. Stochaj; Physiology, McGill University, Montreal, PQ, Canada

Heat shock proteins of the hsp/hsc70 family are essential chaperones, implicated in the stress response, aging, and a growing number of human diseases. At the molecular level, hsc70s are required for the proper folding and intracellular targeting of polypeptides as well as the regulation of apoptosis. Cytoplasmic members of the hsp/hsc70 family shuttle between nuclei and cytoplasm, and they are found in both compartments of unstressed cells. However, hsc70s concentrate in nuclei when cells are exposed to stress. Our objective is to define the molecular mechanisms that underlie the stress-induced nuclear accumulation of hsc70s. We now demonstrate that actin filament-destabilizing drugs concentrate hsc70s in nuclei of cells that are unstressed or recovering from heat exposure. Using human/mouse heterokaryons we show that heat shock inhibits hsc70 shuttling and sequesters the chaperone in nuclei. The inhibition of shuttling in response to stress is transient only, and transport is re-established when cells recover from heat. We have defined one of the mechanisms that prevent hsc70s to move in and out of the nucleus upon stress. As such, hsc70 shuttling is controlled by nuclear retention of the chaperone. This retention depends on two distinct processes, ATP-sensitive binding of hsc70s to chaperone substrates and an ATP-insensitive association with nucleoli. Our studies identified the nucleolar protein fibrillarin and ribosomal protein rpS6 as interacting components that show an increased association with hsc70s in the nucleus of stressed cells. This supports the idea that hsp/hsc70s play a pivotal role in restoring nucleolar functions after heat shock. Taken together, our data suggest that stress abolishes the export of hsc70s to the cytoplasm, thereby limiting their function to the nuclear compartment. We propose that during recovery from stress hsc70 is released from nuclear and nucleolar anchors, a prerequisite to resume shuttling.

1305

**CRM1-Dependent Nuclear Export of *IFN-α1* mRNA Is Mediated through a Structured Target Sequence That Is Conserved in *IFN-α2* and *IFN-α13* mRNAs**

T. Kimura, I. Hashimoto, J. Fujisawa; Microbiology, Kansai Medical University, Moriguchi, Japan

We recently reported the chromosome region maintenance 1 (CRM1)-dependent, but not adenylate uridylate-rich element (ARE)-mediated, nuclear export of the intronless human *interferon-α1 (IFN-α1)* mRNA. To investigate whether there are cis-acting sequences within the *IFN-α1* gene that mediate this CRM1-dependent mRNA export, we conducted deletion mutagenesis of the gene. Based on an in vivo export assay and subsequent

computer analyses of the folding potentials of export-competent fragments of *IFN-α1* mRNA, we found that a 68-nucleotide (nt) structured element allowed the mRNA export. This novel cellular sequence was located to nt 353-420 within the coding region of the *IFN-α1* gene, forming a putative RNA secondary structure that facilitates the mRNA export. This 68-nt element RNA was colocalized in the nucleus with CRM1, whose export was leptomycin B-sensitive. Upon removal of the element, *IFN-α1* mRNA failed to colocalize with CRM1, resulting in the nuclear retention of the RNA. In addition to the *IFN-α1* mRNA, the structured element is also conserved in the human *IFN-α2* and *-α13* mRNAs, which together represent the three dominant species of *IFN-α* mRNA expressed upon viral infection. Since coexpressed human immunodeficiency virus type 1 Rev blocked the expressions of both the *IFN-α2* and *-α13* genes in the same dose-dependent manner as for the inhibition of *IFN-α1* mRNA export, we suggest that the newly identified structured RNA element may be involved in the posttranscriptional regulation of these *IFN-α* gene expressions in a CRM1-dependent manner.

1306

**Osmotic Stress Signaling to the Nuclear Transport Machinery**

J. B. Kelley, B. M. Paschal; Center for Cell Signaling, University of Virginia, Charlottesville, VA

A high nuclear:cytoplasmic (N:C) gradient of the Ras-related GTPase Ran is used to regulate multiple nuclear import and export pathways in eukaryotic cells. Here we report that osmotic stress induced by 0.4 M sorbitol results in a rapid (5-10 min) breakdown of the Ran gradient in HeLa cells. Nuclear import rate measured by microinjection of a fluorescent reporter protein was reduced by 45%. Concomitant with breakdown of the Ran gradient was a dramatic change in the N:C distributions of NTF2 and Mog1, two of the proteins that regulate the Ran gradient in cells. The Ran import pathway may, therefore, be a target of sorbitol-induced stress signaling. Strikingly, 20 min following addition of sorbitol there was a partial recovery of the Ran gradient that correlated with a partial recovery of NTF2 and Mog1 N:C distributions, and nuclear import rate. Recovery was followed by a second drop in the Ran gradient, NTF2 and Mog1 N:C distributions, and nuclear import rate. A second recovery phase was observed between 30 and 60 minutes, suggesting there is a biphasic recovery. Kinase activity profiles of sorbitol-treated cells (35 kinases examined) lead us to study two pathways in Ran gradient regulation, p38 MAP kinase and PKC zeta. Cells pretreated with the p38 inhibitor SB203580 do not display the Ran gradient recovery normally observed after 20 min of sorbitol treatment, however, these cells still displayed recovery at 60 min. A myristoylated pseudosubstrate that inhibits PKC zeta, and a dominant negative form of PKC zeta, each disrupted the Ran gradient even in the absence of sorbitol-induced stress signaling. Thus, constitutive PKC zeta activity is required for the maintenance of the Ran gradient, while p38 mediates the initial recovery of the Ran gradient in response to osmotic stress.

**Nuclear Localization Signal: A Route to the Nucleolus**

H. Htun, Y. K. Lee, Y. X. Luong, T. Lee; Ob-Gyn and Molecular & Medical Pharmacology, David Geffen School of Medicine at UCLA, Los Angeles, CA

Nuclear localization signal (NLS) plays an important role in targeting proteins to the nucleus of eukaryotic cells. Once within the nucleus, the nuclear protein can exist throughout the nucleoplasm as well as in various membrane-less nuclear compartments, the most prominent being the nucleolus. In targeting a fluorescent RNA-binding protein to the nucleus, we have found NLS derived from SV40 large T-antigen to not only cause nuclear uptake but also to target our RNA-binding protein to the nucleolus. As this association with the nucleolus was unanticipated, we examined the role of the RNA-binding as well as type of NLS in nucleolar targeting. Site directed mutagenesis of the RNA-binding domain revealed a minor role for the RNA-binding domain in nucleolar association. However, examination of other NLSs showed that NLSs have differing potential to promote association with the nucleolus. In particular, the SV40 large T-antigen NLS has a greater affinity for the nucleolus than NLS derived from N-myc protein; and both NLSs have a higher affinity than NLS derived from c-myc protein. Positive correlation exists between a NLS' affinity for the nucleolus and its isoelectric point, with a greater propensity for nucleolar association observed for a more basic NLS; however, the extent of nucleolar association depends not only on the isoelectric point but also on the NLS sequence. Actinomycin D treatment disperses the chimeric NLS-containing protein from the nucleolus, indicating a requirement for RNA polymerase I transcription to maintain NLS-mediated nucleolar association. Lastly, we initially found fusions to c-myc derived NLSs to be excluded from the nucleolus; however, upon introduction of additional copies of the c-myc derived NLS, the fusion protein accumulated in the nucleolus. Thus, we propose that all basic NLSs have an inherent propensity to associate with the nucleolus.

1308

**Cohort Relationships Among Members of the Arabidopsis thaliana Hsp70 Molecular Chaperone Machine**

J. A. Miernyk,[1,2] Y. Suo,[2] M. L. Johnston[1]; [1]Plant Genetics Research Unit, USDA, ARS, Columbia, MO, [2]Biochemistry, University of Missouri, Columbia, MO

The Arabidopsis thaliana genome includes 17 genes that encode Hsp70 proteins and 94 genes that encode J-domain molecular chaperone proteins. The only know function of the J-domain is to direct docking between these two members of the Hsp70 molecular chaperone machine. Presumably, relationships among these proteins are specific rather than promiscuous. We have begun the process of defining cohort relationships. It has been experimentally determined that both members of Family 4 of the J-domain proteins, atDjC6 and atDjC37 are nuclear-localized. Based upon in silico analyses, AtHsp70-1, -2, -3, -4, -5, -14, and -15 are potentially nuclear or nucleocytoplasmically-localized. We have used bacterial 2-hybrid analysis to quantify interactions between these Hsp70 and J-domain proteins. Results from these analyses suggest specific interaction between atDjC6 and AtHsp70-1, and atDjC37 and AtHsp70-4 or AtHsp70-1. AtHsp70-6, a mitochondrial chaperone, was used as a control. Interactions with AtHsp70-1 were confirmed by co-precipitation of the recombinant proteins in vitro. We will further confirm these results using the GFP-trap assay, and extend them by using FRET for analysis of in planta interactions among fluorescent protein chimera.

1309

**Analysis of Nuclear Import of Adenoviral Core Protein VII Suggests Redundant Pathways for Import of the Viral Genome**

A. Cassany,[1] H. Wodrich,[2] M. D'Angelo,[1] T. Guan,[1] L. Gerace[1]; [1]Department of Cell and Molecular Biology, The Scripps Research Institute, La Jolla, CA, [2]Adenovirus: Vectorology, Trafficking and Receptors, CNRS UMR 5535, Institute of Molecular Genetics, Montpellier, France

Adenovirus is non-enveloped DNA virus with an ~36kb linear double-stranded genome. During virus infection, adenovirus DNA is thought to enter the nucleus in a complex with its core proteins. The nuclear import of adenovirus DNA can be inhibited in vitro by an excess of basic amino acid-rich protein nuclear localization signals (NLSs), suggesting that NLS(s) of the adenovirus core proteins drive the DNA import. Protein VII, which is the most abundant adenovirus DNA-binding protein (~1000 copies/virion), also is the most tightly bound core protein. We are testing the hypothesis that protein VII is an adaptor that mediates the nuclear import of the adenovirus genome. We found that protein VII contains potent NLS activity by transfection and by microinjection of cultured cells with protein VII fusion constructs. We identified three NLS containing regions in protein VII by deletion mapping, and determined the NLS sequences by point mutagenesis. The recombinant protein VII and its NLS-containing domains strongly and specifically bind to several nuclear import receptors including importin a, importin b, and importin 7. We demonstrated that binding of protein VII to this diverse range of receptors is functionally significant using in vitro nuclear import assays in permeabilized cells reconstituted with recombinant receptors. Considered together, these data suggest that protein VII can act as an adaptor to access several different receptor pathways for nuclear import of the viral genome. This suggests that adenovirus uses highly redundant mechanisms to promote efficient nuclear import of its DNA.

### Identification and Characterization of a Putative Nuclear Export Signal in the Tbx5 Transcription Factor

A. Kulisz,[1,2] H. Simon[1,2]; [1]Pediatrics, Northwestern University Feinberg School of Medicine, Chicago, IL, [2]Developmental Biology, Children's Memorial Research Center, Chicago, IL

In vertebrates, the transcription factor, Tbx5, is important in controlling cardiogenesis and forelimb induction and identity. However, it is not understood how Tbx5 regulates these events in the cell, nor how Tbx5 is regulated. We recently have identified a novel PDZ-LIM protein family member, Lmp4 that specifically binds Tbx5 but not related Tbx proteins. When expressed individually in COS7 cells, Tbx5 is nuclear and Lmp4 localizes with actin filaments. However, when co-expressed in COS7 cells, Lmp4 binds and targets Tbx5 to the actin filaments. Although two nuclear localization signals (NLS) have been identified, it is not known by what mechanism Tbx5 leaves the nucleus. We have identified a leucine-rich nuclear export signal (NES) in Tbx5, which is found in most of the substrates of the CRM1 export protein. Interestingly, within the Tbx2/3/4/5 subfamily Tbx5 and Tbx4 are unique to contain this putative NES. To determine if this NES is functional, mutagenesis was utilized to change critical amino acid(s) within this sequence. The NES-mutant Tbx5 constructs were expressed as EGFP-fusions with and without Lmp4 co-expression and localization was monitored by confocal microscopy and FRAP. All Tbx5 NES-mutants were retained in the nucleus even in the presence of Lmp4. The subcellular localization and interaction with Lmp4 were further analyzed via co-immunopreciptation, transcriptional activity assayed using luciferase reporter constructs, also in the presence of Leptomycin B, which is known to interfere with the CRM1 pathway. Taken together these data suggest that Tbx5 possesses a functional NES, which allows for an alteration in subcellular localization in the presence of Lmp4. This is the first demonstration of a NES in a Tbx transcription factor and offers new insights into a potential mechanism for regulated cytoplasmic localization of the Tbx5 transcription factor.

### Identification of Nucleoporin Binding Sites for Importin in situ at the Nuclear Pore Complex

S. S. Patel, M. Rexach; Biological Sciences, Stanford University, Stanford, CA

Nucleocytoplasmic transport is mediated by karyopherins and proceeds through nuclear pore complexes (NPC) embedded in the nuclear envelope. The first step in the translocation process is the docking of karyopherins to the cytoplasmic face of the NPC. Here we have characterized the docking step for the Kap95-mediated import pathway by reconstituting the binding of purified Kap95-Kap60 heterodimers to intact isolated yeast nuclei at 4°C. We find that on average, each NPC can dock up to 400 molecules of Kap95-Kap60 with an affinity ($K_D$) of 260 nM. Using a highly specific photocrosslinking approach, we found that FG nucleoporins (FG nups) located at the cytoplasmic face (Nup159, Nup42) and at the center of the NPC (Nup116, Nup100, nNup145, Nup57, Nup49, Nsp1) provide the primary docking sites for Kap95 *in situ* at NPCs. In contrast, the FG nups Nup53 and Nup59, and many other abundant non-FG nups and POMs in the center of NPC, did not crosslink to Kap95. Surprisingly, we also did not detect binding of Kap95 to any of the three nuclear basket nups (Nup1, Nup2, Nup60) *in situ*. We conclude that FG nups line the transport conduit of the NPC, and hypothesize that a thermally-operated gating mechanism prevents access of Kap95-Kap60 import complexes to the nuclear basket.

## Organogenesis (1312-1320)

1312

### Functional Screening for the Zygotic Determinants of Germ Layer Specification

N. Sasai, Y. Sasai; Organogenesis and Neurogenesis, Center for Developmental Biology, Kobe, Japan

The animal cap explant that is prepared from the blastula amphibian embryo is pluripotent and has the competence to differentiate into mesodermal tissues in responce to the mesoderm inducers such as FGF or activin. In contrast, the animal cap explant of the late-gastrula stage no more responds to these factors presumably because inhibitory signals are present at this stage. However, the molecular mechanisms underlying the loss of mesodermal competence have been largely unknown. This time, we performed a functional screen using early Xenopus embryos in order to search for zygotic genes which are involved in the ectodermal specification. We prepared a plasmid cDNA library from the animal cap of the late-gastrula stage, and screened 20,000 clones by injecting pools of mRNAs to select the clones that suppressed the expression of the early mesoderm marker Xbra (Xenopus Brachyury). By this screen, we identified seven novel zygotic genes including transcription factors and signaling modulators. Thus, many distinct signals as well as the already-known factors are involved in the ectodermal determination, in addition to maternal factors such as Ectodermin.

1313

### Disabled-2 is Essential for Angiogenesis *in vivo*

S. Cheong, J. Han; Division of Molecular and Life Sciences, Pohang University of Science and Technology, Pohang, Republic of Korea

The molecular mechanisms underlying the formation of embryonic blood vessels are poorly understood. We show here that Disabled-2 (Dab2), a cytosolic adaptor, has a pivotal role for the blood vessel formation in *Xenopus* and regulates the induction of VEGF via TGF-beta signaling pathway. Using the EST data base, we isolated cDNA for *Xenopus* Disabled-2 (XDab2) and examined its potential role in *Xenopus* embryogenesis. It is intriguingly expressed in blood vessels including pronephric sinus, vascular vitelline network, common cardinal vein, anterior cardinal vein, posterior cardinal vein, and intersomitic vein. Loss of function experiments using the morpholino oligonucleotides (MO) show that the formation of intersomitic veins which arise from angiogenesis is disrupted. Moreover, using the dominant negative TGF-beta receptor, we find that TGF-beta signaling is required for embryonic angiogenesis. In animal cap assay, we also show that TGF-beta signaling induces VEGF expression and its induction is decreased by Dab2 MO. However, other target genes of TGF-beta signaling pathway is unchanged by Dab2 MO. Furthermore, Dab2 knock-down embryos are rescued by VEGF. Together, these results suggest that XDab2 is essential for embryonic angiogenesis by regulating VEGF induction through TGF-beta signaling pathway.

1314

**SRG3, A Core Component of Mouse SWI/SNF Complex, Is Essential for the First Angiogenesis in Mouse Yolk Sac**

D. Han, J. Oh, S. Jeon, R. H. Seong; Department of Biological Sciences, Institute of Molecular Biology and Genetics, and Research Center for Functional Cellulomics, Seoul, Republic of Korea

We found that SRG3, a core component of mouse SWI/SNF chromatin remodeling complex, is expressed specifically in the yolk sac visceral endoderm in the early mouse embryo. We have previously shown that mutant mice deficient of the SRG3 expression are peri-implantation lethal. To investigate the role of Srg3 in the post-implantation stage, we set up the transgenic rescue experiment using transgenic mice(Tg+) expressing the SRG3 by chicken β-actin promoter. The rescued embryos(Srg3-/-Tg+) overcame peri-implantation lethality, but degraded after E10.5. Especially, fetus development was delayed and defects in yolk sac blood vessel were observed. In the visceral endoderm of the embryo yolk sacs, the SRG3 expression was virtually absent, and there were the marked reduction of angiogenesis-related genes. These results reveal that SRG3 is essential for the regulation of the yolk sac angiogenesis-related genes during the early mouse embryonic vessel development.

1315

**Role of p53 in Creating and Maintaining Luminal Space During Embryonic Submandibular Salivary Gland Morphogenesis**

T. Jaskoll, D. Witcher, G. Abichaker, M. Melnick; Lab Developmental Genetics, University of Southern California, Los Angeles, CA

Apoptosis has been shown to mediate the formation of lumina during embryonic submandibular salivary gland (SMG) development, with epithelial branches and terminal buds being hollowed out to form the ductal system and the presumptive acini. Centrally-localized epithelial cells undergo apoptosis whereas boundary cells with basement membrane contact survive. With the initiation of apoptosis from the center to the periphery, p53 protein is seen in centrally-localized cells targeted for death. Thus we postulate that p53 signaling is important for the creation and maintenance of luminal spaces during embryonic SMG morphogenesis. To begin to address this hypothesis, E15 mouse SMGs were cultured for up to 12 days (E15+12) in the presence or absence of pifithrin-α (PFTα), an inhibitor of p53 signaling. PFTα-treated E15+6 explants lack polarized epithelial cells and are characterized by lumina partially filled with cells and/or cellular debris. By day 12 of culture (E15+12), p53 inhibition results in the almost complete absence of luminal spaces. Since p53 signaling has been shown to induce cell cycle arrest, we then determined the affect of p53 inhibition on embryonic SMG epithelial cell proliferation. A significant 13% increase in cell proliferation is seen in PFTα-treated E15+3 explants. However, continued PFTα treatment *in vitro* results in a significant 32% decrease in cell proliferation in E15+8 explants and its virtual absence in E15+12 explants. Our results indicate that p53 signaling is not essential for creating lumina, but is necessary for apoptotic cell clearance and maintenance of a hollow lumen. The significant decrease in cell proliferation in PFTα-treated E15+8 and E15+12 SMGs indicates that increased epithelial cell proliferation does not account for the reducted size or absence of lumina. NIDCR (NIH) Grant number RO1 DE014535.

1316

**Heparan Sulfate Modulates FGF10 Function During Submandibular Gland Branching Morphogenesis**

V. N. Patel,[1] K. M. Likar,[1] M. Elkin,[2] I. Vlodasky,[2] M. P. Hoffman[1]; [1]Matrix and Morphogenesis Unit, CDBRB, NIDCR, National Institute of Health, Bethesda, MD, [2]Hadassah-Hebrew University Medical Centre, Jerusalem, Israel

Fibroblast growth factors (FGFs) are a family of heparin-binding growth factors that regulate branching morphogenesis of salivary glands. FGF signaling plays a key role in branching morphogenesis by regulating the gene expression and the activity of their receptors and extracellular matrix proteins. The affinity of FGF binding to FGF receptors is increased by heparan sulfate. In vivo the biological activity of heparan sulfate is regulated by heparanase, an endoglycosidase that degrades heparan sulfate. Chemical inhibitors of heparanase and function blocking anti-heparanase antibodies inhibit salivary gland branching suggesting heparan sulfate cleavage is required for FGF function during branching morphogenesis. The inhibitory effect of anti-heparanase antibodies was rescued by FGF10 but not by FGF7 suggesting heparan sulfate cleavage is required to release endogenous FGF10. Addition of exogenous FGF10 to epithelial rudiments induces cell proliferation at the tips of the ducts resulting in branching and duct elongation. This FGF10 mediated morphology is modified by exogenous heparin fragments containing 2-O and 6-O-sulfation, suggesting heparan sulfate increases the receptor binding of FGF10, and increases proliferation. Real time PCR shows that the genes for heparan sulfate 6-O sulfotransferases are expressed during early stages of SMG development with a profile similar to that of FGF10 expression. In situ analysis shows mesenchymal localization of 6-O-sulfotransferases adjacent to areas of proliferating epithelium. Collectively, our data suggest that defined sulfation patterns and cleavage of heparan sulfate, both regulate FGF10 function during SMG branching morphogenesis.

1317

**FoxF1 and Hex Expression Patterns during Gallbladder Organogenesis in the Zebrafish Embryo**

K. Young, E. Elzey, K. Halmon, L. Hammonds-Odie; Biology Department, Spelman College, Atlanta, GA

The genetic programs required for mesodermal interactions with endodermal cells in development, particularly as they relate to the formation of organs of the digestive system, have been the subjects of intensive study in recent years. During embryogenesis, endoderm-derived organ formation is accomplished through regional signaling pathways that must specify the gut tube to form the thyroid, lungs, liver, pancreas and gallbladder of vertebrates. Several transcription factors have been implicated in murine foregut development, particularly in the development of the liver and

pancreas. However, frequently in studies of biliary system or pancreatic development, the gallbladder is completely ignored, despite the proximity. The goal of this study is to document the expression of the zebrafish homologs of transcription factors for which a role in murine gallbladder development has been demonstrated. More specifically, we have examined the expression patterns of the transcription factors FoxF1 and Hex in zebrafish embryos. Determination of the expression patterns of these transcription factors temporally and spatially will not only help define the molecular control pathways that are involved in gallbladder organogenesis, but will also provide invaluable markers for early gallbladder development to be used in further studies.

**Direct Temporal and Spatial Visualization of Vascular Endothelium and Its Support of Fetal Murine Liver Development**

M. L. Edwards, M. J. Ferkowicz, S. A. Johnson, W. C. Shelley, M. C. Yoder; Herman B Wells Center For Pediatric Research, IU School of Medicine, Indianapolis, IN

The role of the vascular endothelium for hepatoblast proliferation and differentiation in the fetal liver remains unclear. Use of fetal liver kinase-1 (Flk1) null mice has demonstrated a requirement for Flk1 expressing angioblasts in hepatic organogenesis, prior to vascularization of the liver. The temporal and spatial emergence of the endothelium in the developing fetal liver has not been previously described. We tested the hypothesis that the hepatoblasts emerge from the septum transversum and develop independent of a capillary blood supply. Nine to 13.5 days post coitus (dpc) mouse embryos were fixed in acetone and placed in a protein blocking solution, then exposed to fluorescent-labeled antibodies for a variety of cell lineage specific antigens. The tissues were imaged using a Biorad single photon confocal microscope. Between 9 and 9.5 dpc, a vascular plexus encompassing several parallel Flk1 + vessels arising from the vitelline vein and overlying the lateral ventral liver was visualized. The branches of the vitelline plexus appeared to penetrate the superficial hepatic buds. Visualization of the deep tissue of the liver revealed Flk+, CD31+, and VE cadherin+ hemangioblasts yet there were few vascular structures present, even at 12.5 - 13.5 dpc. The developing fetal liver appeared to be supplied by at least two distinct vascular systems. The deep system potentially arises from the left umbilical vein and superficial vessels penetrate from the vitelline plexus. These data support the hypothesis that the vascularization of the liver has at least two independent origins. Furthermore, paucity of vascular structures in the deep hepatic tissue supports the hypothesis that Flk+ hemangioblasts must be present for hepatic development but that a developed system of deep vessels appears subsequent to organization of the hepatic parenchyma.

1319

**Wnt Signals in Pronephric Kidney Tubule Development**

J. P. Lyons,[1] H. Ji,[1] X. Zhou,[2] P. D. Vize,[2] E. A. Jones,[3] G. Weidinger,[4] R. T. Moon,[4] T. DeRoo,[5] K. Vleminckx,[6] P. D. McCrea[1]; [1]Biochemistry and Molecular Biology, UT MD Anderson Cancer Center, Houston, TX, [2]Biological Sciences, University of Alberta, Calgary, AB, Canada, [3]Biological Sciences, University of Warwick, Coventry, United Kingdom, [4]Pharmacology and Center for Developmental Biology, HHMI, University of Washington School of Medicine, Seattle, WA, [5]Molecular Biomedical Research - VIB, University of Ghent, Ghent, Belgium, [6]Molecular Biomedical Reserch - VIB, University of Ghent, Ghent, Belgium

One of the basic and elegant morphologic forms that arises repeatedly during development is the tubule. In addressing the genesis of tubes in differing tissue contexts, studies from independent laboratories have supported the involvement of a number of signaling pathways. For example, in the kidney, published work from the laboratory of A. McMahon (Harvard U.), and later A. Brandli (ETH, Zurich), has indicated that the Wnt-4 ligand is required for vertebrate kidney tubule formation. Because Wnt-4 has the potential to activate both canonical (β-catenin-mediated) or non-canonical Wnt-signaling pathways upon binding Frizzled receptor, the question has remained which branch of the Wnt pathway is indispensable, or perhaps if both branches make significant inputs during tubule generation. We have begun by examining β-catenin-mediated (canonical Wnt) contributions, employing early *Xenopus laevis* embryos as our experimental system. By expressing dominant-suppressive or dominant-active β-catenin constructs that are dexamethasone-inducible (temporal control), and directing micro-injections into the prospective nephric field (spatial control), we have accumulated evidence that canonical Wnt signals are required. In evaluating molecular marker gene expression in conjunction with other assays, β-catenin-mediated signals appears to have a greater impact upon tubule differentiation than upon cell death or proliferation pathways. Continuing work will include study of non-canonical Wnt pathway contributions, which are known in other contexts to be required for the polarization and cytoskeletal activity of cells engaged in developmentally-directed cell movements. While morphogenesis is at once fascinating and complex, we expect that our work upon Wnt-pathway contributions in the developing vertebrate kidney may additionally be relevant to the generation of tubules in other organs and cell types.

1320

**Essential Function of FGF Signaling Pathway During Branching Morphogenesis of Mammary Gland**

P. Lu, A. Ewald, G. Martin, Z. Werb; Anatomy, UCSF, San Francisco, CA

Fibroblast growth factor (FGF) signaling plays an essential role in a variety of developmental processes and its deregulation is known to be responsible for many human malignancies, including breast cancer. Previously, it has been shown that FGF signaling is required for the formation of the mammary gland during embryonic development. However, its role in branching morphogenesis during postnatal mammary gland development has remained unclear. Using a combination of *in vivo* and novel three-dimensional (3D) *in vitro* culture systems, we have examined the role of FGF receptor 2 (FGFR2) in mammary gland branching morphogenesis. We found that *Fgfr2* was expressed in both the Cap Cells and the Body Cells of the terminal end buds at the invasion front, as well as in the luminal epithelium, but not the myoepithelium, of the trailing duct. Removal of *Fgfr2* function in the mammary epithelium using MMTV-Cre caused a severe retardation of branching phenotype in virgin females. By using different reporter lines in this genetic mosaic analysis, we found that epithelial cells lacking *Fgfr2* were out-competed by neighboring non-mutant cells and were absent from the invasion front. We are currently using a time-lapse confocal analysis in a 3D *in vitro* culture system to understand the cellular mechanism of how the competition occurs between *Fgfr2* null cells and non-mutant cells. Together, our results demonstrate FGFR2 is critically required for branching morphogenesis in mammary gland development.

## Cell Polarity II (1321-1336)

1321

### Role of p21-activated Kinases (PAK's) in Polarization in *Saccharomyces cerevisiae*

L. Kozubowski, T. Zyla, D. J. Lew; Pharmacology and Cancer Biology, Duke University Medical Center, Durham, NC

In *Saccharomyces cerevisiae*, the Rho GTPase Cdc42p is essential for cytoskeletal polarization. Normally, the site of polarization is dictated by a set of bud site selection proteins (including the Rsr1p GTPase and its GAP Bud2p). However, even in the absence of bud site selection components, cells polarize effectively to a single random site by a symmetry-breaking mechanism that requires the scaffold protein Bem1p. Cdc42p acts through many effectors, including p21-activated kinases (PAKs: Cla4p, Skm1p, Ste20p), which also bind to Bem1p. To test whether PAKs were collectively required for symmetry-breaking polarization, we asked whether PAK-less cells could polarize in the absence of Rsr1p or Bud2p. We found that in the absence of PAKs and Rsr1p cells could polarize secretion (assessed by Sec4p localization) and form abnormally shaped buds. Thus, unlike Bem1p PAKs are not required for symmetry-breaking polarization. Surprisingly, however, cells lacking PAKs and Bud2p (and therefore predicted to contain high levels of Rsr1p-GTP) failed to undergo sustained polarization. Similarly, PAK-less cells expressing a GTP-locked Rsr1p failed to undergo sustained polarization even though they had wild-type Bud2p. Thus, in the absence of PAKs excess Rsr1p-GTP impairs polarization. These observations are reminiscent of previous findings that *cln1Δ cln2Δ bud2Δ* strains are inviable whereas *cln1Δ cln2Δ rsr1Δ* strains are not (Benton B.K. *et al.*, 1993, EMBO vol. 12 no. 13 pp. 5267-75). Thus, it may be that the G1 cyclins Cln1p and Cln2p phosphorylate PAKs to promote sustained polarization, which is antagonized by excess Rsr1p-GTP.

1322

### Role of Protein Phosphatase Type 1 and Afr1 in Polarized Morphogenesis and Maintenance of Cell Integrity in *Saccharomyces cerevisiae*

J. P. Bharucha,[1] J. R. Larson,[1] J. B. Konopka,[2] K. Tatchell[1]; [1]Biochemistry and Molecular Biology, LSUHSC, Shreveport, LA, [2]Molecular Genetics and Microbiology, SUNY Stony Brook, Stony Brook, NY

Substrate specificity for type 1 protein phosphatase (PP1), a highly conserved phospho-serine/threonine phosphatase, is controlled in part by targeting subunits that direct PP1 to specific substrates. In the yeast *S. cerevisiae,* the catalytic subunit of PP1 (Glc7) is targeted to many subcellular locations in vegetatively growing cells and to the base of mating projections during the mating response. We show here that Afr1, a protein previously implicated in negative regulation of pheromone signaling and polarized morphogenesis, is responsible for the mating-specific targeting of Glc7. Glc7 fails to localize to mating projections in *AFR1* null mutants. Afr1 and Glc7 are shown to interact using FRET and two hybrid assays. It was shown previously that *AFR1* null mutants have aberrant mating projections. Afr1$^{V546A/F548A}$, a variant that fails to bind Glc7, also has aberrant mating projections, suggesting that Glc7 regulates cellular morphogenesis during mating. Chs4, an activator of chitin synthase 3, which is normally located at the necks of mating projections, accumulates at the tips of projections in *AFR1* null cells. Increased expression of *AFR1* results in increased accumulation of GFP-Chs4 throughout mating projections. The septin architecture in mating cells is also aberrant in *afr1* mutants. *AFR1* expression is induced during vegetative growth in response to cell wall perturbing agents such as Zymolyase that activate the Pkc1-Slt2 cell integrity signaling pathway. We show here that Afr1 protein also accumulates in response to Zymolyase. *AFR1* null and *afr1*$^{V546A/F548A}$ mutants are 10-fold more sensitive to Zymolyase than wild-type strains. Together, these results indicate that Afr1-Glc7 has roles in morphogenesis and/or cell wall synthesis during both mating and cell wall stress responses.

1323

### G Protein Regulation of Directional Sensing in Yeast

D. Suchkov, D. E. Stone; Laboratory for Molecular Biology, University of Illinois at Chicago, Chicago, IL

During the mating response of *S. cerevisiae,* cells are able to detect the pheromone gradient and polarize their growth toward their mating partners. It has been estimated that a 1% difference in receptor occupancy across the length of a cell leads to a correct orientation. It is presumed that a network of interacting feedback loops acts to sharpen the shallow attractant gradient, but the mechanisms responsible for this are not clear. We demonstrate that growth of mating projections is preceded by the formation of crescents of Ste2-GFP on the side of the cell facing the pheromone source. This redistribution of the receptor is the earliest known manifestation of directionality in the mating response. Mutations in *CDC24* and *CDC42* conferred a defect in, but did not abolish the formation of receptor crescents. Thus, polarized secretion is not essential for the onset of the ligand-induced redistribution of the receptor. Mutations in the receptor that prevent its internalization were found to prevent formation of a receptor crescent and confer a defect in partner discrimination. The same effects were observed in the cells lacking activity of Yck1 and Yck2 required for the receptor downregulation. Interstingly, we found that Yck1 interacts with Gβ genetically and binds to the Gβγ affinity matrix. Previously, Gα has been implicated in recruitment of MAPK Fus3 to the plasma membrane to phosphorylate cortical substrates. One of such substrate candidates is Gβ, which phosphorylated during the pheromone response. Gα mutant that prevents its interaction with Fus3 and a phosphorylation deficient allele of Gβ were found to negatively affect formation of receptor crescents. On the basis of these and other results, we propose a model in which G protein subunits regulate local feedback loops to promote redistribution of the receptor and regulate directional sensing.

1324

### Establishment of Polarized Cortical Domains Defining the Axes of Ascidians Oocytes and Embryos

C. Sardet, F. Prodon, P. Dru, A. Paix, J. Chenevert; Biologie du Developpement, CNRS, Villefranche sur Mer, France

To understand how the primary animal vegetal (a-v) axis is established we have analyzed oocytes at the Germinal Vesicle (GV) stage and spontaneously maturing (Stage4) oocytes of the ascidian *Ciona intestinalis*. We show that the subcortical mitochondria-rich myoplasm domain and a class of cortical maternal mRNAs (*postplasmic/PEM* RNAs) move into the oocyte periphery during oogenesis. Polarization along the a-v axis is initiated after GV BreakDown (GVBD) by the migration of the meiotic apparatus (MI) towards the egg cortex defining the animal pole. Within 2 hours of GVBD and spindle positioning, the myoplasm domain and cortical *Postplasmic/PEM* RNAs are excluded from the animal pole region. The primary a-v axis of the mature Stage4 oocyte in *Ciona, Phallusia* and *Halocynthia* is defined by these animal vegetal gradients of subcortical myoplasm distribution and of the underlying cortical domain made of a monolayer of cortical Endoplasmic Reticulum attached to the plasma membrane (cER). After fertilization some postplasmic/PEM RNAs (*PEM1, macho-1*) associated with the cER move with it in two major phases

successively driven by microfilaments and microtubules. These translocatios establish the Dorso Ventral (D-V) and Antero-Posterior (A-P) axes(see Prodon et al J. Cell Science 2005). In conclusion: the cortical cER/mRNA domain originally established along the a-v axis during oogenesis and maturation is compacted and relocalized into a posterior macroscopic cortical structure becoming a Centrosome Attracting Body (CAB). This CAB structure acts as an organizer in patterning the embryo along the A-P axis and in generating larger and smaller cells which are respectively the precursors of the muscle cells and of presumptive germ cells.

1325

**Establishment of Apical-Basolateral Cell Polarity at First Embryonic Division via Targeted Exocytosis is Maintained by the Actin Cytoskeleton**

M. Ng, D. Burgess; Biology, Boston College, Chestnut Hill, MA

One result of early cleavage divisions is formation of a simple epithelium composed of cells with distinct apical and basolateral surfaces. Such polarity is thought to be established after the first 3 or 4 divisions with the assembly of tight junctions. We find that early dividing sea urchin eggs establish and maintain distinct apical and basolateral surfaces in the absence of apical tight junctions by use of the actin cytoskeleton. Apical membranes were observed in early live sea urchin embryos using Alexa 488 cholera toxin subunit B (CTB), which binds to ganglioside GM1found in lipid rafts. The CTB label co-localized with integrins in fixed, immunostained embryos. Integrins were detected in isolated detergent resistant membranes, thought to represent lipid rafts. During cytokinesis of the first cell division, CTB was enriched in the cleavage furrow but cleared out from the membrane between the two daughter blastomeres at the end of cell division, due to new membrane addition via targeted exocytosis. In all embryos observed up to the 16 cell stage, the microvillus covered apical plasma membrane surfaces on the outside of the embryo were labeled with CTB whereas basolateral inner plasma membrane surfaces were not. When embryos were dissociated into single blastomeres at the four cell stage, the CTB labeled membrane domains remained polarized throughout the next cell cycle. Treatment of these dissociated blastomeres with Cytochalasin D, to depolymerize actin, disrupted these polarized membrane domains, and the CTB labeled membrane spread evenly along the whole surface of the cells. We conclude that apical and basolateral polarity is established in embryos as early as the two cell stage, well before tight junctions are formed, and that this membrane polarization is maintained by the actin cytoskeleton.

1326

**Investigation of the Cytoskeletal Mechanisms Required for Apical Constriction During *Xenopus* Gastrulation**

J. Lee, R. M. Harland; Dept of Molecular and Cell Biology, UC Berkeley, Berkeley, CA

Cell shape changes are often required during morphogenesis to bend tissues and to shape organs. During *Xenopus laevis* gastrulation, bottle cells in the dorsal marginal zone (DMZ) are the first cells to undergo cell shape changes, transforming from cuboidal-shaped to flask-shaped. These cell shape changes create a crevice to direct the first steps of mesodermal involution. Apical constriction, a morphogenetic mechanism driven by polarized actomyosin contractile machinery, is hypothesized to cause bottle cell formation. Despite its importance during morphogenesis, little is understood about the mechanisms required for apical constriction. We are investigating apical constriction by examining cytoskeletal localization and dynamics during *Xenopus* bottle cell formation. Using fluorescence-conjugated phalloidin, we observed an intense accumulation of F-actin at the apical surface of bottle cells. Curiously, preliminary experiments with the microfilament inhibitors cytochalasin D and latrunculin A do not completely block apical constriction, but instead affect the directionality and pattern of constriction. Using time-lapse videomicroscopy, we also examined the behavior of bottle cells in explants cut lateral to the DMZ, in order to observe bottle cell formation as it happens. In unmanipulated embryos, bottle cells initiate as a small crescent in the central DMZ and spread laterally in both directions until the bottle cells form a complete circle (blastopore) in the vegetal pole of the embryo. In contrast, bottle cells in lateral explants initiate from either end and move towards the center. We are currently investigating whether these lateral bottle cells behave similarly to DMZ bottle cells. We are also assessing the role of microtubules and myosin during apical constriction by examining their localization and by perturbing their dynamics with pharmacological inhibitors. Through these experiments, we hope to gain further insight into the cytoskeletal mechanisms that control apical constriction.

1327

**Intrinsic Chiral Properties of the *Xenopus* Egg Cortex and Left-Right Asymmetry**

M. V. Danilchik, E. E. Brown; Integrative Biosciences, Oregon Health & Science Univ, Portland, OR

Background: A long-standing problem in the development of vertebrate left-right (LR) asymmetry is how an embryo's original bilateral symmetry becomes modified to initiate left- and right-specific regulatory pathways. In the large, cylindrically symmetric egg of *Xenopus laevis* , the earliest steps in dorsal-ventral (DV) axis determination are driven by microtubule-dependent rearrangements of localized maternal components toward the prospective dorsal side. Although LR axis determination is linked to this DV-determining localization process, the earliest steps are not understood. Results: Parthenogenetically activated eggs treated with millimolar concentrations of 2,3-butanedione monoxime undergo a dramatic large-scale counterclockwise torsion, with the cortex of the animal hemisphere shearing in a consistent direction past the vegetal cortex. Parallel microfilament bundles orient along the zone of maximal shear that develops near the egg's equator. Confocal time lapse of GFP-actin-expressing eggs undergoing torsion showed that the cortical torsion is accomplished by incremental shear between adjacent microfilament bundles. Thus, the large-scale torsion is microfilament-dependent. Cortical shear continues unabated following application of nocodazole, cytochalasin B, or jasplakinolide, but is halted by latrunculin B, indicating that the torsion is not organized by microtubules, and likely depends on preexisting f-actin fibers rather than new actin polymerization. Conclusions: A maternally inherited, microtubule-independent property of the *Xenopus* egg cortex is capable of consistently orienting microfilaments circumferentially -not radially- around the animal-vegetal axis, and therefore perpendicular to the embryo's midsagittal plane, regardless of the DV axis orientation. This unusual chiral arrangement may be important for cueing early cytoskeleton-dependent localizations in LR axis determination. Support: NSF IBN-0110985 and IBN-0419664

**Determinants of *Drosophila* Non-muscle Myosin II Heavy Chain (Zipper) Cortical Localization**

R. R. Penkert, S. Liu, K. E. Prehoda; Molecular Biology, University of Oregon, Eugene, OR

The non-muscle myosin II is required for cytokinesis and cell-fate determinant segregation during asymmetric cell division in the *Drosophila*

neuroblast. We have sought to identify the components of Zipper required for cortical localization during asymmetric cell division. Myosin is a hexamer, which is composed of two regulatory light chains (Spaghetti Squash), two essential light chain and two heavy chains (Zipper). Zipper has an N-terminal actin binding head and a long coiled-coil tail. Myosin II monomers are known to assemble into bipolar thick filaments through intermolecular interactions between heavy chain tail domains. Various truncations of the Zipper tail were made and cloned into bacteria and insect cell expression vectors. The purified truncated proteins were analyzed by Circular Dichroism (CD) and Analytic Ultracentrifugation (AUC) to determine folding, stability and oligomerization state. *Drosophila* S2 cells were transiently transfected with these Zipper fragments and localization was determined by fluorescent immunostaining and image analysis. The tail region of Zipper is sufficient for localization but fragments that are unable to form thick filaments lack the ability to properly localize. This suggests that filament formation may be a prerequisite for tail localization and not interactions of the head domain with actin filaments.

1329

**An Intramolecular Interaction within the Cell Polarity Protein Pins Cooperatively Represses Gα Binding at two Internal GoLoco Domains**

R. W. Nipper, K. E. Prehoda; Institute of Molecular Biology, University of Oregon, Eugene, OR

The *Drosophila* cell polarity protein Partner of Inscuteable (Pins) and the heterotrimeric G protein subunit, Gα, are essential components in neuroblast asymmetric division. G proteins are important in asymmetric division, as Gα and Gβγ downstream effectors modulate microtubule dynamics, potentially regulating spindle formation in neuroblasts. Pins dissociates G protein complexes at the apical cortex using three carboxyl terminal GoLoco domains which each sequester Gα subunits. Recent work has described an intramolecular interaction between the N and C terminus of the mammalian Pins homologue, LGN. Here we report Pins undergoes a similar intramolecular interaction between its N-terminal tetratricopeptide repeats (TPR) and C-terminal GoLoco array. As previously reported, this autoregulatory interaction represses overall Gα binding to the GoLoco domains. Here, we further refine the model of the intramolecular interaction within the *Drosophila* Pins protein. We have found the TPR domains differentially regulate the three GoLoco domains within Pins. The TPR region cooperatively represses the two GoLoco domains at the carboxyl terminus, but does not affect the most amino-terminal GoLoco. We propose Pins can bind a basal quantity of Gα though the unaffected GoLoco, even in a closed conformational state, while relief of the intramolecular interaction increases the Gα binding capacity of the GoLoco array. We postulate that differential Gα regulation in Pins may allow for noise suppression and cooperativity in cell polarity signaling.

1330

**Expression and Function of *Fat* Cadherins within Developing Inner Ear**

M. R. Deans, A. Tucker, L. V. Goodrich; Neurobiology, Harvard Medical School, Boston, MA

Mammalian *fat* cadherin genes encode unusually large transmembrane proteins containing 34 cadherin repeats. In *Drosophila*, *fat* regulates planar cell polarity, as well as imaginal disc growth and patterning. Development of the mouse inner ear involves similar processes including the polarization of hair cells within the plane of the sensory epithelia, and generation of the correct numbers and ratio of hair cells and supporting cells. We hypothesize that a conserved Fat pathway regulates some, if not all, of these events. To explore the function of mammalian *fats* we have mapped the distribution of all four *fat* homologs within the developing ear and evaluated the function of *fat1* in mutant mice. *In-situ* hybridization and x-gal staining in transgenic mice indicate *fat1* expression throughout the otocyst at embryonic day 10 (E10) and subsequent restriction to support cells and non-sensory regions by E18. In contrast, *fat3* is present transiently between E14 and P0 in developing sensory epithelia in a pattern similar to the hair cell transcription factor *math1*. *Fat2* and *fat4* are not expressed in the cochlea. The GST070 mouse line carries a gene trap insertion that disrupts *fat1* function. Due to the significance of *fat* in planar cell polarity in flies, we evaluated the $fat1^{GST070}$ mutant mice for hair cell polarity defects by phalloidin and tubulin labeling of whole mount organ of Corti. No polarity defects were seen for inner or outer hair cells. Therefore, based upon gene expression data and mutant analysis, we propose *fat3* as a candidate regulator of planar cell polarity within the developing ear, and are testing this model by generating *fat3* mutant mice.

**The Role of Cdc-42 And Rho-1 in Establishment of Polarity in *C Elegans* Embryos**

S. Schonegg, A. Hyman; MPI-CBG, Dresden, Germany

In the *C. elegans* one-cell embryo the establishment of anterior-posterior axis is marked by the segregation of partioning-defective (PAR) proteins into anterior (PAR-3, PAR-6) and posterior (PAR-1, PAR-2) cortical domains. Concomitantly with establishment of PAR polarity, the embryo undergoes cortical rearrangements leading to differences in contractile activity of the cortex along anterior-posterior axis (contractile polarity). The underlying mechanism of cortical dynamics and its relationship to PAR polarity is unclear. To investigate how modulation of the acto-myosin cytoskeleton affects PAR polarity establishment, we perturbed the acto-myosin cytoskeleton by RNAi of members of the Rho GTPase family, CDC-42, RHO-1 and ECT-2 and analyzed PAR protein distribution and the organization and dynamics of nonmuscle myosin 2 (NMY-2). We show that they are involved in different ways in establishment of polarity. CDC-42 and RHO-1 are required for PAR localization and in particular, RHO-1 is required through the organization of the acto-myosin cytoskeleton to establish the boundary between the anterior and posterior PAR proteins.

1332

**W08f48, Encoding the *C Elegans* Homologue of Cdc37, Plays a Role in Establishing Early Embryo Polarity**

M. A. Beers, K. J. Kemphues; Molecular Biology & Genetics, Cornell University, Ithaca, NY

Establishment and maintenance of cellular asymmetry and polarity is a hallmark of the development of many multicellular organisms. In *C. elegans*, polarity established in the one cell embryo determines the anterior-posterior axis and the identity of the early blastomeres. The *par* genes (*par*titioning defective) are maternal-effect lethal genes that when mutated disrupt polarity in the early embryo. PAR-3, PAR-6 and PKC-3 proteins colocalize at the anterior cortex of the one cell embryo while PAR-1 and PAR-2 proteins colocalize at the posterior cortex. These two protein domains are maintained by mutual exclusion. It has also been shown that the presence of PAR-6 and PKC-3 at the cortex requires PAR-3. We and others have identified W08F4.8, the *C. elegans* homologue of CDC37, as a gene with a role in early embryo polarity. My goal is to determine: 1) in what stage of polarity establishment W08F4.8 participates, 2) where it is located in the cell and 3) how it functions. To address these questions we

have used a combination of RNAi, antibody staining and analysis of different GFP expression lines. My work shows that W08F4.8 RNAi embryos exhibit all of the phenotypes characteristic of *par* mutants. Unlike many of the PAR proteins, a W08F4.8::GFP fusion protein is found in the cytoplasm throughout most of the cell cycle. At nuclear envelope breakdown it becomes enriched in the nucleoplasm and then localizes to the central spindle of the dividing cell. We found that W08F4.8 functions in the establishment phase of polarity determination. Most interestingly, we learned that the reduction of W08F4.8 by RNAi can uncouple the mutual exclusion of the anterior and posterior PAR's and also uncouples the cortical localization of PAR-6 and PKC-3 from their dependence on PAR-3.

1333

**Role of the Actin Cytoskeleton in Early *C elegans* Development**

N. Velarde, F. Piano; Biology, New York University, New York, NY

Early *C. elegans* embryonic development requires key events that involve cortical interactions with the cytoskeleton. I am interested in studying the role of F-actin in the early embryo. To visualize F-actin dynamics *in vivo*, I have generated a transgenic line that uses the F-actin binding domain of *Drosophila* moesin to decorate endogenous F-actin with GFP (PF100). This line appears to be specific for F-actin and allows us to faithfully visualize actin dynamics in *C. elegans*. Using timelapse microscopy, I have been able to gather preliminary evidence that suggests that the cytoskeleton is playing key roles throughout early development of the *C. elegans* zygote. The time periods I have focused on are fertilization and early embryogenesis. Right after fertilization, a transient "actin cap" appears on the presumptive posterior and then dissipates, which may be an important initial step for generating polarity. Prior to the first cell division F-actin becomes enriched in the anterior, similar to the anterior PAR proteins. As seen in *par-3* mutants (Kirby et. al., 1990), depleting the embryo of PAR-6 with RNAi prevents this enrichment, suggesting that PAR-6 and the other anterior PARs may be required for F-actin to accumulate in the anterior. Other known regulators of the PAR protein network also affect the collapse of the F-actin network to anterior half of the embryo. We have also observed the presence of highly dynamic actin comets in the early embryo. Preliminary evidence suggests that these comets may be involved with vesicle or organelle trafficking in the cell. We will present our progress in using this GFP::Moe line to study genetic interactions involving actin dynamics in early development.

1334

**Rotation of 1-cell C elegans Embryos Inside the Egg Shell Reveals an Early Step in Establishment of Left-right Polarity and Embryonic Handedness**

S. Schonegg,[1] A. A. Hyman,[1] W. B. Wood[2,1]; [1]Max Planck Institute for Cell Biology and Genetics, Dresden, Germany, [2]MCD Biology, Univ. of Colorado, Boulder, Boulder, CO

The initial symmetry-breaking mechanism for establishing left-right (L-R) asymmetry and handedness is not understood in any embryo. C. elegans embryos first exhibit obvious L-R asymmetry at the 6-cell stage; however, asymmetry can already be seen during second cleavage, when the mid-body between the two AB daughter cells invariably moves to the right, apparently due to asymmetric closure of the cleavage furrow. This suggests a pre-existing L-R asymmetry in the AB-cell cortex at the 2-cell stage. In searching for possible earlier asymmetry cues, we observed that just prior to initiation of first cleavage, the entire embryo rotates for ~50 sec, through an angle of ~120Â°, inside the vitelline membrane of the egg shell. The screw sense of the rotation is invariant relative to the already established anterior-posterior (A-P) polarity, indicating that the 1-cell embryo has an intrinsic chirality. Strong maternal knock-down (KD) of gene products required for actomyosin function or microtubule formation block the rotation. KD of PAR-2, PAR-3, PAR-6, and other gene products required for establishment and maintenance of early A-P polarity results in partial randomization of the direction and extent of rotation as well as the handedness of the later embryo. These and additional KD experiments indicate that normal chirality of the 1-cell embryo 1) requires integrity of A-P polarity and 2) may be an initial cue for establishment of L-R polarity with correct choice of handedness.

1335

**Mosaic Eyes Protein Forms a Complex and Colocalizes with Homologues of Crumbs and Pals1, and aPKC**

A. M. Jensen,[1,2] Y. Hsu,[1,2] J. Willoughby,[1] A. Christensen[1,2]; [1]Biology, University of Massachusetts, Amherst, MA, [2]Program for Molecular and Cell Biology, University of Massachusetts, Amherst, MA

Previously, we identified the *mosaic eyes* (*moe*) gene that encodes a FERM protein and is required for retinal lamination in zebrafish. Expression of *moe* in photoreceptors suggests that *moe* may also play a role in photoreceptor differentiation or morphogenesis. We sought to determine whether Moe binds to the intracellular domain of vertebrate homologues of crumbs, all of which contain a FERM-binding motif. We first cloned zebrafish *crb1*, *crb2a*, *crb2b*, and *crb3b*, and we found an EST for *crb3a*; we examined their expression in the retina using *in situ* hybridization and observed expression of *crb2a* and *crb2b* in the retina. We made fusion proteins of Moe and crumbs homologue proteins for biochemical analysis. We found that HIS-Moe_FERM pulls-down a protein(s) from lysates that is immunoreactive for anti-CRB3 (by Western, anti-CRB3 recognizes all zebrafish crumbs homologue proteins examined) with a molecular weight predicted for Crb2a and Crb2b. Immobilized HIS-Moe_FERM pulls down GST-tagged intracellular domains of Crumbs homologues and HIS-Moe_FERM immobilized on nitrocellulose binds GST-Crb1$^{intra}$ and GST-Crb2a$^{intra}$. In addition, Moe forms a complex with Nagie oko (Pals1 homologue) and aPKC. We show that anti-Moe and anti-CRB3 immunoreactivity colocalize in photoreceptors. There are two major splice variants of Moe in vertebrates, a long and short isoform; the proteins differ after the FERM domain. Previously we described the long isoform; the mouse short isoform removes about 250 amino acids and adds about 50 unique amino acids at the C' terminus. Mouse photoreceptors express both isoforms, but not all cell types do so. We are examining the roles of the long and short isoforms in potentially regulating crumbs homologue function during the process of light-regulated photoreceptor outer-segment renewal. Preliminary chimera/transplant experiments suggest *moe* is required for normal photoreceptor morphology.

1336

**Regulation of Mosaic Eyes by Calmodulin and Photoperiod in Zebrafish Photoreceptors**

A. Christensen,[1,2] J. Willoughby,[1] Y. Hsu,[1,2] A. Jensen[1,2]; [1]Biology Department, University of Massachusetts, Amherst, MA, [2]MCB Program, University of Massachusetts, Amherst, MA

Mosaic eyes (Moe) is a Band 4.1 family member with significant homology within the FERM domain to other family members. During

development, Moe is required for proper retinal, brain, and kidney morphogenesis. Our lab has shown that Moe forms a complex with homologues of Crumbs and Pals1 proteins and may play a role in photoreceptor morphogenesis. Using immunohistochemistry, we show that Moe colocalizes with Crumbs homologues, Nagie Oko (Pals1 homologue), aPKC and Calmodulin in photoreceptors. In order to further elucidate the role of Moe in photoreceptors, we are examining its regulation. We show that the FERM domain of Moe binds Calmodulin. Western blot analysis of adult retinas with anti-Moe antibody reveals two immunoreactive bands, migrating with molecular weights of 110 and 55 KDa. Further, the expression of each Moe species is photoresponsive; the large Moe band, but not the small, is present during dark periods, whereas exposure to light causes the appearance of the small Moe band and disappearance of the large. There are two major splice variants of Moe in vertebrates, a long and short isoform, which may encode the 110 and 55 KDa proteins observed. The isoforms differ after the FERM domain. Mouse photoreceptors co-express both isoform mRNAs, although not all cell types co-express both. The light/dark-induced shift in molecular weight species possibly reflects a process of selective protein degradation. Based on these data, we hypothesize that the long Moe isoform negatively regulates Crumbs and that a shift to the smaller isoform facilitates the process of light-regulated photoreceptor outer-segment renewal and this regulation depends on exogenous light/dark cues and intracellular calcium levels mediated by Calmodulin. Our observations may offer the first molecular handle on the hitherto unknown mechanism that controls the important process of photoreceptor outer-segment renewal.

## Development & Carcinogenesis (1337-1342)

1337

### Notch Target Genes Bind to and Modulate Function of the Pancreatic Transcription Factor, Ptf1-p48

B. Ghosh, S. D. Leach; Surgery, John Hopkins University School of Medicine, Baltimore, MD

Notch signaling has been shown to have a normal inhibitory effect in the regulation of exocrine differentiation, mediated at least in part by direct inhibition of the pancreatic transcription factor Ptf1-p48. To further elucidate the biochemical mechanism by which Notch inhibits Ptf1 function, we have designed experiments to test the hypothesis that the Notch target genes Hes1, Hey1 and Hey2 can physically interact with Ptf1-p48 to form inactive heterodimers. We have also systematically analyzed the different domain structures of both Ptf1-p48 as well as Hes1, in order to identify specific domains required for this interaction. Co-immunoprecipation analysis in COS7 cells and GST pull down assays indicated that Ptf1-p48 formed a protein complex with each of the three Notch target genes. Evaluation of GST fusion proteins encoding various Ptf1-p48 deletion mutants revealed that only full length Ptf1-p48 was able to bind Hes1. Conversely, deletion mutant analysis of Hes1 indicated that the carboxyl terminal and basic helix-loop-helix domains were necessary for Ptf1-p48 binding. We also confirmed physical interaction between Ptf1-p48 and Hes1 through a yeast two-hybrid approach, using the carboxyl terminal and basic HLH domain of Ptf1-p48 as bait. Finally, in transient transfection experiments using a Ptf1-responsive luciferase reporter in the presence of Ptf1, E47 and different deletion mutants of Hes1, we found significant inhibition of Ptf1 function only in the presence of Hes1 deletion mutants containing both the basic HLH domain and the carboxyl terminal, demonstrating a direct correlation between Hes1's ability to bind Ptf1-p48 and its ability to inhibit Ptf1 function. Taken together, these data provide a mechanism by which Notch and its target genes repress epithelial differentiation in exocrine pancreas, an effect likely to play an important role in the pathogenesis of human pancreatic cancer.

1338

### Implication of Lagy in Lung Carcinogenesis and Development

Y. Chen, I. Petersen; Institute of Pathology, University Clinic Charité, Berlin, Germany

We have isolated a novel human lung cancer-associated gene, LAGY (lung cancer-associated Y protein) by suppression subtractive hybridization (Chen Y. et al., PMID 15386363). The nucleotide sequence of LAGY predicts a small protein of 73 amino acid containing a putative Homeobox domain with molecular mass of 8.1 kDa. Multiple tissue Northern blots analysis revealed that the gene is present in human placenta, lung, brain, heart and skeletal muscle. Gene mapping locates LAGY gene on chromosome 4q11-13.1. The expression of LAGY mRNA levels was widely lost in 5 immortalized human bronchial epithelial cell lines and 18 lung tumor cell lines comprising 4 major histological types including small cell lung carcinoma (SCLC), large cell lung carcinoma (LCLC), squamous cell carcinoma (SCC) and adenocarcinoma (ADC) by Northern blot analysis and semi-quantitative reverse transcription-polymerase chain reaction (RT-RCR). In the survey of 72 primary lung tumors (37 ADCs, 27 SCCs, 4 SCLCs and 4 LCLCs), this gene was significantly down-regulated in all tumors compared to 9 normal lung tissue samples, most prominently in SCC. For this tumor type, there was also a significant reduction for LAGY expression in tumors with increased grade and stage. No expression was detectable in two high grade SCC and 50% of SCLC and LCLC, respectively. Since homeodomain-containing genes are known to transcriptionally regulate key cellular processes and have been associated with carcinogenesis, we suggest that the LAGY gene should be considered as a candidate tumor suppressor in lung cancer development and progression. Furthermore it has meanwhile been shown to be of key importance in cardiac development (Chen F. et al., PMID 12297045).

1339

### Myc-Mediated Regulation of Ephs During Cancer and Development

B. Yekkala, T. A. Baudino; Cell and Developmental Biology and Anatomy, School of Medicine, University of South Carolina, Columbia, SC

Eph receptor tyrosine kinases and their cognate ligands ephrins, participate in numerous developmental processes such as embryonic patterning, axonal guidance and angiogenesis. Additionally, their overexpression has been shown to promote metastases by inducing tumor growth and angiogenesis in many human cancers including colon, prostate and breast. However, the precise mechanism(s) involved in Eph and ephrin regulation remain to be elucidated. The Myc family of basic helix-loop-helix (bHLH) leucine zipper transcription factors (c-Myc, N-Myc and L-Myc) regulate a wide range of cellular processes including proliferation, apoptosis, vasculogenesis and hematopoiesis. Recent studies from our laboratory have demonstrated the regulation of Vascular Endothelial Growth Factor (VEGF) and other angiogenic factors by c-Myc. These data suggest that Myc acts as an angiogenic switch during cancer and development. Therefore, we hypothesized that Myc may also regulate Eph receptor family members. We have investigated this hypothesis by examining Eph gene expression using both *in vitro* and *in vivo* techniques. Using primary mouse embryonic fibroblasts (MEFs) expressing an inducible Myc-ER fusion protein, we examined the expression of all known Eph receptors. Following activation of Myc-ER with 4-Hydroxytamoxifen, we identified *EphB4* and *EphA2* as target genes for c-Myc. We have

selected *EphA2* as our candidate gene for further studies since it has been shown to be dysregulated in many cancers. Our studies suggest that Myc-mediated regulation of *EphA2* is direct, while regulation of *EphB4* is indirect. Moreover, c-Myc activation induces robust *EphA2* promoter activity in MEFs. Furthermore, loss of c-Myc results in a significant reduction in *EphA2* expression in $APC^{Min}$ intestinal polyps. Finally, c-Myc loss *in utero* results in reduced levels of *EphA2.* Taken together, these data suggest that c-Myc plays a critical role in the transcriptional regulation of specific Ephs.

1340

**Chromium Exposure Leads to Chromosome Instability in *C elegans***

A. Sood,[1] J. W. Astin,[2] P. E. Kuwabara,[2] C. P. Case[1]; [1]Dpt. of Orthopaedic Surgery, University of Bristol, Bristol, United Kingdom, [2]Dpt. of Biochemistry, University of Bristol, Bristol, United Kingdom

Humans are exposed to chromium from many sources: industry, the environment and cobalt chrome alloys in surgical implants. Hexavalent chromium is a complex genotoxin causing multiple lesions, including single- and double-strand DNA breaks, oxidative base damage, DNA-DNA cross-links, DNA-protein cross-links and Cr-DNA adducts. It has been established that chromium can initiate the formation of reactive oxygen species through the reduction of Cr(VI) to Cr(III). To understand the basis of chromium genotoxicity *in vivo*, we are using the model organism *Caenorhabditis elegans. C. elegans* is an established model for studying human disease; homologues to over 70% of known human disease genes are present in the genome of *C. elegans.* Dose response studies using the metallic salts potassium dichromate ($K_2Cr_2O_7$) have been performed. Based on these results, a range of concentrations have been tested to determine the sensitivity of the germ line to hexavalent chromium by examining three parameters: brood size, germ line apoptosis and oocyte chromosome number. We find that wildtype animals are sensitive to chromium and display a decrease in brood size and an increase in chromosomal abnormalities, marked by a decrease in the number of bivalents during diakinesis. Animals defective in nucleotide excision repair, such as *xpa-1*, or that lack the checkpoint kinase, *atm-1,* also display chromium hypersensitivity. These animals have reduced brood sizes and an increase in chromosomal abnormalities when compared to wildtype. It is evident that chromium has an adverse effect on *C. elegans* development. Chromosomal abnormalities detected in oocytes are likely to be caused by chromosomal fusions; deletions are unlikely as embryonic lethality is low. We are presently examining whether the chromosomal abnormalities caused by chromium exposure are caused by end-to-end chromosomal fusions. In addition, we are investigating whether chromium exposure also leads to transgenerational chromosomal instability.

1341

**Dopamine Modulation of Cell Migration**

H. O. Lawal,[1] A. Hsouna,[2] T. Hsu,[2] J. M. O'Donnell[1]; [1]Biological Sciences, University of Alabama, Tuscaloosa, AL, [2]Pathology and Laboratory Medicine, Medical University of South Carolina, Charleston, SC

The tracheal development in *Drosophila* has been investigated in detail and is considered to be a model for mammalian angiogenesis since these processes share many gene product requirements. Tracheal cells migrate in response to FGF chemotactic signaling to form the branched tubular network, which delivers oxygen throughout the insect. However, the underlying mechanism of FGF receptor (FGFR) regulation has not been fully elucidated. We report the novel result that three interacting genes in the dopamine synthesis pathway, two that positively regulate and one that negatively regulates dopamine levels, appear to modulate FGFR levels during tracheal development. . Mutants in each of these genes produce tracheal phenotypes characteristic of a perturbation in FGF signaling. Using drugs to modulate dopamine levels in vivo, we have reproduced the tracheal phenotypes of the mutants. Embryos exposed to excess exogenous dopamine exhibit blocked tracheal cell migration, similar to those mutant for the negative regulator, which have elevated dopamine, while pharmacological depletion of endogenous dopamine causes ectopic cell migration, as observed in low dopamine mutant embryos. Migration of primary human endothelial cell can be similarly modified by dopamine modulation. Dopamine may be regulating FGF signaling by down-regulating the FGFR levels through endocytosis. Using an FGFR-GFP chimeric protein, we observe that FGFR, which is normally localized at the plasma membrane, is found in cytoplasmic compartments in embryos exposed to dopamine, while the receptor accumulates at the plasma membrane in dopamine-depleted embryos. Using pharmacological agonists and antagonists of dopamine receptor signaling, we show that dopamine may be acting through its receptors to modulate FGF levels. Taken together, our results suggest that dopamine acts through its receptor to regulate cell motility by modulating the FGFR levels.

1342

**The Role of LIM Proteins Ajuba and LIMD1 in the Nucleus**

E. M. Langer,[1] Y. Feng,[1] K. L. Kroll,[2] G. D. Longmore[1]; [1]Medicine and Cell Biology, Washington University School of Medicine, Saint Louis, MO, [2]Molecular Biology and Pharmacology, Washington University School of Medicine, Saint Louis, MO

Ajuba and LIM domains-containing protein 1 (LIMD1) are members of the cytosolic family of LIM domain-containing proteins that localize to sites of cell-cell and cell-matrix adhesions in epithelial cells and fibroblasts, respectively. Both of these proteins also shuttle to the nucleus, but little is known about the mechanisms by which they translocate to the nucleus, the identity of their nuclear targets, or the signaling pathway(s) they affect. The LIM region of Ajuba, which localizes to the nucleus, was used as bait in a yeast two-hybrid screen to identify the protein Snail as an interacting partner of Ajuba. Further analysis by co-immunoprecipitation confirmed that Ajuba interacts with Snail and its family member Slug. Snail and Slug are transcriptional repressors that mediate epithelial mesenchymal transitions in physiological processes such as gastrulation and neural crest delamination as well as in pathological processes such as cancer metastasis. In transient luciferase assays, Ajuba appears to cooperate with Snail in transcriptional repression of the E-cadherin promoter. In order to determine if this interaction is functional, we have used the *Xenopus laevis* model system in which Snail family members have well-described roles in neural crest specification and migration. To date, there appears to be only one Ajuba-like ortholog in *Xenopus*, which is most similar to LIMD1. We cloned the *X. laevis* ortholog of LIMD1 and detected its endogenous expression in developing embryos through *in situ* hybridization. Expression of LIMD1 overlaps with that of Snail and Slug, particularly in the neural crest. Microinjection of LIMD1 mRNA into embryos results in an expansion of the neural crest area, mimicking the effect of Slug overexpression. These results suggest that Ajuba and LIMD1, through their interaction with Snail family members, may play an important role in epithelial mesenchymal transitions.

## Synapse Formation & Function I (1343-1359)

1343

### Function of α-Dystrobrevin Isoforms in AChR Cluster Formation and Stabilization

B. T. Pawlikowski, M. M. Maimone; Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

In skeletal muscle, α-dystrobrevin (αDB) is expressed throughout the sarcolemma with high concentrations at the neuromuscular junction (NMJ). Alternative splicing generates three major αDB isoforms in adult (αDB1, αDB2, αDB3) and two more in early development (αDB1(-), αDB2(-)). Mice lacking αDB display multiple abnormalities including muscular dystrophy and NMJ defects that suggest a role for αDB in maturation of acetylcholine receptor (AChR) clusters. At adult NMJs, AChR clusters have a complex pretzel-shaped architecture which can be recapitulated in muscle cell culture in the absence of nerve or agrin. Using a primary muscle culture system generated from αDB knockout (αDB-KO) mice, we investigated the role of αDB in the formation of complex agrin-independent AChR clusters. In myotubes lacking αDB, complex AChR clusters were not observed, although they readily formed in wildtype myotubes. To determine which αDB isoforms could mediate formation of complex AChR clusters, individual αDB isoforms were expressed in αDB-KO myotubes using retroviral infection. Expression of αDB1 or αDB1(-) individually led to formation of complex AChR clusters similar to those observed in wildtype cells, whereas expression of αDB2, αDB2(-) or αDB3 individually resulted in few poorly developed clusters. These data suggest that αDB plays a role in the formation of complex AChR clusters and that protein domains uniquely present in αDB1 isoforms mediate this function. Similar analysis of agrin-induced AChR clusters, which are much less complex, showed that these clusters are less stable in the absence of αDB and that individual expression of αDB1, αDB1(-) or αDB2 (but not αDB2(-) or αDB3) could restore the stability to wildtype levels. Taken together these data demonstrate differential functions of individual αDB isoforms in the formation and maintenance of AChR clusters and suggest roles for specific protein domains of αDB.

1344

### Agrin and Laminin Induce Acetylcholine Receptor Clustering by Convergent, Rho GTPase-Dependent Signaling Pathways

G. Teressa, C. A. Weston, P. Hallock, J. Prives; Pharmacological Sciences, Stony Brook University, Stony Brook, NY

Under physiological conditions cell signaling is typically a complex phenomenon involving simultaneous utilization of several signaling pathways. During neuromuscular junction formation several identified molecular factors are utilized to trigger aggregation of muscle cell surface acetylcholine receptors (AChRs) adjacent to nerve endings. Two extracellular matrix proteins found in synaptic clefts, neural agrin and laminin, are each known to induce clustering of AChRs on the surface of cultured muscle cells by activation of separate transmembrane signaling mechanisms. To characterize the signaling pathways that regulate these aspects of synaptogenesis, we have compared the molecular events that couple agrin and laminin signaling to AChR clustering in C2 muscle cell cultures. Clustering of AChR was induced by overnight exposure of myotubes to soluble agrin, soluble laminin, or substrate bound laminin. The AChR clusters displayed characteristically different morphologies in each case, suggesting underlying differences in the clustering process or in the endpoint reached. In contrast to laminin, agrin-induced clustering was accompanied by increased tyrosine phosphorylation of AChR β subunits. Substrate-coated laminin induced clusters were unique in size, complexity and in showing co-localization with phosphorylated FAK. However, in all cases AChR clustering was accompanied by, and dependent on activation of the Rho GTPase signaling pathway. Thus, agrin, soluble laminin and substrate-coated laminin induced activation of Rac, and Rho, as measured with biochemical assays. Moreover, AChR clustering by these stimuli was abolished by dominant negative Rac and Rho mutants, as well as the Rho kinase inhibitor Y-27632. These findings provide evidence that the agrin and laminin signaling pathways converge such that these signals are coupled to AChR clustering by the actions of Rac, Rho, and Rho kinase. l

1345

### The β-subunit Intracellular Loop is Sufficient for Postsynaptic Clustering of the nAChR

S. Yechikhov, L. S. Borges, Y. I. Lee, M. Ferns; Physiology and Membrane Biology, UC Davis, Davis, CA

At the developing vertebrate neuromuscular junction, postsynaptic localization of the nAChR is regulated by agrin-MuSK signaling and requires an intracellular, membrane-tethered protein called rapsyn. However, the intracellular domains of the nAChR that interact with scaffolding proteins to mediate clustering are unknown, and it is unclear how such interactions are regulated by agrin. To define the subunit(s) and domains that mediate postsynaptic clustering of the AChR, we generated chimeric proteins consisting of CD4 extracellular and transmembrane domains fused to each of the AChR subunit large intracellular loops. When expressed in cultured muscle cells, CD4 and all the CD4- subunit chimeras were expressed on the myotube surface, but strikingly, only CD4-β loop coclustered with the endogenous AChR in response to agrin treatment. To map the domain mediating localization of the β loop, we tested a series of CD4-β loop deletion mutants and found that a 37 amino-acid sequence (aa 370-406) was sufficient for agrin-induced clustering. This sequence contains a conserved tyrosine (Y390) previously implicated in AChR clustering, and indeed, we found that agrin treatment induced rapid phosphorylation of Y390 in CD4-β loop chimeras and mutation of this residue completely abolished clustering. Finally, we found CD4-β 370-406 acted in a dominant-negative fashion when overexpressed in myotubes, inhibiting agrin-induced aggregation of the endogenous AChR by ~25%. Together, these results identify a domain specifically in the β subunit loop that is sufficient for clustering. Moreover, they suggest that protein interactions with this domain contribute to postsynaptic localization of the nAChR and that this is regulated by agrin-induced phosphorylation.

1346

### Effect of siRNA-Mediated Inhibition of APC on Agrin-induced Acetylcholine Receptor Clustering in C2C12 myotubes

Y. Yao,[1,2] L. Zhang,[2] Z. Wang[1,2]; [1]Department of Cell and Neurobiology, Zilkha Neurogenetic Institute, University of Southern California Keck School of Medicine, Los Angeles, CA, [2]Department of Neurobiology, University of Pittsburgh School of Medicine, Pittsburgh, PA

Synaptogenesis at the neuromuscular junction (NMJ) is characterized by the aggregation of nicotinic acetylcholine receptors (AChRs) into high-density clusters on the postsynaptic muscle membrane. The signaling mechanisms that trigger AChR cluster formation and the cytoskeletal elements involved in immobilizing the receptors remain poorly understood. In a previous study, we have shown that adenomatous polyposis coli (APC) binds directly to the beta-subunit of muscle AChR in yeast two-hybrid and *in vitro* binding assays. APC is colocalized with AChRs in the mouse NMJ. The present study was undertaken to determine whether APC is required for the expression and agrin-induced clustering of AChRs in

muscle cells. C2C12 myocytes were infected with adenovirus expressing siRNA directed against APC. The green fluorescent protein (GFP) was co-expressed to allow easy identification of cells infected with the viral vector. The majority (>95%) of C2C12 myotubes were GFP-positive at 3 days post-infection. Immunoblotting of detergent extracts of the myotubes revealed a striking reduction (~82%) in the levels of the targeted protein APC. Immunofluorescent staining showed that inhibition of APC prevented the formation of large AChR clusters on the surface of myotubes exposed to neural agrin. Moreover, the levels of AChRs on myotubes surface were also reduced as determined by $^{125}$I-alpha-bungarotoxin binding assay. Northern blotting indicated that the levels of messenger RNAs for AChR subunits were not altered. In contrast, no change in APC protein levels, AChR clustering and expression was observed in C2 cells infected with adenovirus expressing siRNA directed against GAPDH. Our results suggest that APC may play a role in agrin-induced AChR clustering as well as trafficking or stability of AChRs in skeletal muscle cells. (Supported by NIH grant RO1-NS38301 and the Muscular Dystrophy Association).

### Isolation and Characterisation of GluR1-Containing Clathrin Coated Vesicles

P. G. R. Hastie,[1] K. J. Heesom,[2] S. R. White,[1] B. Costley-White,[1] G. Banting,[2] J. M. Henley[1]; [1]MRC Centre for Synaptic Plasticity, University of Bristol, Bristol, United Kingdom, [2]Department of Biochemistry, University of Bristol, Bristol, United Kingdom

Objective: To identify proteins co-transported with GluR1 containing α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors. It is believed that AMPA receptors go through both constitutive and activity dependent cycles of exo- and endocytosis in a clathrin-dependent manner. We provide further evidence for this by using a dominant negative mutant of AP180, a component of the clathrin coat machinery, to block AMPA receptor endocytosis in cell lines. However, vesicles containing AMPA receptors have not been biochemically isolated. We therefore devised a method to capture GluR1-containing clathrin coated vesicles (CCVs) from whole pig brain by immunoaffinity isolation. The advantage of enriching these vesicles over whole cell studies is that it is possible to identify novel proteins involved in AMPA receptor trafficking. These may not directly interact with the receptor or may be unknown proteins expressed at levels below normal detection thresholds. The proteomic content of these vesicles was therefore analysed by 2D SDS-PAGE and mass spectoscopy. This approach identified a number of hits including some uncharacterised proteins. These mostly lacked membrane association domains and modifications and may be trafficked in the vesicle lumen. AMPA receptors may be specifically selected as cargo to be incorporated into a CCV or be incorporated with other proteins which are then returned to the source membrane by retrograde transport. Immunoblot analysis suggests that NR1-containing N-methyl D-aspartate (NMDA) receptors and GluK6/7-containing kainate receptors are not co-transported with GluR1-containing AMPA receptors. These results favour a model of positive selection, implying some form of physical segregation of AMPA receptors from other membrane proteins. Interactions with the postsynaptic density are unlikely to be involved as CCVs form at extrasynaptic sites although there may be a role for membrane microdomains, eg lipid rafts.

1348

### Analysis of the Synaptic Vesicle Proteome: Pros and Cons Using Three Different Gel Separation Techniques in Combination with Mass Spectrometry

J. Burré,[1] H. Schägger,[2] T. Beckhaus,[3] C. Corvey,[3] M. Karas,[3] H. Zimmermann,[1] W. Volknandt[1]; [1]Neurochemistry, Johann Wolfgang Goethe-University, Frankfurt, Germany, [2]Biochemistry I, Johann Wolfgang Goethe-University, Frankfurt, Germany, [3]Pharmaceutical Chemistry, Johann Wolfgang Goethe-University, Frankfurt, Germany

Synaptic transmission between neurons relies on synaptic vesicles. Therefore, the analysis of the synaptic vesicle proteome is essential for the identification of components involved in vesicle mobilization, migration to the presynaptic plasma membrane, docking and fusion as well as recycling of synaptic vesicles via endocytosis. To date, a considerable variety of synaptic vesicle proteins has been identified that govern these processes. To identify novel proteins and to complete the synaptic vesicle proteome, we subjected synaptic vesicles to different gel-based approaches in combination with mass spectrometry. Synaptic vesicles were isolated from rat brain synaptosomes by hypoosmotic shock and subcellular fractionation techniques as well as by immunoisolation. Proteins were separated using three different gel separation techniques and were analysed by mass spectrometry after tryptic in-gel digestion. Approaches comprised the two-dimensional gel systems BAC/SDS-PAGE and dSDS-PAGE along with matrix-assisted laser desorption/ionization-time of flight-mass spectrometry (MALDI-TOF-MS) as well as one-dimensional SDS-PAGE followed by nano-liquid chromatography/tandem mass spectrometry (nano-LC/MS/MS). We identified a total of ~230 proteins. In addition, we demonstrate that the three experimental systems supplement each other. 1D-electrophoresis lead to the identification of 180 proteins. For comparison we identified 94 and 93 proteins using BAC/SDS-PAGE and dSDS-PAGE, respectively. Only 42 proteins were identified in all three experimental approaches. Interestingly, a number of hitherto unknown proteins were identified, some of them by one approach, others by two. Taken together, these data demonstrate that the parallel application of different gel systems is essential for achieving a complete organelle proteome analysis.

### *C elegans* UNC-44 Neural Ankyrin Binds to PP2A, CLASP2, and Calcium

P. Gong, A. J. Otsuka; Department of Biological Sciences, Illinois State University, Normal, IL

Neural UNC-44 AO13 ankyrin is required for proper axon guidance (Otsuka *et al., J. Cell. Biol*., 129:1081-1092, 1995; Boontrakulpoontawee and Otsuka, *Molec. Genet. Genom*., 267:291-302, 2002; Otsuka *et al*., *J. Neurobiol.*, 50:333-349, 2002). In yeast two-hybrids, the carboxyl domain of AO13 ankyrin interacted with members of two protein families: the protein phosphatase 2A (PP2A) B' subunits [encoded by *W08G11.4* and *C13G3.3* (Gong and Otsuka, *Molec. Biol. Cell* (suppl.), 14:124a, abst. #685, 2003)] and the +TIP, CLASP2, encoded by *cls-2*. By deletion analysis, W08G11.4 and C13G3.3a proteins interacted with a 141-aa region of UNC-44 (residues 6658-6798) containing a two-EF-hand domain. This region bound radioactive calcium in overlay assays. Site-directed mutations revealed that the EF hand 14-aa repeats [S(L/V)(T/S)SL(G/A)EFERLEKE] are important for W08G11.4 binding, but less so for C13G3.3a. Specifically, W08G11.4 binding is prevented by changes that alter the calcium-binding loops or charge clusters in the EF-hand stem. As expected for a S/T phosphatase substrate, phosphoserine mimics in the EF-hand loop regions did not prevent B'-subunit binding. The amino and carboxyl ends of W08G11.4 were found to be necessary for binding to UNC-44. There is the possibility that UNC-44 is a calcium sensor modulating, or modulated by, the UNC-44 phosphorylation state. Although CLASP2 associates

microtubules with the cell cortex, the adapter molecules remain unknown. In other systems, CLASP2 binds to the plus ends of microtubules at the leading edge of migrating cells, is inhibited by phosphorylation, and is controlled by PI3-kinase and GSK-3β pathways. In *C.* elegans, CLASP2 antibodies labeled the cytoplasm of many cells and, in some cases, labeled the cell periphery. The interaction between UNC-44 and CLASP2 leads to the hypothesis that UNC-44 may act to capture CLASP-tipped pioneer microtubules that are exploring the limits of growth cone filopodia.

**An Investigation of the *C elegans* JIP3 Homolog, UNC-16, in Synaptic Vesicle Transport and Maturation**

H. M. Brown, A. Goncharov, D. Byrd, Y. Jin; Molecular, Cellular and Developmental Biology, University of California, Santa Cruz, Santa Cruz, CA

Synaptic vesicles are specialized carriers for neurotransmitters. Vesicular biogenesis at the Golgi and subsequent transport by microtubule-based motor proteins known as kinesins is essential for the accumulation of synaptic vesicles at synapses. Extensive biochemical, morphological and physiological studies, however, have shown that the chemical composition, the size and the shape of newly synthesized, actively transported synaptic vesicles differ from those that are present at functional synapses. These observations thus imply that synaptic vesicles require a "maturation" step to be accumulated at synapses and to carry out their function. At least two pathways are implicated in vesicle maturation; precursor vesicles may mature following an initial fusion with the plasma membrane or through an intermediate endosomal compartment. We have previously characterized the *C. elegans* JIP3 homolog, UNC-16, for its role in regulating synaptic vesicle localization. The JIP3 protein family has been shown to physically interact with the conventional kinesin-I complex, and function as cargo adaptors. Transport of synaptic vesicles also requires the UNC-104 kinesin. In further phenotypic and genetic double mutant analyses of *unc-16* and kinesins involved in synaptic vesicle transport, we have identified a kinesin-1 independent role for UNC-16. Cellular analysis of markers to multiple subcellular compartments shows that *unc-16* affects a specific subset of cargos, including endosomal compartment residents. Preliminary studies suggest that UNC-16 may be involved in synaptic vesicle maturation through endosomal regulators.

1351

**Fer Kinase Regulates Presynaptic Vesicle Localization Through β-catenin Regulation**

S. Lee,[1] S. Ng,[1] S. X. Bamji,[2] J. Balsamo,[3] J. Lilien,[3] L. F. Reichardt[1]; [1]Department of Physiology, University of California, San Francisco, San Francisco, CA, [2]Department of Cellular and Physiological Sciences, Brain Research Centre, University of British Columbia, Vancouver, BC, Canada, [3]Department of Biological Sciences, University of Iowa, Iowa City, IA

Cadherins are calcium-dependent intercellular adhesion molecules that have been proposed to play important roles in synaptic development in association with catenins and other signaling proteins. Recently β-catenin has been shown to function as a scaffold protein to recruit and anchor PDZ domain-containing proteins to cadherin clusters which in turn localize synaptic vesicles at nascent synapses. Maintenance of cadherin complexes is known to be regulated through phosphorylation and dephosphorylation of β-catenin, but the kinases and phosphatases that are responsible for β-catenin regulation during presynaptic development are not clear. Here we report the role of the nonreceptor tyrosine kinase Fer in presynaptic development. Inhibition of the association of Fer with p120 catenin by a cell-permeable peptide resulted in increased tyrosine phosphorylation of β-catenin and its dissociation from cadherin complexes in hippocampal neurons. Synaptic vesicle clusters were dispersed along the axons and dispersion was prevented by expression of a β-catenin mutant unable to be phosphorylated at a key cadherin interaction site (Y654F). The peptide also increased the dynamics of vesicle puncta movement significantly. Overexpression of a kinase-dead mutant of Fer also resulted in synaptic vesicle dispersion, implying that the kinase activity of Fer is required for proper localization of synaptic vesicles. Taken together, our results suggest that Fer, recruited by p120 catenin to the cadherin complex, may activate an adjacent phosphatases to dephosphorylate β-catenin, which enables β-catenin to act as a scaffold to localize synaptic vesicles.

1352

**Serum- and Glucocorticoid Inducible Kinase (SGK) Destabilizes Microtubules in Hippocampal Neurons**

Y. C. Yang,[1] C. H. Lin,[2] E. H. Y. Lee[1]; [1]Division of Neuroscience, Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan Republic of China, [2]Graduate Institute of Life Sciences, National Defense Medical Center, Taipei, Taiwan Republic of China

Tau is involved in the regulation of microtubule (MT) dynamics, axonal transport and neuronal morphology. Hyperphosphorylation of Tau proceeds to neurodegeneration in Alzheimer's disease. Previous reports have shown that mRNA of serum- and glucocorticoid inducible kinase (*sgk*) is increased at brain lesion site and after rats are exposed to an enriched environment. Enhanced expression of *sgk* was found to facilitate memory formation in rats. According to the AKT/SGK substrate motif on Tau, SGK might be a candidate Tau protein kinase. In the present study, we examined the role and mechanism of SGK-1 in regulation of Tau phosphorylation and MT polymerization. Results from kinase assay showed that active SGK (ΔSGK) specifically phosphorylated Tau at Ser214 both *in vitro* and *in vivo*. Immunostaining results indicated that SGK-1 is co-localized with Tau in hippocampal neurons. Further, SGK and phospho-Ser214 of Tau were found to co-localize and concentrate at where MT is disorganized. *In vitro* MT polymerization results revealed that ΔSGK disassembled MT through phosphorylation of Tau at Ser214. Transfection of pEGFP-*sgk* to cultured hippocampal neurons significantly inhibited neurite outgrowth. However, co-transfection of pEGFP-*sgk* and pDsRed-*tau*S214A reversed the impairing effect of pEGFP-*sgk* on hippocampal neurite outgrowth. Further, ΔSGK directly disassembled self-polymerized MT and taxol-induced pre-polymerized MT in a dose-dependent and ATP-independent manner. These results provide the first and direct evidence that SGK not only phsophorylates Tau to affect MT polymerization and neurite outgrowth, but also acts as a MT destabilizer to directly disassemble MT in hippocampal neurons. (This work was supported by a Grant from the National Science Council of Taiwan NSC 93-2321-B-001-009)

**Recombinant Prion Protein Induces Rapid Polarization and Axonal Outgrowth in Embryonic Rat Hippocampal Neurons in Culture**

J. M. Kanaani (Kanaaneh),[1] S. B. Prusiner,[2] J. Diacovo,[1] G. Legname,[2] S. Baekkeskov[1]; [1]Dept. of Medicine, Microbiology/Immunology, and Diabetes Center, University of California San Francisco, San Francisco, CA, [2]Institute of Neurodegenerative Diseases, Dept. of Neurology and Biochemistry and Biophysics, University of California San Francisco, San Francisco, CA

While a β-sheet-rich form of the prion protein ($PrP^{Sc}$) causes neurodegeneration, the biological activity of its precursor, the cellular prion protein ($PrP^{C}$), has been elusive. In this study, we have developed an *in vitro* assay to study the effect of purified recombinant prion protein (recPrP) on the polarization and neurite outgrowth of rat fetal hippocampal neurons in culture. Overnight exposure of one-day-old fetal rat hippocampal neurons for 22 h to Syrian hamster recPrP (SHaPrP) or mouse recPrP, folded into an α-helical rich conformation similar to that of $PrP^{C}$, dramatically enhanced the development of neuronal polarity and neurite extention in a dose-dependent manner. Thus, cultures treated with 0.45 μM SHaPrP showed a 1.9-fold increase in neurons with a differentiated axon, a 13.5-fold increase in neurons with differentiated dendrites, a five-fold increase in axon length, and the formation of extensive neuronal networks. Formation of synaptic-like contacts was increased by a factor of 4.6 after exposure to recPrP for seven days. Neither the N-terminal nor C-terminal domains of recPrP nor the PrP paralogue doppel (Dpl) enhanced the polarization of neurons. The pattern of immunostaining of neurons incubated with SHaPrP using antibodies specific for the hamster $PrP^{C}$, suggests binding of SHaPrP to a ligand that is distributed throughout the neuronal surface and that bound SHaPrP is not internalized. Inhibitors of PKC and of Src kinases, including p59Fyn, blocked the effect of recPrP on axon elongation, while inhibitors of phosphatidylinositol 3-kinase showed a partial inhibition, suggesting that signaling cascades involving these kinases are candidates for transduction of recPrP-mediated signals. The results predict that full-length $PrP^{C}$ functions as a growth factor involved in development of neuronal polarity.

### The Receptor Tyrosine Kinase EphB2 is Polarized to the Dendritic Membrane of Cultured Hippocampal Neurons

K. Osborne,[1] I. Ethell[2]; [1]Neuroscience, University of California Riverside, Neuroscience Department, Riverside, CA, [2]Neuroscience, University of California Riverside, Biomedical Sciences Division, Riverside, CA

The receptor tyrosine kinase EphB2 has been shown to be important in the formation of dendritic spines in hippocampal neurons (Ethell et al., 2001; Penzes et al., 2003; Henkemeyer et al., 2003). The dendritic spines are postsynaptic sites of the majority of excitatory axon-dendritic synapses in the central nervous system, and their formation is a critical aspect of synaptic development. While there is increasing knowledge of Eph signaling, little is known about their localization. The differential targeting of Eph receptors may be important to their function in neurodevelopment, including cell migration, axon guidance and synaptogenesis. In synapses, it is traditionally thought that Ephs function postsynaptically while their ligands ephrins act presynaptically. Recent work has shown that the traditional synaptic arrangement of Ephs and ephrins can be inverted, as in the CA1 hippocampal region (Grunwald et al. 2004). Here we investigate the localization of EphB2 in hippocampal neuron cultures. In brief, we transfected cultures at 7 DIV with GFP and EphB2-Flag and evaluated the cell surface EphB2 axodendritc distribution at 8 DIV. Our preliminary data show that EphB2 is polarized to the somatodendritic domain of cultured hippocampal neurons. This is of particular importance since recent work has shown that dendritically localized EphB2 is needed for dendrite morphogenesis and maintenance of dendrites in mature neurons (Hoogenraad et al. 2005). Future work will consist of identifying sorting motifs governing the targeting of EphB2 to dendrites and examining the axodendritic distribution of EphB2 in CA1 and CA3 neurons as well as the role of EphB2 polarity in neuronal development. This work is supported by NIMH grant MH67121.

### Brain-Derived Neurotrophic Factor Regulation of AMPA Receptor Trafficking

H. Nakata, S. Nakamura; Department of Biochemistry and Cellular Biology, National Institute of Neuroscience, Kodaira, Tokyo, Japan

The change of the number of postsynaptic α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA)-type glutamatergic receptors (AMPARs) by neuronal activity is implicated in the synaptic plasticity. The activation of N-methyl-D-aspartate receptor (NMDAR) has been known to trigger the delivery of AMPARs into the synaptic membrane in hippocampal excitatory synapses. Brain-derived neurotrophic factor (BDNF) and other neurotrophins are also essentially involved in synaptic plasticity, at presynaptic and postsynaptic sites. Notably, BDNF was shown to unmask silent synapses in the developing mouse barrel cortex. Here, we investigated the role of BDNF on the AMPAR trafficking at postsynaptic sites of the cultured cortical pyramidal neurons. Using fluorescence resonance energy transfer (FRET) technology and Cameleon probe (A. Miyawaki, RIKEN) for $Ca^{2+}$ imaging, along with immunocytochemistry for the separate measurement of surface and intracellular AMPAR subunit GluR1, the dendritic spine-shaft pairs were assessed for the effect of BDNF and its signaling pathways involved. We report that BDNF application increased the surface expression of GluR1 at the postsynaptic densities, similar to the effect of NMDAR stimulation performed by two-photon uncaging of MNI-glutamate. The essential signaling was $Ca^{2+}$ transients evoked by the activation of receptor tyrosine kinase TrkB/PLCγ pathway. Both the intracellular $Ca^{2+}$ rise, $Ca^{2+}$ release from the intracellular $Ca^{2+}$ channel inositol trisphosphate receptor ($IP_3R$), and $Ca^{2+}$ influx through subsequent activation of store-operated cation channel TRPC (transient receptor potential canonical) contributed to the surface expression of GluR1 in the postsynapses. These results suggest an important role of BDNF in the regulation of AMPAR trafficking directly at the postsynaptic membrane via diverse $Ca^{2+}$ signaling.

### Interaction of Neurotrophin-3 and Fibroblast Growth Factor (FGF2) in the Development of the Cochlear Nucleus (CN) of the Mouse Embryo

D. K. Morest; Neuroscience, University of Connecticut Health Center, Farmington, CT

How do NT3, FGF2, and their receptors affect cellular events in CN development? Immunohistochemistry was used to localize factors at particular stages of the normal morphogenetic sequence. An in vitro model was used to discover each factor's effects and interactions at particular stages in the sequence. By specific antibody staining in F1 offspring (CBA/JxC57BL/6J), TrkC protein appeared in the neural precursors prior to E11 and continued in the same cells until after birth. NT3 appeared in the precursor cells during migration (E13-E15) and disappeared shortly after birth (P1). TrkC and NT3 coincided in the same structures, including the formative phases of axons, terminals, and their synaptic targets. Thus NT3 tracks the morphogenetic sequence within a window defined by TrkC. In vitro, the anlage of the CN was explanted from E11 embryos. Neuroblasts migrated onto a Vitrogen substrate and began to differentiate, forming neurites, growth cones, and neuronal markers. The cultures were divided into seven groups and fed with defined medium, with or without FGF2, BDNF, and NT3 supplements, alone or in combinations, for 7 days. By time-lapse imaging, FGF2 alone had the most positive effect on proliferation and migration. FGF2 and NT3 produced the most increases, apparently synergistic, on neurite outgrowth and fasciculation. Synaptic vesicle protein (SV2) was more abundant in cultures treated with FGF2

and NT3 or BDNF. Immunocytochemical observations in vitro showed that NT3 and its receptor TrkC were greatest when cultures were treated with NT3 and FGF2 or BDNF. The results support the hypothesis that FGF2 promotes proliferation and migration, NT3 and BDNF stimulate neurite outgrowth, while NT3 and FGF2 promote fasciculation and synapse formation. Supported by NIH grant DC006387.

1357

**Dendritogenesis and Localization of NMDA and AMPA Receptors in Rat Primary Hippocampal Neurons are Controlled by an Endoplasmic Reticular Protein Sigma-1 Receptor**

S. Tsai, T. Hayashi, T. Su; Ddps/cnbr/irp, NIDA-NIH, Baltimore, MD

Sigma-1 receptors (Sig-1R) are endoplasmic reticular proteins that have been implicated in schizophrenia, Alzheimer's disease, depression, amnesia, and drug abuse via mechanisms that have yet to be totally understood. Sig-1R were shown by us to regulate the level of gangliosides which have been demonstrated at least to be important in dendritogenesis. We hypothesize therefore that one of the important functions of Sig-1R in the brain may involve dendritogenesis. We employed the small interfering RNA (siRNA) strategy to test this hypothesis in rat primary hippocampal neurons. A knockdown of Sig-R with the siRNA against Sig-1R causes a near depletion of gangliosides in the neuron. The siRNA treatment concomitantly impairs the growth and development of dendrites. Specifically, the siRNA-transfected neurons have shorter dendrites and possess fewer branches on the dendrite. The transfected neurons also form fewer dendritic spines while possessing more filopodia greater in length. These filopodia apparently fail to retract to form mature dendritic spines, thereby continuing to extend themselves as long filopodia. Further, the knockdown of Sig-1R by siRNA reduces the levels of synapse markers PSD-95 and synaptophysin, and dramatically changes the localization of NMDA receptors and AMPA receptors. NMDA receptors or AMPA receptors are present in the form of clusters in siRNA-transfected neurons, and exist mainly at the dendritic shafts and not at spine heads where they normally localize. These results suggest that Sig-1R play a critical role in dendritogenesis and in the maturation of dendritic spines perhaps by regulating the level of gangliosides in the brain. As gangliosides are important constituents of lipid rafts, it is tempting to speculate that Sig-1R may regulate dendritogenesis by affecting the formation of lipid rafts in the neuron.

1358

**Integrin-Dependent Remodeling of Dendritic Spines and Synapses in Cultured Hippocampal Neurons**

Y. Shi, I. M. Ethell; Division of Biomedical Sciences, Neuroscience Program, University of California, Riverside, Riverside, CA

The dendritic spines are postsynaptic sites of the majority of excitatory axon-dendritic synapses in the central nervous system and are responsible for synaptic transmission and synaptic plasticity. Many different factors and proteins have been shown to control dendritic spine development and remodeling. We and others have previously shown that interactions between the EphB family of receptor tyrosine kinases and their cognate ligands, the ephrin-Bs, play an important role in dendritic spine formation in hippocampal neurons. The extracellular matrix (ECM) components and their cell surface receptors, integrins, have been also found in the vicinity of synapses and shown to regulate synaptic efficacy and play an important role in long-term potentiation (LTP). The molecular mechanisms by which integrins affect synaptic efficacy have begun to emerge, however, their role in structural plasticity is poorly understood. Here we show that integrins are involved in dendritic spine/synapse remodeling in cultured hippocampal neurons. Beta 1, beta 3 and beta 5 subunits of integrin are localized in dendritic spines/synapses of hippocampal neurons in vitro and in vivo. Treatment of cultured hippocampal neurons with arginine-glycine-aspartate (RGD)-containing peptide, which mimicks effects of ECM on integrin signaling, induces elongation of existing dendritic spines and promoted formation of new filopodia. Moreover, these effects are also accompanied by F-actin reorganization and synapse remodeling. Furthermore, block of NMDA receptor by its antagonist MK801 prevents RGD-induced actin reorganization at synapses. Our data show that RGD treatment induces actin reorganization through NMDA receptor-mediated activation of calcium/ calmodulin-dependent kinase II (CaMKII) suggesting that integrin regulation of NMDAR/CaMKII-mediated actin reorganization might be responsible for ECM-mediated spine remodeling in hippocampal neurons.

**Spin90 as a Novel Regulator of Dendritic Spine Morphology**

S. Lee, K. Lee, S. H. Kim, W. K. Song, S. Chang; Department of Life Science, Gwangju Institute of Science and Technology, Gwangju, Republic of Korea

SPIN90 (SH3 Protein Interacting with Nck, 90 kDa) is an Nck-binding protein that contains one SH3 domain, three PRDs and a serine/threonine-rich region. SPIN90 has been known to regulate actin polymerization and is highly expressed in the brain, but its role in the neuronal system is unknown. We have found that in addition to its localization in presynaptic terminals, SPIN90 highly exists in the dendritic spines of cultured hippocampal neurons. It turned out that localization of SPIN90 in the dendritic spines is due to its association with PSD-95 through PRD-SH3 interaction. To further investigate the role of SPIN90 in the dendritic spines, we overexpressed SPIN90 in hippocampal neurons in culture. When expressed in early developing neurons, SPIN90 induced a dramatic increase in dendritic filopodial length and number. Consistently, upon expressing it in mature neurons, the protrusions emerging from dendritic shaft of transfected neurons show significant increase in average length and density. The knockdown of expression by SPIN90 specific siRNA dramatically reduces dendritic spine density. Finally we proved that chemically induced LTP has resulted in the clustering of SPIN90 into dendritic spines. Our results suggest that SPIN90 associates with PSD-95, thus localizing in the dendritic spines where it modulates actin dynamics to regulate dendritic morphology. Our results also raise the possibility that SPIN90 could be the regulator of dendritic spine morphology during the synaptic plasticity. Table of Contents

**Subcellular Mechanisms in Monocrotaline-induced Pulmonary Hypertension: Megalocytosis, Golgi Blockade and Enhanced Unfolded Protein Response (UPR)**

S. Mukhopadhyay,[1] P. B. Sehgal[2]; [1]Cell Biology and Anatomy, New York Medical College, Valhalla, NY, [2]Cell Biology and Anatomy and Medicine, New York Medical College, Valhalla, NY

Monocrotaline-induced pulmonary hypertension in the male rat is an irreversible hit-and-run disease process in that a single exposure to this plant alkaloid [half-life of active pyrrolic derivative (MCTP) is ~3 sec in water] leads to clinical manifestations (pulmonary hypertension) 10-14 days later. The cellular consequences include enlargement of endothelial and smooth muscle elements in pulmonary arteries as well of Type II alveolar epithelial cells ("megalocytosis"). These enlarged "growing but non-dividing" cells contain increased ER, enlarged Golgi and exhibit reduced cell-cycle traverse. We have previously proposed that MCTP leads to a block in ER-Golgi trafficking and alters the mitosis-sensor functions of the Golgi (the Golgi blockade hypothesis) resulting in disruption of caveolin-1/raft function and a block of entry into mitosis. We now report that there is an activation of the UPR sensor pathways in MCTP-induced megalocytosis. In confocal immunofluorescence assays of megalocytotic lung epithelial cells (A549), Ire1α was translocated to the nucleus, while ATF6 and XBP-1 accumulated in a tight perinuclear region together with the Golgi marker GM130. PERK showed strong perinuclear and nuclear accumulation and there was in increase its target phospho-eIF2α, which also showed marked nuclear accumulation. Additionally, the chaperone ERp57/Grp58 showed nuclear translocation, while protein disulfide isomerase (PDI) gained a strong circumnuclear provenance. By Western Blotting, there was an increase in the cellular levels of the transcription factors STAT3, STAT1 and XBP-1 as well as an increase in nuclear phospho-eIF2α. These data indicate that the UPR pathways are activated following MCTP-induced Golgi Blockade and this likely contributes to the development of the megalocytosis phenotype.

**Morphological Alterations of Cellular Secretory System by Human Cytomegalovirus**

J. Seo,[1] W. J. Britt[2]; [1]Microbiology, School of Medicine, University of Alabama at Birmingham, Birmingham, AL, [2]Microbiology, Pediatrics, Neurobiology, School of Medicine, University of Alabama at Birmingham, Birmingham, AL

The function of cellular organelles in the assembly of large DNA viruses such as human cytomegalovirus (HCMV) is not well understood. Studies of herpesvirus assembly have identified a membranous, juxtanuclear compartment, the virus assembly compartment (AC), as a site of virion structural protein accumulation late in infection. We hypothesized that cells infected with HCMV undergo morphological changes of compartments within the secretory system that promote formation of the AC. We initiated studies to define the role of viral functions in the formation of this modified cellular compartment. Late in infection, components of the secretory system appeared to be organized into concentric shells that surrounded viral proteins present in the interior of the AC. Protein markers of the ERGIC initially were widely distributed in the infected cell but coalesced late in infection into a more discrete structure that remained peripheral to the AC. Markers of the TGN were found in the inner layers of this structure late in infection. Interestingly, the distribution of the TGN was more diffuse early in infection and overlapped with the juxtanuclear structure, but late in infection it was localized to the outer layers of the AC. The adapator protein AP-1 overlapped with TGN, while AP-3 co-localized with the viral proteins in the AC late in infection. Because the juxtanuclear structure appeared to be an immature, less well defined structure early in infection that compacted as the infection progressed, it appears that morphoplogic alterations in the cellular secretory pathway are linked to virus assembly and that these changes correlate temporally with virus production. Our findings suggest that the morphological alteration of cellular secretory system induced during viral assembly in HCMV infected cells could represent virus-specified modification of cellular organelles to facilitate cytoplasmic assembly of this DNA virus.

**pH-dependent Golgi Retention of β4-Galactosyltransferase I**

B. E. Schaub, E. G. Berger, J. Rohrer; Institute of Physiology, University of Zurich, Zurich, Switzerland

β-1,4-galactosyl- (GalT) and α-2,6-sialyltransferase (SiaT) co-localize in the trans cisternae of the Golgi apparatus (GA) where they catalyze elongation and termination of complex N-glycan chains, respectively. Upon addition of monensin, SiaT remains in the GA whereas GalT dissociates into swollen vesicles, where it co-localizes with trans-Golgi network (TGN) markers such as TGN46 and cation-independent mannose-6-phosphate receptor. Both GalT and SiaT contain four domains, the cytoplasmic tail (CT), the transmembrane domain (TMD), the stem region (STEM), and the catalytic domain. To determine the domains involved in the monensin response of GalT, we created several chimeric constructs where we swapped domains of GalT with those of SiaT and replaced the catalytic domain with GFP. Furthermore, we also mutated the potential phosphorylation sites in the CT of GalT. These constructs were stably transfected in HepG2 cells to study the dynamics of response to monensin by time-lapse video microscopy. The localization patterns of the GalT-SiaT-GFP chimeras were compared to endogenous giantin by means of double immunofluorescence of fixed cells and as time lapse immunofluorescence videos in living cells, using a Laser Scanning Confocal Microscope. Our results strongly suggest that the CT is necessary for monensin sensitivity of GalT whereas the TMD and the STEM regions might play a supporting role. Moreover preliminary data show that phosphorylation of GalT is not required for monensin sensitivity. Supported by SNF 31-66578.01 to EGB and SNF 31-67274.01 to JR.

**Discovery of the Molecular Determinants of GlcNAc6ST-1 Function**

M. M. Desko, J. J. Kohler; Chemistry, Stanford University, Stanford, CA

The Golgi-resident enzyme *N*-acetylglucosamine-6-sulfotransferase-1 (GlcNAc6ST-1) is responsible for the sulfation of GlcNAc on the L-selectin ligand residing on endothelial cells, which is implicated in lymphocyte homing. GlcNAc6ST-1 is a type II transmembrane protein consisting of a cytosolic N-terminal domain, a transmembrane domain, a proline-rich stem region that is 75 amino acids in length and a catalytic domain; the stem region and catalytic domain both extend into the Golgi lumen. Flow cytometry data obtained using the L-selectin-ligand specific antibody G72 show that mutation of proline residues within the stem region affects the ability of GlcNAc6ST-1 to sulfate GlcNAc in the context of the tetrasaccharide sialyl Lewis$^x$. The proline to alanine mutation also affects the subcellular localization of the protein. Conversely, mutation of stem region asparagine and threonine residues has no effect on enzyme localization or enzyme activity. GlcNAc6ST-1 has been previously reported to form a homodimer. To study dimerization of GlcNAcST-1, we developed a new microscopy assay. Our assay relies on the ability of the C-terminal KDEL sequence to direct localization to the endoplasmic reticulum (ER). HeLa cells transfected with EYFP-tagged GlcNAc6ST-1 alone show normal Golgi localization of the enzyme, as analyzed by confocal microscopy. When HeLa cells are transfected with both EYFP-tagged GlcNAc6ST-1 and KDEL-tagged GlcNAc6ST-1, EYFP fluorescence is observed in the ER, indicative of the formation of higher order enzyme complexes. Our assay provides an efficient way to determine the molecular determinants of GlcNAcST-1 dimerization and will also be applicable

to other Golgi-resident enzymes, several of which have been shown to form homo- and heterodimers.

**Rab3D Localizes to Early Golgi Compartments in Rat Intestinal Goblet Cells**

L. van Weeren,[1] A. M. de Graaff,[1] A. Ultee,[2] J. A. Valentijn[3]; [1]Biochemistry and Cell Biology, University of Utrecht, Faculty of Veterinary Medicine, Utrecht, The Netherlands, [2]Pathobiology, University of Utrecht, Faculty of Veterinary Medicine, Utrecht, The Netherlands, [3]Molecular Cell Biology, Leiden University Medical Center, Leiden, The Netherlands

The small GTP-binding protein, rab3D, has been implicated in regulated exocytosis for its predominant localization to secretory granules in various cell types. However, deletion-mutation studies have suggested that rab3D is rather involved in the biogenesis of secretory granules. In support of this, it has been shown in several cell types that rab3D also localizes to the trans-Golgi network (TGN). We here report the surprising observation that rab3D associates with early Golgi compartments in intestinal goblet cells and in Brunner's gland acinar cells. Rab3D expression in intestine was demonstrated by SDS-PAGE and Western blotting of homogenates prepared from rat duodenum and colon. In addition, rab3D was detected in lysates of human colonic mucous epithelial cells (HT29-5M21). Confocal laser-scanning microscopy revealed rab3D immunofluorescence in goblet cells of duodenum and colon. Rab3D was also present in duodenal Paneth cells and Brunner's gland acinar cells. In these two cell-types rab3D localized to secretory granules while in the latter, the Golgi area also displayed strong labeling. In the goblet cells of both duodenum and colon, rab3D labeling was concentrated in the Golgi area whereas mucous granules were almost devoid of signal. In colon, rab3D immunofluorescence from goblet cells was stronger in the crypts than in the villi. There was no co-localization between rab3D and the TGN marker, TGN-38. In contrast, rab3D co-localized partially with the cis-Golgi marker, GM-130, and with the cis- to trans-Golgi marker, beta-COP. Strong co-localization was observed between rab3D and the lectins, *Griffonia simplicifolia* agglutinin II, and soybean agglutinin, which have been described as markers of medial- and cis-Golgi, respectively. Post-embedding immunoelectron microscopy confirmed the rab3D localization to cis- and medial-Golgi cisternae. Taken together, these data suggest a novel role for rab3D in an early Golgi trafficking pathway.

1365

**A Member of the Dynein Light Chain Roadblock/LC7 Family, Robl1, Interacts Differentially With Rab6A and Rab6A'**

B. Wanschers,[1] R. van de Vorstenbosch,[1] S. M. King,[2] J. Fransen[1]; [1]Cell Biology, NCMLS, Nijmegen, The Netherlands, [2]University of Connecticut Health Center, Farmington, CT

Small GTPases of the Rab family are key regulators of intracellular membrane transport. To date more then 60 members, including isoforms, are recognized. In the past we have identified three Rab6 isoforms: Rab6A, Rab6A' (generated via alternative splicing of a duplicated but distinct exon within the Rab6A gene) and Rab6B (a brain specific isoform). Rab6A is implicated in the regulation of retrograde intra-Golgi and Golgi to ER transport whereas Rab6A' in addition can regulate a transport step from late endosomes to the Golgi apparatus, characterized by the internalization of Shiga toxin (Mallard *et al*., J Cell Biol 156, 653-64, 2002). In a search for specific Rab6 interacting proteins, several novel binding partners were identified. One novel interactor is Robl1, a member of the dynein light chain family that is structurally related to proteins which have been implicated in modulating the GTPase activity of small GTPases (Koonin and Aravind, Curr Biol 10, R774-6, 2000). The interaction between Rab6 isoforms and Robl1 was further established by co-immunoprecipitation studies. Interestingly, pull-down assays with either GTPγS- or GDP-loaded Rab6A or Rab6A' revealed that Robl1 preferentially binds to Rab6A when it is GTP-bound and to Rab6A' in its GDP-bound state. Microscopic studies demonstrated that Robl1 colocalizes with Rab6 at the Golgi apparatus and is actually recruited there by Rab6. Given the nature of the Robl1 protein, we also checked whether expression of Robl1 has an effect on the intrinsic GTPase activity of Rab6 isoforms. However we did not observe such a modulating effect. On the basis of these data we suggest that the Robl1-Rab6 interaction may act as an anchor for attaching vesicle- or Golgi membranes to the dynein complex.

**Trs130 is Required for the Specificity Switch of A Dual-Ypt/Rab GEF**

N. Segev, N. Morozova, Y. Liang, R. Cox, S. Chen, E. Yoo; Biological Sciences, University of Illinois, Chicago, IL

Intracellular trafficking in eukaryotes is regulated by Ypt/Rab GTPases. These GTPases are activated by guanine-nucleotide exchange factors (GEFs). When in the GTP-bound state, Ypt/Rabs interact with effectors that mediate individual steps of the protein trafficking pathways. An attractive possibility is that Ypt/Rabs and their accessory factors not only regulate the separate steps of protein transport pathways, but also coordinate these separate steps. Here, we propose a novel mechanism for such coordination in the Golgi. The modular multi-protein Golgi-associated complex, TRAPP, acts as a GEF for Ypt1 and Ypt31/32, the GTPases that regulate entry into and exit from the yeast Golgi, respectively. Trs130 is a TRAPP subunit that is found in late but not early Golgi, is conserved from yeast to man, and is a candidate for several human disorders. We show that Trs130 determines the specificity of the dual-GEF complex: it is required for switching the GEF activity of TRAPP from a Ypt1-GEF to a Ypt31/32-GEF. Unlike the wild-type complex, TRAPP purified from trs130ts mutant cells neither contains the Trs130 protein, nor acts as a Ypt31 GEF. However, its Ypt1-GEF activity is higher than that of the wild type. We propose that TRAPP acts as a Ypt1 GEF in early Golgi, whereas in late Golgi Trs130 is required for switching this activity off, and turning the Ypt31/32 GEF activity on. Such a switch-able dual-specificity GEF would ensure activation of Golgi Ypts at the correct cisterna, thereby coordinating entry into and exit from the Golgi apparatus.

**Mammalian GRIP-domain Proteins Form alpha-helical Homodimers Which Are Localised to Distinct Sub-domains of the trans-Golgi Network**

F. J. Houghton, M. R. Luke, M. A. Perugini, P. A. Gleeson; Biochemistry & Molecular Biology, University of Melbourne, Bio21, Parkville, Australia

Intracellular transport from the TGN (trans-Golgi network) to the plasma membrane has been found to involve a family of golgin proteins, all of which contain the GRIP or 45-residue Golgi targeting domain (1,2). On the basis of the high content of heptad repeats, GRIP domain proteins are predicted to contain extensive coiled-coil regions that have the potential to mediate protein-protein interactions. Four mammalian GRIP domain proteins have been identified which are targeted to the TGN through their GRIP domains: p230, golgin-97, GCC88 and GCC185 (Golgi localised

coiled-coil protein). Here we have investigated the ability of the four mammalian GRIP domain proteins to interact. Using a combination of immunoprecipitation experiments of epitope-tagged GRIP domain proteins, cross-linking experiments and yeast two-hybrid interactions, we have established that the GRIP proteins can self-associate to form homodimers exclusively. Two-hybrid analysis indicated that the N- and C- terminal fragments of GCC88 can interact with themselves, but not with each other, suggesting that the GRIP domain proteins form parallel coiled-coil dimers. Analysis of purified recombinant golgin-97 by CD spectroscopy indicated a 67% alpha-helical structure, consistent with a high content of coiled-coil sequences. These results support a model for GRIP domain proteins as extended rod-like homodimeric molecules. The formation of homodimers, but not heterodimers, indicates that each of the four mammalian TGN golgins has the potential to function independently. This is consistent with recent data, which indicates that these golgins are localised to distinct sub-domains of the TGN (4,5). 1. Brown et al. (2001). Traffic 2,:336-344, 2. Luke et al (2003). J Biol Chem 278, 4216-4226, 3. Gleeson et al (2004). Traffic 5,: 315-326. 4. Luke et al (2005). Biochem J 388, 835-841 5. Lock et al (2005). Submitted

**Trans-Golgi network Golgins**

M. C. Derby, P. A. Gleeson; Department of Biochemistry and Molecular Biology, Bio21 Molecular Science and Biotechnology Institute, Melbourne, Australia

The four mammalian golgins, p230/golgin-245, golgin-97, GCC88 and GCC185, are targeted to trans-Golgi network (TGN) membranes[1] where they are proposed to play a role in the maintenance of TGN structure or protein trafficking. All four proteins exist as homodimers, and are predicted to form extensive regions of coiled-coils. They share a modestly conserved C-terminal region, the GRIP domain, which is responsible for their G-protein-dependent recruitment to the TGN. Membrane recruitment of both p230 and golgin-97 is mediated by ARF-like GTPase 1 (Arl1)[3]. Using transient transfections of cultured mammalian cells, confocal microscopy and microRNA interference (miRNA) we explored the TGN localization and function of GCC88 and GCC185. When expressed as tagged versions in the same cell, the GRIP domains of GCC88 and GCC185 are both localized to the TGN, but display only partial overlap. Overexpression of full-length GCC185 resulted in the loss of GCC185 Golgi staining, and the appearance of small GCC185-labelled punctate structures. These GCC185-labelled structures did not affect the TGN localization of the other GRIP proteins. Unlike p230 and golgin-97, GCC88 and GCC185 do not interact with Arl1 in vivo, indicating that the GRIP domains differ in their specificity for G proteins. Depletion of GCC185 protein levels by miRNA results in a disruption of GM130 and p230, from tight Golgi staining to extended or large punctuate staining, implicating GCC185 in the maintenance of Golgi structure. These differences in localization and binding at the TGN indicate that the mammalian GRIP proteins may be recruited by different mechanisms to distinct sub-domains of the TGN. We propose that GCC185, along with the other GRIP domain proteins, functions to maintain the integrity of distinct TGN domains. 1. Luke, ML *et al* (2003) *J. Biol. Chem.* **278** 4216-26 2. **Characterization of the Golgi Matrix Proteins Grh1p and Uso1p in Pichia pastoris**

S. K. Levi; Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL

The Golgi plays a central role in the secretory pathway, and it consists of membranous cisternae that sort newly made proteins to various intra- and extracellular destinations. In most species, the Golgi cisternae are stacked in an ordered fashion. A set of proteins that collectively form the Golgi "matrix" has been implicated in generating this stacked structure. The matrix is also thought to play a role in vesicle tethering to the Golgi, and has recently been shown to interact with signaling proteins, suggesting that it may serve as a structural scaffold for the Golgi. However, there are conflicting data that suggest different mechanisms by which the matrix functions, and the identities of the matrix components are not known with certainty. I am characterizing two putative Golgi matrix proteins in the budding yeast *Pichia pastoris*. Unlike *Saccharomyces cerevisiae*, *P. pastoris* has a stacked Golgi. Grh1p, a homolog of mammalian GRASP65, co-localizes with the transitional endoplasmic reticulum marker Sec13p. Grh1p exhibits dynamic behavior typical of Golgi resident proteins. Uso1p, a homolog of the mammalian Golgins p115 and GM130, also localizes in the vicinity of the Golgi. Analysis of the Uso1p domains that display homology to GM130 and to p115 is currently underway. Our preliminary results indicate that *P. pastoris* is a powerful model system for analyzing the Golgi matrix.

**Characterization of the Golgin Proteins Rud3 and Coy1 in *Pichia pastoris***

L. A. Satkamp,[1] B. S. Glick[2]; [1]Biochemistry and Molecular Biology, University of Chicago, Chicago, IL, [2]Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL

A substantial fraction of proteins produced in eukaryotic cells traverse the Golgi apparatus, an organelle responsible for targeting and modification of cellular proteins. Typically, a Golgi consists of stacks of pancake-like cisternae that represent biochemically distinct cis, medial and trans compartments. The molecular interactions governing the stacking of these cisternae are thought to involve so-called golgin proteins. Golgins are coiled-coil proteins believed to be necessary for vesicle tethering and for the structure of Golgi stacks. These proteins contain specific domains for association with Golgi membranes and with particular proteins, which include other golgins as well as certain GTPases. Evidence is increasing for regulatory functions of golgins, in addition to their structural roles. For example, a role for the golgin GRASP65 has been established in the regulation of spindle dynamics in mammalian cells. Homologues to mammalian golgins have been identified in the budding yeasts *Saccharomyces cerevisiae* and *Pichia pastoris*. Surprisingly, a stacked structure is not necessary for secretion in budding yeasts. The Golgi cisternae of *S. cerevisiae* rarely form stacks and are dispersed throughout the cytosol, while the cisternae of *P. pastoris* do form discrete stacks of 3-5 cisternae. A comparative analysis of golgins in these two systems provides a unique opportunity to identify specific proteins and domains important for Golgi stacking. The goal of this project is to investigate the role of two golgins, Rud3 and Coy1, in the stacking of Golgi cisternae in *P. pastoris*. Initial experiments will involve a basic characterization of the functions and localizations of these proteins by microscopy. Subsequent studies will explore how the specific properties of Rud3 and Coy1 may contribute to the distinct types of Golgi organization in the two yeasts.

**Golgins in the Golgi of *Trypanosoma brucei***

I. Barinaga-Rementeria Ramirez,[1] A. Price,[2] H. Ho,[1] C. He,[1] J. Yelinek,[1] G. Warren[1]; [1]Cell Biology, Yale University School of Medicine, New Haven, CT, [2]VaxInnate, New Haven, CT

The protozoan parasite, *T. Brucei*, is proving to be a useful organism to study the biogenesis of the Golgi apparatus. There is only a single Golgi stack which duplicates by a process of de novo biogenesis, with components being supplied to the new Golgi by both the old Golgi and the new ER exit site. Golgins are coiled-coil proteins that have been implicated in the structure and function of the Golgi apparatus. To study their role during biogenesis there is the need to identify *T. Brucei* homologs. This process has been confounded by the difficulty of distinguishing golgins from other coiled-coil proteins in the *T. Brucei* database. To overcome this hurdle we have been exploiting the fact that many mammalian golgins are Rab effectors. The *T. Brucei* homolog of Rab1 has been identified and expressed as a GST-construct. An enriched Golgi fraction has been purified from the parasite using a putative GlcNAc transferase as the marker. Incubation of detergent extracts of these Golgi membranes with immobilized Tb-Rab1 has led to the identification of several candidate proteins.

**Role of Basic Amino Acid Residues in the Cytosolic Region of Type II Membrane Proteins on Golgi Localization in Plant Cells**

K. Matsuoka, S. Takata, K. Toyooka, Y. Goto; RIKEN Plant Science Center, Yokohama, Japan

Using membrane anchored prolyl hydroxylase (PH) as a model protein, we have been analyzing the transport of type II membrane proteins from the endoplasmic reticulum (ER) to the Golgi apparatus in plant cells. We reasoned the role of basic amino acid residues in the cytosolic region of PH using a transient expression system and GFP fusion technique. We found that two basic amino acids joined together or separated with one or two amino acids was sufficient for the efficient Golgi localization. Using this information, and proteome information of Arabidopsis we predicted possible type II membrane proteins that localize to the Golgi apparatus and subsequent organelles. We found that many type II homologs for glycosyl transferases and several classes of plant specific proteins contain this localization signal before their type II sinal anchor. Currently we are analyzing the localization of some of these proteins. Results of these analyses and related analyses on the role of COPII proteins for the ER export will be discussed.

1373

**The COG Complex-mediated Recycling of Golgi Enzymes is Essential for Normal Protein Glycosylation**

A. Shestakova, S. Zolov, V. Lupashin; Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR

The Conserved Oligomeric Golgi (COG) complex is the cis-Golgi localized oligomer responsible for intra-Golgi transport and glycoprotein modification. The COG complex consists of eight subunits, Cog 1-4 (Lobe A) and Cog5-8 (Lobe B) and is proposed to be involved in the tethering of recycling intra-Golgi vesicles to appropriate Golgi cisternae. In this work we used prolonged siRNA-induced knockdown of Cog3p (COG3 KD) in Hela cells to uncover the molecular link between function of the COG complex and defects in protein glycosylation. Immunoanalysis of prolonged COG3 KD cells showed enhanced degradation of Golgi enzymes, resulting in a defective glycosylation of plasma membrane (CD44) and lysosomal (Lamp2) glycoproteins. Although immunoblotting after acute COG3 KD did not detect any change in SDS-PAGE mobility of glycoproteins, pulse chase technique revealed heterogeneity in CD44 and Lamp2 glycosylation, arguing that defective glycosylation arises soon after the COG complex dysfunction and is being exaggerated with duration of COG3 KD. Localization of underglycosylated CD44 and Lamp2 was similar in control and COG3 KD cells, indicating that the COG complex was not directly required for anterograde traffick and protein sorting in mammalian cells. For the first time we demonstrated that in COG3 KD cells components of Golgi glycosylation machinery were redistributed to COG complex dependent (CCD) vesicles. These vesicles were analyzed by glycerol velocity gradient and *in vitro* system, which reconstitutes vesicle docking/fusion. COG7 KD caused similar defects in respect to both Golgi trafficking and protein glycosylation. We conclude that the COG complex functions to tether constantly recycling transport vesicles carrying Golgi enzymes, thus providing appropriate localization of Golgi glycosylation machinery.

1374

**Biogenesis of the Golgi Apparatus in *Trypanosoma Brucei*: Digital Reconstructions from Serial Thin Section Electron Micrographs**

J. T. Yelinek, C. Y. He, H. H. Ho, G. B. Warren; Department of Cell Biology, Yale University, New Haven, CT

The biogenesis of the Golgi apparatus is comprised of two phases: duplication and partitioning. A variety of protozoa have been used to study the duplication phase of the Golgi biogenetic pathway due to their simple morphology and the presence of a single Golgi stack.. One such organism is *T. brucei*, the causative agent of African sleeping sickness in man and Nagana in ruminants. *T. brucei* is also well suited for morphological studies due to its small size, simple anatomy, and ordered duplication and division of organelles. These traits allow complete cells to be imaged both at the level of light and electron microscopy, and placed in the context of the cell cycle based on morphological markers of development. Photobleaching experiments using *T. brucei* have shown that the old Golgi contributes material to the growing new Golgi. Fluorescence microscopy also shows that a new ER export site appears concomitantly with the new Golgi. The ultrastructural morphology of Golgi intermediates, as well as the earliest stages of Golgi growth, cannot be identified at the level of light microscopy. This requires electron microscopy coupled with peroxidase cytochemistry of HRP-tagged Golgi proteins. By combining this with serial sectioning and 3D rendering, we hope to provide a complete picture of the Golgi during the cell cycle of this protozoan parasite.

1375

**MEK1 and the Importance of Golgi Unlinking for Mitotic Entry**

T. N. Feinstein, M. A. Puthenveedu, A. D. Linstedt; Department of Biological Sciences, Carnegie Mellon University, Pittsburgh, PA

The role of the protein kinase MEK1 at the G2/M cell cycle transition remains controversial. Inhibition of MEK1 by RNA interference or by using the MEK1/2-specific inhibitor U0126 caused a significant delay in the passage of synchronized HeLa cells into M-phase. Consistent with the hypothesis that the delay was caused by a block in a MEK1 pathway acting to disperse the Golgi apparatus, the MEK1 dependency at G2/M was abrogated if Golgi proteins were dispersed prior to M-phase by treatment of cells with brefeldin A. MEK1 may act on the Golgi to unlink the

membranes or to cause their repositioning. As a test we depleted GRASP65 which we found unlinks Golgi stacks without altering their positioning. Strikingly, cells with unlinked Golgi stacks due to GRASP65 knockdown were MEK1-independent at G2/M suggesting that the MEK1 pathway is required to unlink the Golgi for normal mitotic entry. To test for a direct role, we expressed a nonphosphorylatable form of the GRASP family member GRASP55, which we had previously shown undergoes MEK1-dependent mitotic phosphorylation. Expression of the GRASP55-S222,225A, but not wildtype, blocked progression into mitosis. These findings support a model in which unlinking of the Golgi ribbon by MEK1-dependent GRASP phosphorylation is a prerequisite for normal mitotic entry, possibly by releasing and/or activating pro-mitotic signaling factors.

1376

**Correlated Light and Electron Microscopy of Golgi During Cell Division**

G. M. Gaietta,[1] B. N. G. Giepmans,[1,2] T. J. Deerinck,[1] J. Llopis,[3] L. Ngan,[1] S. R. Adams,[2] R. Y. Tsien,[2,4] M. H. Ellisman[1]; [1]Neurosciences / NCMIR, UC San Diego, La Jolla, CA, [2]Pharmacology, UC San Diego, La Jolla, CA, [3]Facultad de Medicina y C.R.I.B., Universidad de Castilla - La Mancha, Albacete, Spain, [4]Howard Hughes Medical Institute, UC San Diego, La Jolla, CA

The fate of the Golgi apparatus during mitosis is controversial, with evidence for (Lippincott-Schwartz & Zaal, 2000) and against (Warren, 1993; Yaffe, 1996; Nunnari & Walter, 1996, Pecot & Malhotra 2004) coalescence with the endoplasmic reticulum. We recently developed methods that facilitate correlated light microscopic studies of living cells followed by electron microscopic examination using the same molecular labeling system (Gaietta et al., 2002). We have now generated and imaged a fusion consisting of the first 117 residues of the mouse isoform of alpha-mannosidase II (containing the cytoplasmic, transmembrane and part of the luminal domains), GFP, a linker ESSGS, and finally the newly optimized tetracysteine motif FLNCCPGCCMEPGGR (Martin et al, 2005). When expressed in HeLa cells, this chimeric protein specifically localizes in the trans-Golgi network (TGN). The mannosidase component guarantees docking into the Golgi membrane, with the fluorescent protein / tetracysteine tag within the lumen. The GFP is visible at light microscopic resolution without further treatment, whereas the tetracysteine tag can be acutely reduced with a membrane-permeant phosphine, labeled with ReAsH, monitored in the light microscope (especially 2-photon excitation), and photoconverted for electron microscopy, allowing correlated 4-dimensional optical recording on live specimens followed by ultrastructural analysis of the same regions by electron tomography. We find in HeLa cells that at cytokinesis the Golgi generally forms four co-linear clusters, two per daughter cell. Within each daughter, the smaller cluster near the midbody gradually migrates to rejoin the major cluster on the far side of the reforming nucleus. The vesicles remain in close association with the microtubular network and generally remain distinct from the endoplasmic reticulum during mitosis. Supported by NIH-RR04050 and NIH-1P20-GM72033.

1377

**PKA Inhibition Triggers Golgi Autophagy**

E. Bejarano, M. Cabrera, L. Vega, J. Hidalgo, A. Velasco; Cell Biology, University of Seville, Seville, Spain

Protein kinase A (PKA) is stably associated to the Golgi complex during interphase. To analyze the role of PKA in Golgi structural maintenance cells were depleted of PKA RIIα regulatory subunits using a specific interfering RNA (siRNA). Under these conditions, PKA Cα catalytic subunits redistributed to the cytosol and the Golgi complex underwent fragmentation. By electron microscopy Golgi fragments were found to correspond to vesicular structures reminiscent of autophagosomes. Indeed, Golgi disruption induced by siRNA incubation was abrogated by treatment with the autophagy inhibitor 3-methyladenine. Furthermore, Golgi fragments colocalized with LC3, a marker of the autophagosome membrane. A similar effect was originated by inducing PKA displacement from the Golgi complex to cytosol indicating that the disassembly process was due to PKA mislocalization. Inhibition of PKA catalytic activity also gave rise to enzyme redistribution and autophagic Golgi disassembly. In contrast, PKA activation protected the Golgi complex from disruption during the autophagic response developed by cells subjected to amino acid starvation. These data suggest a role for Golgi-associated PKA activity in autophagy regulation. They also indicate that part of the autophagy process involves dismantling and degradation of the Golgi complex

1378

**ER-Derived Assembly of a Functional Golgi Apparatus in HeLa Cells Reflects the Recycling Kinetics of Golgi Membrane Proteins**

S. Jiang, B. Storrie; Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR

In yeast, Golgi apparatus assembly is from ER-exit sites in a manner consistent with the predictions of cisternal maturation, i.e., cis-first assembly. We have tested whether this outcome is true for ER-derived Golgi apparatus assembly in HeLa cells. We find that brefeldin A (BFA) + H89 treatment substantially disperses all Golgi proteins into an ER-like distribution. Golgi glycosyltransferases, e.g., co-distribute with ER membranes by co-staining with the ER markers, PDI or Sec61p. Golgi matrix protein distribution is slightly granular and co-localizes with residual ER-exit site staining. Upon drug washout, all four Golgi matrix proteins accumulated with the same kinetics into post-ER, nascent Golgi structures. The matrix binding transmembrane protein, giantin, exhibited the same rapid accumulation. Significantly, other Golgi transmembrane proteins such as Golgi glycosyltransferases, glycosidases, TGN46 and GPP130 accumulated in newly formed Golgi structures more slowly and importantly in the same time order as their recycling kinetics as revealed by an ER-exit block or overexpression of Rab6a. Kinetics was trans-first. Restricting nascent Golgi structures to close proximity to ER-exit sites by microtubule depolymerization accelerated Golgi assembly. With a 2 h 15°C-block in the presence or absence of nocodazole, however, Golgi glycosyltranferase accumulation remained in the ER. Golgi functionality in cargo transport was a late event and required full Golgi assembly. The comparative kinetics of ER-derived Golgi assembly was the same with BFA treatment alone. We propose a model of ER-derived Golgi assembly in mammalian cells in which assembly is nucleated by matrix proteins, follows a trans-first order, and is related to the ER-cycling kinetics of Golgi proteins. Supported by a grant from the National Science Foundation.

**Golgi Fragmentation During Apoptosis : Does the Cytoskeleton Play a Role?**

S. Mukherjee, R. Chiu, L. Novikov, D. Shields; Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY

The Golgi apparatus exists as a series of membrane stacks arranged in a perinuclear lace-like reticulum whose structure is maintained, in part, by the actin and tubulin cytoskeleton. In mammalian cells the Golgi apparatus undergoes extensive fragmentation during apoptosis. Several laboratories including our own have shown that a number of coiled-coil proteins (golgins) involved in maintaining Golgi structure and function,

including p115 (~962 residues) are cleaved during apoptosis. p115 is cleaved by caspases-3 and -8 to generate a C-terminal fragment (CTF) of ~205 residues, which when expressed in otherwise healthy cells potently induces apoptosis**.** By using deletion analysis, we have identified a 25 amino acid motif, whose expression is sufficient to cause apoptosis in a variety of cell types. To further investigate the mechanism of Golgi fragmentation during apoptosis, we have now analyzed the role of the cytoskeleton. When apoptosis was induced by treating cells with Fas antibody to activate the Fas receptor or with staurosporine, a general kinase inhibitor, Golgi fragmentation and cleavage of some golgin polypeptides preceded changes in microtubule organization. Additionally, no significant changes in microtubule morphology were evident early during the apoptotic response, although the Golgi apparatus was fragmented completely. In contrast, the organization of the actin cytoskeleton was differentially sensitive to apoptosis inducing agents. During staurosporine treatment, dramatic changes in actin morphology preceded Golgi breakdown, whereas in Fas treated cells, actin fibers were relatively unaffected. Furthermore, while the Golgi apparatus was fragmented completely during apoptopsis, little change was observed in ER organization. Our results suggest that during the induction of apoptosis, disruption of the actin or tubulin cytoskeleton is not a necessary prerequisite for Golgi fragmentation. Thus Golgi breakdown during apoptosis is a consequence of caspase mediated cleavage of several Golgi matrix proteins.

1380

**Centrosome and Golgi Complex Reorganization during Myogenesis Can Proceed without a Coherent, Dynamic Microtubule Network**

K. J. M. Zaal,[1] E. Reid,[1] G. G. Gundersen,[2] T. Zhang,[1] E. Ralston[1]; [1]NIAMS, NIH, Bethesda, MD, [2]Anatomy/ Cell Biology, Columbia University, New York, NY

During differentiation of skeletal muscle cells, microtubule-organizing sites (MTOC) are redistributed to the nuclear membrane and to cytoplasmic sites. The Golgi complex (GC) is fragmented and its elements, associated with ER exit sites (ERES), redistribute to the nuclear membrane as well. It is assumed that microtubule reorganization causes GC reorganization. To test this, we have assessed the reorganization of GC, MTOC, and ERES in C2 muscle cells with disrupted or massively stabilized microtubule networks. Myoblasts cultured with 200 ng/ml nocodazole in both growth and differentiation media rounded up, failed to fuse, and retained only small fragments of microtubules. Nevertheless, differentiated (myogenin-positive) cells showed a normal MTOC redistribution. GC achieved a circumnuclear redistribution in 70% of the cells, but a “perfect” redistribution in only 10%. Myoblasts overexpressing a C-terminal fragment of EB1 lost directed motility and formed abnormally wide, short myotubes with a disrupted microtubule network, but showed normal MTOC and GC redistribution. Treatment with 10 to 250 nM taxol stopped cell motility and affected cytokinesis but not MTOC reorganization. GC reorganization took place but was often incomplete. ERES often failed to redistribute, even in cells in which the GC did. Finally, treatment with the ruthenium complex 1-OH, a specific GSK3-beta inhibitor (Williams et al, 2005, Angew. Chemie, 44, 1984) reduced microtubule dynamics without preventing MTOC reorganization. However, GC was bipolar rather than circumnuclear in 70% of these cells. Thus, microtubule manipulation allowed us to uncouple MTOC, GC, and ERES reorganizations and to show that 1) MTOC reorganization is resistant to alterations of the microtubule network; 2) it is a prerequisite of GC reorganization, while ERES reorganization is not; 3) GC reorganization is initiated but only rarely completed in the absence of normal microtubules.

**Reassembly of an Intact Golgi Complex Requires Both Phospholipase $A_2$ ($PLA_2$) Activity and Microtubules**

B. L. Judson, W. J. Brown; Molecular Biology and Genetics, Cornell University, Ithaca, NY

We have previously found that $PLA_2$ antagonists cause the normally interconnected Golgi ribbon to break up into large fragments of stacked Golgi cisternae that remain located in the juxtanuclear region. Using the reversible $PLA_2$ antagonist, ONO-RS-082, it appeared from static immunofluorescence images that following washout of the drug, disconnected stacks rapidly and dramatically sprouted membrane tubules that served to reassemble an intact Golgi ribbon. Considering these results together, we concluded that the maintenance and assembly of normal Golgi architecture is dependent on the $PLA_2$-mediated, dynamic formation of inter-Golgi membrane tubules. Here we have used live-cell, time-lapse microscopy to image the reformation of Golgi complex during the reassembly process. Using HeLa cells stably expressing GFP-galactosyltransferase, we found that fragmented Golgi ribbons undergo a burst of tubule formation following washout of ONO-RS-082. Quantifying these results shows an obvious difference: $4.3 \pm 3.8$ tubules/cell/10 min before washout; $29.9 \pm 11.9$ tubules/cell/10 min after washout. These tubules often formed bridges between separate stacks, although tubules also extended out into the cytoplasm. Whether or not there was directed movement of tubules from one stack to another could not be determined. However, we have found that formation of these inter-stack tubules was facilitated by microtubules because treatment with nocodazole greatly inhibited their formation and reassembly into an intact Golgi ribbon. These studies show that a late stage of Golgi reassembly occurs via membrane tubules, whose formation is dependent on $PLA_2$ activity and microtubules. (Supported by NIH grant DK51596)

**Identification of a Lysophospholipid Acyltransferase with a Novel Role in Golgi Membrane Dynamics**

J. A. Schmidt, W. J. Brown; Molec. Biol. and Genetics, Cornell University, Ithaca, NY

Phospholipase ($PLA_2$) and lysophospholipid acyltransferase (LPAT) activities appear to have antagonistic roles in the formation of Golgi membrane tubules and retrograde trafficking to the ER: Golgi tubule formation is promoted by $PLA_2$ activity and inhibited by LPAT activity. These enzymes may alter the shape of membrane bilayers to regulate the formation of trafficking intermediates. The overall goal is to identify specific LPATs that regulate Golgi membrane dynamics. The DNA sequences for six putative human transmembrane (TM) LPATs have recently been discovered; however, the functions of most are unknown. Here we report the identification of a specific TM LPAT (LPATγ) that regulates Golgi membrane tubule formation. When transfected into HeLa cells, LPATγ-GFP was primarily localized to the Golgi complex and also to ER membranes. Interestingly, over-expression of LPATγ significantly inhibited the rapid formation of Golgi membrane tubules that are induced by brefeldin A (BFA). Additionally, retrograde trafficking of Golgi membranes to the ER in BFA-treated cells was significantly slower. LPATγ may control Golgi membrane dynamics either by aiding in the fission of Golgi-derived vesicles that consume membrane tubules, or by re-acylating tubule-forming lysophospholipids that were generated by $PLA_2$s. These data are the first to show a direct role for a TM LPAT in regulating Golgi membrane trafficking. (Supported by NIH grant DK51596)

### Three Color Image Collection for Segmentation and Analysis of Protein Subcellular Location Patterns in Polarized Monolayers of CaCo2 Cells

E. M. Goellner,[1] E. Garcia Osuna,[2] R. F. Murphy[3]; [1]Chemical Engineering and Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA, [2]Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA, [3]Biological Sciences and Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA

Automated analysis of the location of proteins is useful in determining statistical differences in protein patterns that may be undetectable to the human eye. The goal of this project is to collect three-dimensional, three-channel fluorescence microscope images of the CaCo2 cell line. CaCo2 are human colon cancer epithelial cells, which will be used as a model system for extending current automated subcellular location pattern analysis methods to polarized epithelia and tissues. Unlike in prior experiments on single cultured cells, the polarized monolayers require a method for determining the boundaries of each cell before pattern analysis can be accomplished. Achieving an acceptable method of data collection to facilitate segmentation has been a main goal of this project. The protocol we have developed involves tagging a protein of interest such as a Golgi or mitochondrial protein using primary antibodies and Alexa-488 conjugated secondary antibodies. In order to perform automated segmentation, it is necessary to also have a nuclear image and a continuous plasma membrane image. DRAQ5 was used to stain the nuclei. A primary antibody against the cadherin family of proteins and a secondary antibody conjugated to Alexa-564 dye provided the continuous plasma membrane staining desired. This staining was homogeneous and easily recognized by automated segmentation algorithms. The resulting three-color images are appropriate for automated segmentation as well as subcellular location pattern analysis of the proteins of interest. Future work will include results for automated classification of proteins imaged using this protocol.

### Immunohistochemical Study on the Distribution of Sodium Dependent Vitamic C Transporters in the Adult Rat Brain

D. H. Shin, G. H. Mun, M. J. Kim, J. H. Lee, J. Y. Park, J. S. Kang, J. H. Kim, Y. I. Hwang, H. J. Kim, Y. B. Chung, S. H. Oh, W. J. Lee; Department of Anatomy, Seoul National University College of Medicine, Seoul, Republic of Korea

Sodium-dependent Vitamin C co-transporters (SVCTs) was known to transport the reduced form of ascorbic acid into the cell. And they were reported to be expressed in different types of the cells within the various organs. Especially in central nervous system, only *SVCT2* mRNA was known to be expressed mainly in neurons and some types of neuroglial cells. However, since there were very few data on the expression of SVCT proteins in the brain, we tried to report the comprehensive data on the distribution of SVCT proteins in the rat brain using immunohistochemical technique for the first time. In our study on the adult rat brain, SVCT2 IRs were intensely localized in the neurons of cerebral cortex, hippocampus, and Purkinje cells of cerebellum while much weaker SVCT2 IRs were also found in the other brain regions as well. Judging from double immunohistochemical data, most of the cells expressing SVCT2 IRs were likely to be neurons or microglia even though the cells in choroids plexus or ependymal cells around the ventricles also exhibited SVCT2 IRs. As the subcellular localization of SVCT proteins is necessary for understanding the exact role of the protein, the current overall mapping of SVCT IRs in the rat brain could be the basis for the further studies on the relating subject. *Shin DH and Mun GH contributed equally to this study. **For correspondence, please send E-mail to kinglee@snu.ac.kr

### Differential Expression of Zinc Transporters between Fetal (FHs) and Adult (Caco-2) Human Intestinal Cells Results in Divergent Effects of Zinc Exposure

M. Jou,[1] S. L. Kelleher,[1] A. Philipps,[2] B. Lonnerdal[1]; [1]Nutrition, University of California Davis, Davis, CA, [2]Pediatrics, University of California Davis Medical School, Davis, CA

Zinc (Zn) homeostasis in adults is primarily regulated by changes in intestine expression and localization of Zn-specific transporters such as Zip4 (primary Zn importer), ZnT-1 (Zn efflux), ZnT-2 (vesicular Zn sequestration) and MT-1 (intracellular metal-chelator). However, Zn absorption and excretion is higher and less regulated, respectively, in premature infants, suggesting that mechanisms regulating intestinal Zn homeostasis may be immature. We used cultured fetal (FHs) and adult (Caco-2) intestine cell lines to determine differences in Zn uptake, Zn transporter expression (MT-1, ZnT-1, ZnT-2 and Zip4) and effects of acute (1h) Zn exposure (50µM). While basal Zn uptake rates were similar between cell lines, Zn uptake was higher (3-fold) in fetal cells which were also more sensitive to Zn exposure than adult cells (FHs, LD50 = 75µM; Caco-2, LD50 =135µM). Our data suggest that these differences may be a result of differential expression of Zn-specific transporters as fetal cells do not express Zip4, but have higher Zip1 (2-fold) and Zip3 (3-fold) and lower ZnT-1 (~50%) and ZnT-2 (~20%) expression compared to adult cells. While acute Zn exposure post-transcriptionally increased Zip4 and ZnT-1 protein levels resulting in no effect on MT-1 (an indicator of cellular stress or Zn levels) in adult cells, Zn exposure increased MT-1, ZnT-1 and ZnT-2 mRNA and ZnT-1 protein levels in fetal cells. We speculate this difference is due to the inability of fetal cells to tightly regulate Zn uptake as a result of the absence of Zip4 expression. In conclusion, our data suggests that the lack of Zip4 expression in fetal intestine cells may be responsible for differences in Zn absorption observed between preterm infants and adults, resulting in the lack of sensitive regulation at this age.

### Mammary Gland Zinc Transport is Regulated by Prolactin through Changes in Zip3 and ZnT2

S. L. Kelleher, W. Chowanadisai, B. Lonnerdal; Nutrition, University of California Davis, Davis, CA

The mammary gland transports an extraordinary amount of zinc (Zn) to meet neonatal requirements. Human milk normally contains adequate Zn to meet these requirements; however, numerous reports have documented transient neonatal Zn deficiency in breast-fed infants as a consequence of low milk Zn concentration which cannot be corrected by maternal Zn supplementation. We have previously identified several Zn transporters in the mammary gland; however, mechanisms which regulate Zn transport into milk are not well understood. To examine this regulation we used gene silencing to knockdown Zip3 and ZnT2 in mouse mammary epithelial cells (MECs) which resulted in reduced Zn uptake (25% of normal) and Zn efflux (50% of normal), respectively, indicating that Zip3 and ZnT2 play major roles in mediating Zn uptake and secretion into milk. To verify the

dependence of human MEC Zn secretion on ZnT2, we identified a woman with low milk Zn concentration (0.3 mg Zn/L) and documented a point mutation in exon 2 of SLC30A2 (ZnT2) that results in a substitution of arg for his at amino acid 54. Using site-directed mutagenesis we determined that this mutation results in mis-localization of ZnT2 from the Golgi to a peri-nuclear compartment in MECs, likely preventing Zn efflux through the secretory pathway. Prolactin treatment (1μM) of normal mouse MECs resulted in Zip3 accumulation at the plasma membrane concurrent with increased Zn uptake as well as increased Zn secretion across the luminal membrane concurrent with increased ZnT2 protein abundance and ZnT2 movement to a vesicular compartment. Taken together, our results indicate that Zip3 and ZnT2 play major roles in mammary epithelial cell Zn uptake and efflux, respectively and suggest that prolactin plays a regulatory role in mediating Zn transport into milk.

## GPR4, a Proton-Sensing Receptor in the Kidney

X. Sun, S. Petrovic; Medicine, University of Cincinnati, Cincinnati, OH

A G-protein-coupled receptor, GPR4, functions as a proton-sensing receptor stimulating cAMP production. pH-dependent stimulation of cAMP production occurs within the physiological pH range. Interestingly, GPR4 is highly expressed in the lungs and kidney, the two organs essential for blood pH regulation. However, the cellular distribution of GPR4 in these tissues is currently unknown. This study was designed to determine the localization of GPR4 in the mouse and rat kidney. By using real-time PCR, we find that GPR4 mRNA is expressed in the kidney cortex and medulla at the similar level. Immunofluorescent labeling of the kidney tissue sections with GPR4 antibody reveals GPR4 expression in the nephron segments resembling kidney collecting ducts. We used aquaporin 2 (AQP2) antibody as a marker of the kidney collecting duct. The doublelabeling with GPR4 and AQP2 antibodies demonstrates the co-localization of GPR4 and AQP2 in the kidney collecting duct. The collecting duct is comprised of two types of polarized epithelial cells: intercalated cells (ICs), critical for the acid-base regulation, and principal cells, which handle salt and water homeostasis and selectively label with AQP2 antibodies. The doublelabeling studies indicate that GPR4 is expressed in both cell types either uniformly distributed throughout the cytoplasm, or confined to the apical membrane and subapical vesicles. In some cells, labeling is present in the basolateral membrane. We also examined rats subjected to the increased acid or alkaline load. GPR4 immunostaining is much more pronounced in the kidneys of acid-loaded then alkali-loaded animals. In conclusion, the proton-sensing receptor GPR4 is selectively expressed in the kidney collecting duct, the nephron segment critical for the final adjustment of acid-base status. A change in acid-base status affects GPR4 expression. This data indicate that GPR4 may act as an acid-sensor in the kidney.

## Intracellular $Ca^{2+}$ Changes of Vomeronasal Organ; Imaging Analysis of Response to Pheromones

H. Akutsu, Y. Satoh; School of Medicine, Iwate Medical University, Morioka, Iwate, Japan

[Objective] Sensory neuron of vomeronasal organ (VNO) may detect pheromones in various materials including urine. In present study, we investigated whether VNO of male rats respond to female urine. To this end we observed changes of intracellular $Ca^{2+}$ concentration ($[Ca^{2+}]_i$), which play a key role in cell functions. Imaging for $[Ca^{2+}]_i$ changes in intact tissues can provide a overview of physiological responses, therefore we prepared VNO specimens keeping intrinsic structural integrity. [Materials & Methods] VNO was dissected from adult male Wistar rat (10-14 weeks, body weight: 230-300g) and slice specimens (150 μm in thick) were cut by a vibratome. After the $Ca^{2+}$-sensitive dye loading, the slice specimens were set on cover-glass of perfusion chamber. The changes of $[Ca^{2+}]_i$ of VMO were imaged and analyzed by a real-time confocal laser scanning microscope (Nicon RCM/Ab). To avoid photodamage, images were acquired at 1 sec interval. Urine was collected from female Wistar rat (8-14 weeks, diestrous and proestrous), and diluted 1:1000 with HEPES-buffered Ringer solution (HR). [Results] Few spontaneous oscillatory fluctuations of $[Ca^{2+}]_i$ were observed. During perfusion of diluted urine from proestrous females, some epithelial neurons showed transient increase of $[Ca^{2+}]_i$. Oscillatory fluctuations were also observed. After the urine perfusion, the oscillatory response occurred in other neurons, although the urine was washout by normal HR. The response diminished when extracellular $Ca^{2+}$ was removed. Response to male or diestrous female urines were less. [Conclusion] Imaging of $[Ca^{2+}]_i$ changes on tissue specimens indicated that the heterogeneous responses of neurons of VNO. Various substances in estrous female urine induced responses in different manner, for example; in some cases, remove of urine substances induces cell response. The imaging method is useful to evaluate pheromone mechanism.

## Model Wounds to Study the Collective Motility of Epithelial Cells

M. Poujade,[1] E. Grasland-Mongrain,[1] B. Ladoux,[2] A. Buguin,[1] P. Silberzan[1]; [1]Section de Recherche, Institut Curie, Paris, France, [2]MSC, Université Paris VII, Paris, France

The mechanical wounding of an epithelial monolayer triggers the motility of the border cells who then migrate to heal the monolayer while keeping intact the cell-to-cell contacts. However, the exact mechanism for the acquisition of this collective motility remains unclear. Some models involve the death of the cells that are removed from the wound. Some others are based on a permeabilization of the border cells. The signaling between cells through autocrine growth factor production is also often cited. In the experiments presented here, the wound does not damage the cells. We perform this task by using microfabricated structures to mask part of the surface to the cells during the growth of the film. To this end, we make thin masks out of a silicone elastomer by micro-molding. When the cell monolayer reaches confluence, the mask is removed without damaging the cells and we monitor the healing of this model wound by time lapse video microscopy. By using microfabrication, we can test many wounds whose widths vary from 20 μm to 500 μm or more, in a parallel way. We find that the presentation of free surface to a monolayer of MDCK cells in sufficient to trigger the motile phenotype. The cells invade this surface at a rate comparable to previous studies using damaging wounds. We have precisely measured this velocity of healing and find that the position of the border is a parabolic function of time ($X \alpha t^2$). This behavior is markedly different from the spontaneous filling of naturally occurring holes within a monolayer when it approaches confluence. In this last case, the motility is driven by the cell proliferation whereas it is only of secondary influence in the wound healing situation.

## ERK1/2-dependent Phosphorylation and Relocalization of HSP27 in Keratinocytes Undergoing DLK-induced Differentiation

H. Robitaille,[1] R. Blouin,[2] K. Robitaille,[2] L. Germain[1]; [1]Laboratoire de Recherche des Grand Brûlés/LOEX and Département de Chirurgie,

Université Laval, Québec, PQ, Canada, [2]Département de Biologie, Université de Sherbrooke, Sherbrooke, PQ, Canada
Hsp27 is part of the small heat shock proteins (sHsp) family. It is involved in many cellular processes including cell death and differentiation. Indeed, Hsp27 is an important anti-apoptotic protein but also a molecular chaperone protecting the cell from protein agregation of misfolded proteins. In t27 is associated with keratin filaments in the very late phase of keratinocyte differentiation. We previously showed that overexpression of DLK, a MAPKKKinase preferrentially expressed in the granular layer of the epidermis, induces the terminal differentiation of keratinocytes and activate the ERK1/2 and JNK MAPK pathways. In this study, we studied the expression and subcellular distribution of Hsp27 during epidermal cell differentiation using both an in vitro model of reconstructed skin and cultures of normal keratinocytes infected with an adenoviral vector for DLK. The MEK inhibitor PD98059 and the JNK inhibitor SP600125 were also used to determine the role of these pathways in the distribution and the phosphorylation of Hsp27 during keratinocyte differentiation. We first showed that Hsp27 is upregulated during keratinocyte differentiation (in vivo and in vitro) and is also phosphorylated on serine 82 in the very late phases of keratinocyte differentiation. Moreover, our results indicate that Hsp27 became insoluble and phosphorylated in normal human keratinocytes 48 hours after expression of DLK. The insolubility and the phosphorylation of Hsp27 in DLK-expressing keratinocytes were partially inhibited by the MEK inhibitor PD98059. Taken together, these results suggest that DLK may regulate the subcellular distribution and phosphorylation of Hsp27 through a mechanism involving ERK1/2 activation during human keratinocyte differentiation.

1391

**Rapid Inhibition of STAT1 Signalling in Epithelia by TGFβ**

C. Reardon, D. M. McKay; Intestinal Disease Research Program, McMaster University, Hamilton, ON, Canada
Background: Interferon-γ (IFNγ) and transforming growth factor-β (TGFβ) are multi-functional cytokines that are key regulators of mucosal immunity, typically functioning in a reciprocal cross-inhibitory manner. Objective: To determine the ability of TGFβ to modulate IFNγ-induced signal transducer and activation of transcription-1 (STAT1) signalling in enteric epithelial and immune cells. Methods: Epithelia (Hep-2, HT-29) or mononuclear cells (THP-1) were pre-treated with TGFβ (1ng/mL; 0-60min), exposed to IFNγ (20ng/mL; 30min) and STAT1 DNA-binding activity, phosphorylation, and methylation was assessed by electrophoretic mobility shift assays (EMSA), immunoblotting, and autoradiography. Some epithelia were transfected with an expression plasmid encoding, SMAD7 which blocks TGFβ-SMAD signalling. Results: Epithelia, but not mononuclear cells, pre-treated with TGFβ for 15-60 min were hypo-responsive to IFNγ stimulation as indicated by reduced STAT1 DNA binding on EMSA (n=3-4). Despite this, immunoblotting for tyrosine$^{701}$ or serine$^{727}$-STAT1 revealed no difference in IFNγ ± TGFβ treated cells (n=3), indicating that the effects of TGFβ are downstream of IFNγ receptor-Janus kinase-STAT1 phosphorylation events. Additionally, STAT1 methylation was unaltered in IFNγ ± TGFβ treated cells (n=4). Functionally, IFNγ-induced upregulation of interferon response factor 1 (IRF-1; a STAT1 dependant gene) in epithelia was blocked by TGFβ pre-treatment. The ability of TGFβ to interfere with IFNγ-STAT1 signalling was not observed in epithelia over-expressing SMAD7. Conclusions: These results indicate that TGFβ activated SMAD signalling rapidly suppresses IFNγ-driven STAT1 signalling by reducing DNA-binding without effecting STAT activation; an event seemingly specific to epithelia. We speculate that this is a novel mode of action of TGFβ, and that full delineation of this mechanism may be a novel way to block the effects of pro-inflammatory cytokines and enhance the effect of TGFβ's reparatory properties.

1392

**Skin Barrier Acidity Measurement of Young and Aged Mice Using Two-photon FLIM**

P. Xu, E. Choi, M. Dermerjian, D. Crumrine, S. Chang, T. Mauro; Dermatology, UC San Francisco, San Francisco, CA
OBJECTIVE: It has been understood that one important factor related to the upper epidermis (stratum corneum) barrier function, is the epidermal acidity and pH gradient. We investigated in this paper the difference in acidity between young and aged mice, and for each case, its acidity in intracellular and extracellular domains. METHODS: Two-photon fluorescence lifetime imaging (FLIM) is used to identify pH values within the stratum corneum. The fluorophore, 2',7'-bis-(2-carboxyethyl)-5/6-carboxyfluorescein (BCECF), has a lifetime dependent on the ambient pH. Hairless mice, aged 12weeks and 12months, are used as models for young and aged skin. RESULTS: All measurements revealed acidic to neutral trend among the intra- and extra- cellular pH in both young and aged, with exception that the aged mice has a nearly flat intracellular acidity. It is also consistent that in both cases, extracellular domain is more acidic than intracellular by less than one unit of pH, while they converge towards the end of the SC at around 10 um deep. Young mice exhibit a more acidic SC barrier than the aged counterpart by 1-2 units of pH. The relative value between the intra- and extra- cellular pH is more random in the aged mice than the young ones. CONCLUSIONS: The hypothesis that young skin has a more acidic barrier than aged was proved experimentally and quantitatively. The overall trend from acidic to neutral along the depth of the SC is identical from the young and the aged, but the detailed gradient is different. Physiological mechanisms causing the difference, and pathological difference manifested by the difference, are topics to be studied further.

**Keratin Filament Organization Defines Distinct Populations of Epithelial Stem Cells Within the Bulge of Vibrissae Hair Follicles**

D. Larouche,[1] X. Tong,[2] C. J. Roberge,[1] P. A. Coulombe,[2] L. Germain[1]; [1]Department of Surgery, Laboratoire d'Organogenèse Expérimentale (LOEX), Hôpital du Saint-Sacrement, Université Laval, Québec, PQ, Canada, [2]Departments of Biological Chemistry and Dermatology, The Johns Hopkins University School of Medecine, Baltimore, MD
Defining the intrinsinc features of post-natal stem cells (SC) is of great interest given their relevance to tissue homeostasis and therapeutic applications. The bulge, a specialized region of the outer root sheath (ORS) in hair follicles, houses a large fraction of stem cells in hair-covered skin. Focusing on rodent vibrissae follicles, which feature a prominent bulge, we used light and electron microscopy along with keratin expression to typify candidate stem cells exhibiting slow-cycling properties. Two types of slow-cycling cells occur in the vibrissae bulge. One group, Bb cells, occurs in the outermost basal layer of the bulge and exhibits a loosely organized keratin network correlating with expression of K5, K15, K17 and K19. The other group, Bs1 cells, occurs in the suprabasal layers proximal to Bb cells and feature a very prominent network of densely bundled keratin filaments correlating with K5/K17 expression. These filament bundles are missing in K17 null mice, giving rise to cell fragility within the Bs1 compartment, which likely accounts for the absence of vibrissae hair shafts in these mice. Bulge epithelial cells located in the more internal suprabasal layers (Bs2 cells) are contiguous with ORS from the lower portion of the follicle. Bs2 cells are not slow-cycling and contain K5, K6,

K14, K15, and K17, which presumably yields a keratin network of intermediate density. These findings significantly extend recent studies pointing to heterogeneity within the hair follicle stem cell niche, identify specific keratins as effectors of this heterogeneity, and point to a special role for K5/K17 filaments in a newly defined subset of candidate stem cells. Supported by the CIHR and the NIH. LG is holder of the Canadian Research Chair (CIHR) on Stem Cells and tissue engineering

**Toll-like Receptors are Expressed in Cholangiocytes and Mediate Epithelial Defense Response to Cryptosporidium parvum Infection via Upregulation of Beta-defensin 2**

S. P. O'Hara, X. Chen, J. B. Nelson, P. L. Splinter, N. F. LaRusso; Center for Basic Research in Digestive Diseases, Mayo Clinic, Rochester, Rochester, MN

Infection of epithelial cells by *Cryptosporidium parvum* triggers a variety of host cell innate and adaptive immune responses including release of cytokines/chemokines and upregulation of anti-microbial peptides. The mechanisms that trigger these host-cell responses are unclear. Thus, we evaluated the role of Toll-like receptors (TLRs) in host-cell responses during *C. parvum* infection of cultured human biliary epithelia (i.e., cholangiocytes). We found that normal human cholangiocytes in situ and in culture express all known TLRs. Moreover, *C. parvum* infection of cultured human cholangiocytes induced the recruitment of TLR2 and 4, but not other TLRs, to the infection sites. Activation of downstream effectors of TLRs including interleukin-1 receptor-associated kinase (IRAK), p-38, and NF-kB, was detected in infected cholangiocytes. Transfection of cholangiocytes with dominant negative (DN) mutants of TLR2 and 4 and myeloid differentiation protein 88 (MyD88), an adaptor protein for TLRs, inhibited the activation of IRAK, p-38 and NF-kB induced by *C. parvum*. Moreover, *C. parvum* upregulated the message and protein of human ß-defensin (HBD) -2, but not HBD-1 and HBD-3, in directly infected cells; also, inhibition of TLR2, 4 and MyD88 with DN mutants were each associated with a reduction of *C. parvum*-induced HBD-2 expression. A significantly higher number of parasites were detected in cells transfected with MyD88-DN than in control cells at 48-96 hours after exposure to parasites, suggesting MyD88-deficient cells were more susceptible to infection likely due to repression of HBD-2 expression. Consistent with this interpretation, we found that addition of recombinant HBD-2 to sporozoite preparations significantly decreased parasite viability. These findings demonstrate that cholangiocytes express a variety of TLRs, and suggest that TLR2 and TLR4 mediate cholangiocyte defense responses to *C. parvum* via upregulation of HBD-2.

1395

**Characterizing a Mutation that Prevents Pharyngeal Morphogenesis in *C elegans***

V. Praitis,[1] M. Miller,[1] A. Schacht,[1] J. Mushi,[1] Z. Yilma,[1] L. Yohannes,[1] S. Kniss[2]; [1]Biology, Grinnell College, Grinnell, IA, [2]Biology, University of Chicago, Chicago, IL

In *C. elegans*, pharyngeal morphogenesis is divided into several discreet steps including the creation of a pharyngeal primordium, reorientation of anterior pharyngeal cells, formation of stable epithelium between the buccal cells, pharynx, and intestine, and changes in cell shape (Portereiko & Mango, 2001). We have identified a weakly semi-dominant temperature-sensitive embryonic lethal mutation that causes defects in pharyngeal morphogenesis, resulting in embryos with the *pun* (*p*harynx *un*attached) phenotype. *ru5* embryos grown at the restrictive temperature undergo normal embryonic development until the bean stage when pharynx and mouth epithelial sheets fail to connect to each other. Temperature shift experiments show the altered gene product is only required during pharyngeal morphogenesis. To further characterize the *ru5* phenotype, we examined the expression pattern of proteins found in the pharynx and head hypodermis during this stage of development. Our results indicate that early developmental events and the establishment of the pharyngeal primordium occur normally in *ru5* embryos grown at the restrictive temperature. Reorientation of the anterior pharynx also appears normal, as the expression patterns of anterior markers such as AJM-1 and SMA-1 in *ru5* embryos are indistinguishable from wild type. However, the localization of these proteins in the arcade cells and in the head hypodermis is abnormal and the invagination associated with the buccal cavity does not occur in *ru5* embryos. These results suggest the failure to form a stable epithelium is due to defects in the organization, movement, or shape of the arcade cells or anterior hypodermis. We are currently working to identify the *ru5* gene product.

1396

**Characterization of the SH3BP4 C-Terminal Death Domain**

E. D. Koppelman, J. B. Kolberg, J. R. Dunlevy; Anatomy & Cell Biology, University of North Dakota, Grand Forks, ND

SH3BP4 has multiple protein-protein interaction domains at the N-terminus that are characteristic of the Eps15-Homology (EH) network family of proteins involved in endocytosis and intracellular sorting. SH3BP4 also contains a C-terminal death domain (DD) characteristic of proteins involved in apoptosis. Currently, this combination of protein-protein binding domains has not been reported in other proteins. The objective of this study is to characterize the subcellular localization and morphological effects of SH3BP4 death domain over-expression. Cultured human retinal pigment epithelial (ARPE-19) cells were transiently transfected with N-terminal Binding Domain (BD), full-length and C-terminal Death Domain (DD) SH3BP4 fusion proteins for 24, 48 and 72 hours. Western blot analysis was used to determine fusion protein levels while microscopy studies were used to characterize subcellular localization and nuclear morphology. Fusion protein levels were found to be elevated at 24 and 48 hours, but decreased substantially by 72 hours for each SH3BP4 construct while subcellular localization studies showed a distinct localization pattern for each SH3BP4 fusion protein. The N-terminal BD protein showed diffuse cytoplasmic and nuclear localization. The full-length fusion protein localized primarily to the plasma membrane and nuclear periphery. The C-terminal DD localized primarily to the plasma membrane and these cells also exhibited a rounded morphology. In nuclear morphology assays, an increase in nuclear condensation was observed for each of the SH3BP4 constructs compared to non-expressing controls. However, cells expressing the C-terminal DD had an increase in the percentage of cells with condensed nuclei compared to the SH3BP4 N-terminal BD and full-length fusion proteins. In conclusion, this study showed that the C-terminus of SH3BP4 may be critical for plasma membrane localization and that over-expression of the C-terminal DD appears to induce nuclear condensation and cell rounding which are morphological characteristics of apoptosis.

### Structure and Functions of the Cytoplasmic Body Formed by Adenovirus E1B 55-kDa Protein

D. Liao, L. Y. Zhao, J. Liu; Anatomy and Cell Biology, University of Florida, Gainesville, FL

The adenovirus E1B 55-kDa protein (E1B) binds to N-terminal domain of p53 (TAD) and suppresses p53 activities. E1B forms a cytoplasmic body that retains p53, and this sequestration correlates with its ability to inhibit p53-mediated apoptosis. Mutagenesis revealed that p53 residues 23-27 are strictly required for p53 to localize to the body. p53 mutants L344A and L348A/L350P failed to localize to the body; thus oligomerization and nuclear export of p53 are important for its localization to the body. Although E1B body forms in the absence of p53, coexpression of p53 and E1B enhanced its formation. Thus p53 may stabilize E1B body. Two point mutants of Ad12 E1B, R225A and H245A, whose equivalent residues of Ad5 E1B are required for binding to p53, exhibited different properties: the former affected neither formation of the body nor the localization of p53 to it. In fact, R225A formed more elongated body. In contrast, E1B H245A failed to form the cytoplasmnic body. Cellular proteins are suggested to assist the localization of p53 to the E1B body, but absence of *MDM2* or *MDM4* neither affected the formation nor the sequestration of p53 in the body, although MDM2 binds to the same p53 peptide. Attachment of p53 aa 11-27 to p73 that does not interact with E1B resulted in sequestration of p73 in the body and this did not affect the transcriptional potential of p73. Interestingly, although such sequestration strongly stabilized p73, it markedly reduced p73-induced apoptosis. Surprisingly, our data revealed that Ad12 E1B inhibited wild-type p73-mediated apoptosis in the absence of physical interaction, probably through inhibiting an event downstream of p73-mediated apoptotic mechanisms. Our data thus implicate a role for p73 in the induction of apoptosis that is independent of transactivation.

### Repression of Human Telomerase Reverse Transcriptase using Artificial Zinc Finger Transcription Factors

J. Choi, J. Sohn, J. Yoon, H. Lee, B. Yeh, H. Kim; Department of Biochemistry and Institute of Basic Medical Sciences, Yonsei University Wonju College of Medicine, Wonju, Republic of Korea

Telomerase activation is a key step in the development of human cancers. Expression of the catalytic subunit, human telomerase reverse transcriptase (hTERT), represents the limiting factor for telomerase activity, and that the regulation of hTERT should mainly occur at the transcriptional level. In this study, we used artificial zinc finger protein (ZFP) transcription factors to repress expression of hTERT in human cancer cell lines. We created potent transcriptional repressors by fusing a designed ZFP targeted to the hTERT core promoter region. KRAB repressor domain fused artificial ZFPs that bind a 12-bp recognition sequence within the promoter of the endogenous hTERT gene gives a >10-fold reduction in luciferase reporter assay. We also observed that transfection of ZFP in telomerase-positive cells promotes the reduction of hTERT mRNA level and decreases telomerase activity. In conclusion, the repression of telomerase expression by artificial ZFPs targeting the promoter region of the hTERT presents a promising strategy for inhibiting the growth of human cancer cells.

### Role of Actin Bundling Protein Fascin in Cancer Metastasis

D. Vignjevic,[1] K. P. Janssen,[2] G. Bousquet,[1] S. Robine,[1] D. Louvard[1]; [1]Institute Curie, Paris, France, [2]Klinische Forschergruppe, Technische Universitaet, Muenchen, Germany

Cancer cells become metastatic by acquiring a motile and invasive phenotype. This step requires remodelling of the actin cytoskeleton and the expression of exploratory, sensory organelles known as filopodia. Previously, it has been tested whether efficient bundling of actin filaments within filopodia, is critical for filopodia formation. Fascin was the only actin bundling protein found to be localized along the whole length of all filopodia. Targeted depletion of fascin by siRNA lead to the substantially reduced number of filopodia. Because of their structure, filopodia can easily infiltrate between cells and by identifying appropriate targets for adhesion, generate traction forces to move the cell body. Fascin may promote metastasis, by participating in the formation of filopodia. Using qRT-PCR and immunohistochemistry, we found that fascin expression was significantly increased in human and mouse intestinal tumors compared with normal epithelium, in tumor stage depended manner. Expression was unchanged in benign lesions and early tumor stages, but significantly upregulated in invasive and metastatic lesions Next, we tested weather fascin can promote invasion and migration of human adenocarcinoma cells HT29: 1) in vitro, in trans-filter assays and 2) in vivo, by tail vein injection of cells into SCID mice. Fascin expressing cells had higher migrational potential in vitro; and in vivo led to more frequent distant metastasis in the lungs. Moreover, mice injected with fascin positive cells developed severe paralysis. Paralysis was caused by development of tumors along the spine, which invaded a back muscle. Those tumors were positive for villin (enterocytes marker) and fascin, which confirmed that they derived from the injected cells. We propose that up-regulation of fascin, by promoting the formation of filopodia, could be a significant component in the acquisition of invasive phenotype in carcinomas.

### Role of Rho-like Proteins of the RhoBTB Family in Oncogenesis

J. Berthold,[1] S. Ramos,[1] M. Kopp,[1] P. Aspenstrom,[2] Y. Xiong,[3] P. Zigrino,[4] C. Mauch,[4] F. Rivero[1]; [1]Center for Biochemistry I, University of Cologne, Cologne, Germany, [2]Ludwig Institute for Cancer Research, Biomedical Center, Uppsala, Sweden, [3]Lineberger Comprehensive Cancer Center, University of North Carolina, Chapel Hill, NC, [4]Department of Dermatology, University of Cologne, Cologne, Germany

Rho proteins have been implicated mainly in the regulation of the cytoskeleton, but also in vesicle trafficking, phagocytose and transcriptional activation. They also participate in tumorigenesis, where some of them are overfunctional. A subfamily of Rho GTPases, RhoBTB proteins, is represented by three isoforms in vertebrates. They consist of a GTPase domain, a proline-rich region and two BTB domains. BTB domains are involved in the formation of cullin 3-dependent ubiquitin ligase complexes. RhoBTB2/DBC2 has been proposed as a candidate for a tumor suppressor gene involved in breast cancer. We investigate the role of RhoBTB proteins in oncogenesis and the signal transduction pathways in which these proteins are involved. Using two-hybrid and co-immunoprecipitation studies we found that RhoBTB2 and 3 interact specifically with cullin 3 through both BTB domains. We also show that RhoBTB2 and RhoBTB3 homo- and heterodimerize. The ring box protein Roc1 enhances the interaction between RhoBTB and Cullin 3. RhoBTB3 might also be degraded in the proteasome: cells transfected with RhoBTB3 and treated

with a proteasomal inhibitor showed a clear accumulation of the protein. Furthermore, we found that RhoBTB3 interacts with ubiquitin conjugating enzyme. To address the role of RhoBTB in tumorigenesis we analyzed the expression profile of RhoBTB genes using a cancer profiling array. RhoBTB expression was decreased in all kidney samples and 80% of breast samples versus their matched normal tissue. For 50 cases of breast and 20 of kidney significantly decreased expression of RhoBTB1 and RhoBTB3 versus the matched normal tissue was observed. The expression change of RhoBTB3 and Cullin 3 correlates. We envision a model in which RhoBTB proteins target specific substrates for degradation by formation of cullin complexes and suppression of RhoBTBs results in accumulation of the target followed by cell proliferation.

**Intracellular Trafficking, Cell Surface Protein Interactions and Regulated Cleavage of Heparin-Binding Epidermal Growth Factor-like Growth Factor (HB-EGF) in Polarized Epithelial Cells**

A. H. Braun,[1,2] J. L. Franklin,[1] R. J. Coffey[1]; [1]Gastrointestinal Cancer and Epithelial Cell Biology, Vanderbilt University, Nashville, TN, [2]Internal Medicine (Cancer Research), West German Cancer Center, University of Duisburg-Essen, Germany

The EGF receptor (EGFR) is an important regulator of multiple cellular processes from embryonic development to epithelial tissue homeostasis and carcinogenesis. EGFR ligands are synthesized as transmembrane precursors that are targeted to specific cell surface compartments, from which mature soluble ligands are released through proteolytic cleavage of their ectodomains. The regulation of ligand trafficking, processing and ectodomain shedding is critical for their biological function. We have investigated the targeted delivery, cell surface protein interactions and regulated cleavage of HB-EGF in polarized MDCK II cells. HB-EGF is detected predominantly at the basolateral membrane (immunochemistry), but is mainly released from the apical surface in a metalloprotease-dependent manner (data generated with a newly-developed HB-EGF ELISA). Metabolic-labeling and pulse-chase analyses, as well as studies with non-cleavable mutant HB-EGF, confirm these observations (confocal immunofluorescence and selective cell-surface biotinylation). Seven-membrane-spanning receptor (LPA, bombesin) or PMA stimulation may induce recruitment of metalloproteases and/or their activators into HB-EGF complexes, resulting in regulated release of HB-EGF. Data on proteins interacting with full-length or non-cleavable HB-EGF as well as HB-EGF's cytoplasmic tail will be presented (mass spectrometry). Amongst metalloproteases implicated in HB-EGF cleavage, we have identified a role for ADAM-10/kuzbanian, ADAM-17/TACE and MMP-7/matrilysin by pharmacological (Way-022, Ex-01) or siRNA blockade and exogenous expression (ADAM-10, ADAM-17, MMP-7) in a battery of human breast and colorectal cancer cell lines. The expression of HB-EGF in normal and neoplastic epithelial tissue as detected with antibodies recognizing N- or C-terminal domains will be shown and correlated to the expression of ADAM-10 and -17. Differential expression and processing of HB-EGF and metalloproteases implicated in its cleavage in normal versus malignant tissue indicate that HB-EGF-related events are promising targets for cancer therapy.

1402

**Heterologous Expression and Characterisation of the *Agaricus bisporus* Lectins Which Inhibit *in vitro* Proliferation of Human Colon Cancer Cells**

J. Henderson,[1] B. Herman,[2] D. Eastwood,[2] D. West,[1] S. Sreenivasaprasad,[2] K. Burton[2]; [1]School of Science and the Environment, Coventry University, Coventry, United Kingdom, [2]Warwick HRI, Warwick University, Coventry, United Kingdom

*Agaricus bisporus* is an economically important edible fungus. Despite its importance, the *A. bisporus* genome has remained underexploited. Previous studies have identified a lectin from *A. bisporus* which inhibits epithelial colon cancer cell growth. Colorectal cancer is one of the second most common cause of cancer-related deaths in he Western world with 28,000 cases per year in the United Kingdom. The *A. bisporus* lectin is part of a group of proteins that can bind to the Thomsen-Friedenreich antigen (T0antigen) which is over-expressed in malignant and premalignant colonic epithelium. This T-antigen consists of the disaccharide sialyl-2, 3-galactosyl-β1-3-N-acetyl-galactosamine-α (Galβ1-3GalNAc). Binding of the *A. bisporus* lectin causes dose-dependent inhibition of the proliferation of these cells and is a reversible, non-cytotoxic effect. Recently, it has been shown that the lecin blocks nuclear localisation signal dependent nuclear protein import. Up to five isoforms the lectin have been detected in crude mushroom extract. It is yet unknown if these isoforms are formed by post-translational modification of a single lectin or whether there are more than one lectin gene involved or, it is a combination of both possibilities. In orer to test the functionality of the different lectin isoforms and to unveil the mechanism of action of the anti-proliferative effect it is essential to have access to high quantities of the purified single lectin(s). The work presented deals with the cloning and characterisation of lectin genes in *A. bisporus* and their heterologous expression.

**The Antitumoral and Biochemical Effects of Gossypol on Human Cervix Cancer Cell Line ME-180**

E. Simsek, E. Arslan Aydemir, K. Fiskin; Biology, Akdeniz University, Antalya, Turkey

Gossypol, a yellow polyphenolic compound extracted from cotton plants, has been found to be a contraseptive, an antimicrobial, anti-viral, anti-parasitic and anticancerogenic agent. Recently, gossypol has been shown to inhibit the growth of several tumour cell lines and has been suggested to be a potential anticancer drug. The antitumour activity of gossypol has been reported in many previous studies. The aim of our study was to investigate whether gossypol induced cell death by DNA fragmentation on ME-180 cervix cancer cells; and whether it was a potent inhibitor of some antioxidant enzymes; like catalase, glutathione reductase and glutathione-S-transferase. Firstly, we investigated the effects of gossypol on growing tumour cells. The cells were incubated with four different doses (5,10,15 and 20µM ) for 24, 48 and 72 hours. After gossypol treatment, the cytotoxic effects were measured with MTT tests. Using DNA agarose gel electrophoresis, cellular internucleosomal DNA fragmentation of the cells treated with gossypol and untreated were examined. Consequently, gossypol caused different fragmentation on tumour cells due to apoptosis. After gossypol administration, different levels of activities were found in the enzymes of the control and treated cells. Gossypol was found to be a potent inhibitor of catalase, glutathione reductase and glutathione-S-transferase. Gossypol could realise this activity accompanied with dose and time dependent manner. Here, it is shown that treatment of ME-180 cells with gossypol not only induces apoptosis , but also a potent inhibitor of this three enzymes. The research results have been appraised by statistical analysis, compared with other research results.

**Nuclear Interactions of Topoisomerase II and Phospholipid Scramblase 1**

J. P. Wyles, Z. Wu, S. E. L. Mirski, S. P. C. Cole; Cancer Biology and Genetics, Queen's University, Kingston, ON, Canada

DNA Topoisomerase (topo) II is a nuclear enzyme essential for cell division and is a well established target for several clinically effective chemotherapeutic agents. All vertebrates have two isoforms of topo II (α and β), and although they are highly homologous and both catalyze the same DNA cleavage, strand passage and DNA reunion reactions, they are differentially regulated and have distinct cellular functions and drug interactions. Most of the sequence variations between topo IIα and β are found in their COOH-terminal domains (CTDs), suggesting that these regions may be responsible, at least in part, for their functional differences. To better understand the basis for the different properties of topo IIα and β, yeast two-hybrid analysis was used to identify protein partners of their CTDs. One of the proteins identified by this approach was phospholipid scramblase 1 (PLSCR1). The interactions of PLSCR1 and topo II were further confirmed by (i) GST pull-down assays with GST-topo IIα and β CTD fusion proteins and detergent-solubilized endogenous PLSCR1; and (ii) co-immunoprecipitations of endogenous PLSCR1 and endogenous full-length topo IIα and β in HeLa cell nuclear extracts. Subsequent GST pulldown assays defined a conserved region of topo IIα (residues 1431-1441, GAKKRAAPKGT) as mediating binding to PLSCR1. PLSCR1 is typically regarded as a plasma membrane protein that plays an important role in apoptosis. However, a fraction of PLSCR1 is located in the nucleus and has been implicated in cellular differentiation and proliferation, as have both isoforms of topo II. Our studies reveal for the first time a potential role for PLSCR1 in topo II-mediated cell differentiation and proliferation pathways. Supported by the Canadian Cancer Society through the National Cancer Institute of Canada. JPW is the recipient of a Terry Fox NCIC Postdoctoral Fellowship.

**Alteration of Calcium Signaling of Primary Cultured Keratinocytes in SERCA2$^{+/-}$ Mice**

J. Hong,[1,2] D. Shin,[1] H. Byun[1]; [1]Dept of Oralbiology, Yonsei University, Seoul, Republic of Korea, [2]Brain Korea 21 project, Seoul, Republic of Korea

The calcium homeostasis is connected to various cell functions that are involved in intracellular signal transduction. The sarco/endoplasmic reticulum $Ca^{2+}$-ATPases (SERCAs), plasma membrane $Ca^{2+}$-ATPases (PMCAs), and inositol trisphosphate receptors ($IP_3Rs$) are controlling $Ca^{2+}$ gradients in cellular membrane. This mechanism of SERCAs, PMCAs, and $IP_3Rs$ is essential for $Ca^{2+}$-mediated signaling and other biological processes. Moreover, free calcium ion has been served as a modulator of keratinocyte for proliferation and differentiation in mammalian skin. We found that SERCA2 heterozygous mutant mice (SERCA2$^{+/-}$) showed a very high rate of squamous cell carcinoma. It occurred to mice which are from 53 to 81 weeks. However, it is unknown that precise cause-effect relationship between $Ca^{2+}$ signaling and squamous cell carcinoma. In this study, we investigated $Ca^{2+}$ signaling in primary cultured murine epidermal keratinocyte from SERCA2$^{+/-}$ mice. Although there was no difference of the $[Ca^{2+}]_i$ entry in the wild type and the SERCA2$^{+/-}$ mice, SERCA2$^{+/-}$ mice appeared low initial $[Ca^{2+}]_i$ increasing in response to uridine 5'-trisphosphate, a potent $Ca^{2+}$-mobilizing agent, and sustained $[Ca^{2+}]_i$. In addition, SERCA2$^{+/-}$ mice seemed to more increased $[Ca^{2+}]_i$ than wild type mice, after depletion of intracellular $Ca^{2+}$ stores with cyclopiazonic acid (CPA), a specific inhibitor of SERCA pump. Western blot analysis revealed lower expressions of SERCA2, PMCA, and $IP_3R3$ in SERCA2$^{+/-}$ mice compared to wild-type mice respectively, but $IP_3R$ activity of SERCA2$^{+/-}$ mice is similar to wild type mice. The results indicated that $Ca^{2+}$ signaling and expression levels of $Ca^{2+}$-related proteins in primary cultured keratinocytes from SERCA2$^{+/-}$ mice were altered, but the precise mechanism of squamous cell carcinoma by decreased expression of SERCA2 will be further studied. This study was supported by a grant of the Ministry of Health & Welfare, Republic of Korea (A050002).

**Consequences of Modulating *GLI-1* Expression in a Basal Carcinoma Cell Line**

P. Romagnoli,[1] R. Sestini,[2] P. Di Gennaro,[1] S. Bacci,[1] L. Domenici,[1] P. Pinzani,[2] P. Carli,[3] M. Genuardi[2]; [1]Department of Anatomy, Histology and Cell Biology, University of Florence, Firenze, Italy, [2]Department of Clinical Physiopathology, University of Florence, Firenze, Italy, [3]Department of Dermatological Sciences, University of Florence, Firenze, Italy

*GLI-1* is an oncogene amplified in human gliomas and several other tumours, which encodes a transcription factor mediating the transduction of Sonic Hedgehog signal. The expression of *GLI-1* is typical of basal cell carcinoma and is supposed to be responsible for increased proliferation rate, expression of the antiapoptotic protein BCL-2 and reduced adhesion to the basal lamina because of inhibited expression of laminin. These events may be relevant to tumour pathogenesis. Tacrolimus (FK506) is an immunomodulatory molecule with extensive homology with rapamycin; the latter can antagonize the cellular transformation caused by *GLI-1* overexpression, independent of immunomodulation. We tested whether tacrolimus was active on the expression of *GLI-1* and if so which were the consequences on downstream genes in the basal carcinoma cell line TE 354.T. *GLI-1* mRNA expression was estimated by real-time PCR with Taqman probes; BCL-2 and laminin were estimated by

immunohistochemistry and BCL-2 also by Western blot; basal lamina material was evaluated by electron microscopy; the proliferation index was estimated by bromodeoxyuridine incorporation and apoptosis was estimated by TUNEL assay. The cell line under study expresses *GLI-1* mRNA and expresses BCL-2 and laminin proteins with variable intensity among cells. Tacrolimus caused partial inhibition of *GLI-1* transcription, accompanied by reduced expression of BCL-2, increased expression of laminin, and increased secretion of basal lamina material. Tacrolimus did not influence the cell growth rate, proliferation index, nor apoptosis. The results support the hypothesis of a role of *GLI-1* in the regulation of the expression of BCL-2 and in the secretion of basal lamina proteins by basal carcinoma cells and lead to propose tacrolimus as an efficient tool to study the effects of inhibiting *GLI-1* expression in cells spontaneously expressing this transcription factor.

**Induction of Synthesis of Metallothionein by Platinum Based Drugs**

R. Prusa,[1] J. Petrlova,[2] O. Blastik,[2] V. Adam,[2] J. Kukacka,[1] R. Kizek[2]; [1]Clinical Biochemistry and Pathoiochemistry, Charles University, 2nd Medical Faculty, Prague 5, Czech Republic, [2]Chemistry and Biochemistry, Mendel University of Agriculture and Forestry, Brno, Czech Republic

Neoplastic diseases represent one of the most prevalent human disorders. Many of those are generally treated by platinum-complexes. Effectiveness of such treatment depends on the therapeutic concentration of the drug commonly influenced by binding to proteins (e.g. metallothionein). The metallothionein (MT) family is class of low molecular, intracellular and cysteine-rich proteins presenting high affinity for metal ions. Metallothionein is a well-known heavy metal binding protein maintaining metal ion homeostasis. In human organisms MTs are usually abundant at low concentrations levels. Their marked expression is caused by many exogenous and endogenous factors such as UV radiation, heavy metals, xenobiotic species, reactive oxygen species etc. The aim of this work was to study the interaction of MT with Pt compounds. The proper interaction was observed *in vitro* by means of electrochemical techniques using the oxidation-reduction and/or catalytic signals (Brdicka reaction, and peak H). Chronopotentiometric stripping analysis was the most sensitive and, therefore, the most suitable technique for studying of interaction between platinum and MT. The interaction was observed by means of changes in electrochemical signal (peak H) of MT on the surface of hanging mercury drop electrode. Finally, the suggested technique was used for analysis of blood serum of the patients treated with standard platinum compounds. The MT amount increased in this patients´ serum more than 10 times in comparison with non-treated patients. The results thus show that the MT amount has a significant negative influence on the therapy of neoplastic diseases. **Acknowledgements.** *This work was supported by grants: GACR 525/04/P132 and RASO 2005.* **References** [1] V. Adam, et. al. 99 (2005) 353. [2] R. Prusa, et. al. Clin. Chem. 51 (2005) A56. [3] R. Prusa, et. al. Clin. Chem. 50 (2004) A28. [4] R. Kizek, et. al. Anal. Chem. 73 (2001) 4801.

**Ligand Activation of FGFR-1 Isoforms Induces Differential Signaling Responses**

P. Zhang,[1] J. A. Thompson[2]; [1]Dept of Biochemistry and Molecular Genetics, University of Alabama at Birmingham, Birmingham, AL, [2]Dept of Surgery, Dept of Biochemistry and Molecular Genetics, University of Alabama at Birmingham, Birmingham, AL

Overexpression of FGF ligands and the alternative spliced FGFR-1β isoform have been found in malignant pancreatic adenocarcinoma, the fourth leading cause of cancer death in US. In normal adult tissue FGFR-1 is typically expressed as the α isoform. To examine the biological significance of this feature, FGF receptor-negative endothelial cells (RVEC) were stably transfected with expression vectors encoding either FGFR-1α or FGFR-1β human cDNA. In the presence of FGF-1 treatment, these two isoform transfectants exhibited differential phenotype, migratory behavior, and responses to oxidant stress, ionizing radiation and chemotherapy. These observations have prompted us to examine the intracellular substrates activated by the two receptor isoforms. Immediate early, transient activation of c-YES and FAK were limited to FGFR-1β signaling and correlated with altered phenotype, increased migration, and resistance to cytotoxic treatments. Activation of FRS2, SHC and N-Ras were identified in both isoforms, resulting in sustained activation of ERK1/2 MAPK and mitogenic behavior. Immediate early, transient activation of the stress-associated MAPKs, p38 and JNK, was restricted to FGFR-1α signaling in an extracellular calcium- and PKC-dependent manner. Ligand-activated FGFR-1α transfectants demonstrated increased sensitivity to cytotoxic treatments. Taken together, these differential signaling pathways may provide mechanistic insight into the onset, progression, and treatment of tumorigenesis.

1410

**Study of Binding of Platinum Cytostatic Drug to DNA Structure: Therapeutic Concentration of Platinum Cytostatic**

R. Prusa,[1] V. Adam,[2] J. Petrlova,[3] J. Zehnalek,[3] R. Kizek[3]; [1]Clinical Biochemistry and Pathoiochemistry, Charles University, 2nd Medical Faculty, Prague 5, Czech Republic, [2]Anylytical Chemistry, Masaryk University, Faculty of Science, Brno, Czech Republic, [3]Chemistry and Biochemistry, Mendel University of Agriculture and Forestry, Brno, Czech Republic

Although cisplatin, cis-diamminodichloroplatinum(II), has been successfully used in the chemotherapy of cancer for more than 25 years, its biochemical mechanism of action is still unclear. The aim of this paper was to study of binding of platinum cytostatic to DNA structure using of platinum biosensor. Moreover, we applied the biosensor to analyse platinum in human blood serum - therapeutic concentration assay. Metallothionein modified hanging mercury drop electrode (HMDE) surface was used as a platinum biosensor. The platinum and Pt-DNA adduct were detected by adsorptive transfer stripping (AdTS) differential pulse voltammetry (DPV). It is necessary for the study of the anti-cancer drugs effectiveness to detect their therapeutic level. That is why we applied the MT modified HMDE for determination of *cis*-platin in the human blood serum. The detection limit (3 S/N) of cisplatin was about 10 pmole in 5 µl. In addition therapeutic effect of cisplatin relates to conformational changes in the DNA structure. The interaction between Pt(II) and DNA probably proceeds via guanine (G) molecules. Here, we used the biosensor to study of amounts of Pt bound to DNA. Detection limit of MT biosensor calculated for Pt-DNA adduct was hundreds of nanograms per millilitre. The suggested approach shows the possible way for simple, sensitive and rapid detection of cisplatin and Pt-DNA in the human body fluids at the picomole level. The biosensor could be applied to study of binding of platinum to DNA structure. **Acknowledgements.** *This work was supported by grants: GA CR No. 525/04/P132 and RASO 2005.* **References** [1] R. Kizek et. al.: Anal. Chem. 73 (2001) 4801. [2] R. Prusa et. al.: Clin. Chem. 50 (2004) A28. [3] E. Palecek et. al.: Anal. Chem. 76 (2004) 5930.

## Metabolic Diseases (1418-1442)

### DHEA-induced Antiproliferative Effect in MCF-7 Cells is Androgen- and Estrogen- Receptor Independent

R. López Marure, V. Gayosso Tellez, L. F. Montaño Estrada; Fisiología, Instituto Nacional de Cardiología, México D. F., Mexico

Dehydroepiandrosterone (DHEA), an adrenal hormone derived from cholesterol, can be metabolized to estrogens (estradiol) and androgens (testosterone). In this work, we evaluated if the antiproliferative effect induced by DHEA in MCF-7 cells is direct, or indirect through its conversion to estradiol or testosterona. Cell proliferation was evaluated by violet crystal staining and the androgen and estrogen receptors were blocked by ICI 182,780 and flutamide inhibitors. DHEA had an antiproliferative effect at supraphysiological concentrations, however when it was used at physiological concentrations, it increased the proliferation of MCF-7 cells. Estradiol induced an increase on the cell proliferation, at physiological concentrations, whereas testosterone had a weak inhibitory effect at 100 μM. DHEA-S (its inactive sulfate ester) had no effect upon the cell cycle. DHEA-induced antiproliferative and proliferative effect was not blocked by inhibitors of androgen or estrogen receptors, thus indicating that its effect is secondary to a direct interaction with a "putative" receptor rather than conversion into steroid hormones. These results suggest that DHEA could be used at supraphysiological concentrations in the treatment of breast cancer.

### Antisense Experiments Demonstrate Cancer-Specific Encoding of Functional tNOX Through an Exon 4 Minus Splice Variant

X. Tang,[1] D. Morre,[2] D. M. Morre[1]; [1]Foods and Nutrition, Purdue University, West Lafayette, IN, [2]Medicinal Chemistry and Molecular Pharmacology, Purdue University, West Lafayette, IN

Real-time quantitative PCR and in vitro cytotoxicity assays were combined to demonstrate encoding of functional tNOX, a cancer specific and growth-related cell surface protein, via an Exon 4 minus splice variant. Total RNA from HeLa cells treated with antisense oligonucleotides for 6 h was isolated followed by measurement of specific tNOX mRNA using real-time quantitative RT-PCR. Cells were transfected with oligonucleotides using Lipofectamine 2000 transfection reagent. tNOX mRNA levels of each sample were calculated relative to control cells transfected with Lipofectamine and determined by the cycle threshold method normalized for GAPDH mRNA. Antisense to tNOX Exon 4 mRNA blocked the generation of full-length tNOX mRNA but not Exon 4 minus mRNA. An oligonucleotide with the scrambled sequence was without effect. Antisense to Exon 5 mRNA did inhibit the production of both Exon 4 minus mRNA and full length tNOX mRNA. Again, scrambled antisense to Exon 5 mRNA was without effect. Antisense to Exon 5 mRNA decreased the amount of tNOX protein on the surface of cancer cells. As a control, antisense mediated down-regulation of tNOX Exon 5 minus mRNA also was demonstrated as detected using Exon 4/Exon 6 primers. Exon 5 antisense blocked the cell surface expression of tNOX whereas Exon 4 antisense was without effect. Additionally, HeLa cells transfected with Exon 5 antisense were no longer inhibited by the green tea catechin tNOX inhibitor (-)-epigallocatechin-3-gallate. A relationship of tNOX to unregulated growth of cancer cells was provided by data where growth of HeLa cells was inhibited by transfection with the Exon 5 antisense oligonucleotides. Growth inhibition was followed by apoptosis in greater than 80% of the population of transfected cells.

### Elucidation of Novel Mechanisms that Control Metastatic Cell Growth

G. S. Goldberg,[1] Z. Jia,[1] Y. Shen,[1] H. Ichikawa[2]; [1]Molecular Biology, UMDNJ, Stratford, NJ, [2]Cancer Transcriptome Project, National Cancer Center Research Institute, Tokyo, Japan

Anchorage independence and motility are hallmarks of metastatic tumor cell growth. Tumor cell growth and morphology can be normalized by contact with nontransformed cells. The Src tyrosine kinase phosphorylates specific sites on the focal adhesion adaptor protein Cas to promote nonanchored cell growth and migration. We studied the effects of Src and Cas on the expression of over 14,000 genes to identify molecular events that underlie these activities. Gene expression in tumor cells that were normalized by neighboring nontransformed cells was used as an additional filter to identify genes that control metastatic cell growth. This process enabled the identification of genes that appear to play roles in anchorage independent cell growth and migration. By independently investigating (1) anchorage independent cell growth, (2) migration, and (3) the effects of neighboring cells on tumor cells, we have developed an efficient method to identify novel mechanisms that control fundamental aspects of cell growth and metastasis.

### Biological and Biochemical Characterization of a Novel Dual-Specificity Phosphatase, Neuroendocrine-Associated Phosphatase (NEP)

J. Wang,[1] C. Lin,[1] C. Yang,[1] T. Tan,[2] Y. Chen[1]; [1]Division of Molecular and Genomic Medicine, National Health Research Institutes, Miaoli County, Taiwan Republic of China, [2]Department of Immunology, Baylor College of Medicine, Houston, TX

A novel neuroendocrine-associated phosphatase (NEP) was characterized for its biochemical and biological properties. NEP showed a sequence characteristic of dual-specificity phosphatase (DSP) and was preferentially expressed in neuroendocrine cells/tissues as well as in skeletal muscle and heart. Expression of NEP was not significantly induced by oxidative stress or serum but was upregulated in PC12 cells during nerve growth factor (NGF)-induced differentiation. NEP was a cytosolic protein and *in vivo* did not have significant effects against activation of ERK, JNK, and p38-MAPK induced by various stimuli. Although NEP and mitogen-activated protein kinase (MAPK) phosphatase-1 (MPK-1) showed similar phosphatase ability toward *p*-nitro phenylphosphate (*p*NPP), NEP did not evidently dephosphorylate MAPKs as did MKP-1 *in vitro*. Our results indicated that, unlike other DSPs, down-regulation of MAPKs was not the major function of NEP. Furthermore, NEP induced by NGF during PC12 cell differentiation may be involved in NGF/TrkA signaling pathway.

### The Role of GlUT1 in HTLV Infection

I. M. Lisinski, N. Takenouchi, F. Kazunori, K. Yao, F. W. Ruscetti, K. Jones, S. W. Cushman, S. Jacobsen; NIDDK, NIH, Bethesda, MD

GLUT1 was recently described as a receptor for the retrovirus HTLV. The entry of retroviruses into target cells involves the interaction of two envelope glycoproteins, a surface glycoprotein (SU) and a transmembrane glycoprotein (TM), with at least one specific host cell receptor. To

determine the importance of GLUT1 in virus infection, we first established a system that would allow us to over express GLUT1 in target cells, and monitor the relative amount of GLUT1 expressed on the cell surface. We transfected COS cells with GLUT1 and a mutant form of GLUT6 [GLUT6 (LL/AA)], both tagged with an hemagglutinin (HA) epitope to determine cell-surface expression by FACS. Quantitative Western blot analysis of bis-glucose photolabeled cells was also used to measure cell-surface expression. First we show that GLUT1 cell-surface expression is almost undetectable in untransfected, compared to GLUT1 over-expressing, COS cells. Cell-surface expression of mutant GLUT6 (LL/AA), but not wt GLUT6, is also similar to that of GLUT1 in transfected COS cells. Second, we demonstrate that over expression of GLUT1 does not increase HTLV SU binding suggesting that virion binding reflects interactions with cell-surface proteins other than GLUT1. Finally, to study the role of GLUT1 in HTLV-1 infection, we developed a co-culture assay, using live HTLV-1 producing cells, to monitor *de novo* infection of GLUT1 over expressing COS cells. In this case, the percentage of infected COS cells is drastically increased with HA-GLUT1-transfected cells (46.4%) compared to non-transfected and HA-GLUT6 (LL/AA)-transfected cells (2.0%). Thus, GLUT1 appears to have an important role in HTLV infection, but not binding; we propose that GLUT1 mediates vesicular uptake of bound virus through its subcellular trafficking properties.

1416

**Adenosine Receptor $A_3R$ Agonist Inhibits Cholangiocarcinoma Growth via Galpha$_i$-dependent Activation of $IP_3$ with Associated Downregulation of cAMP, Erk1/2 and Akt**

S. S. Glaser,[1] H. Francis,[1] S. DeMorrow,[1] J. Venter,[2] R. Reichenbach,[3] R. Summers,[2] B. Green,[2] A. Coots,[2] Y. Ueno,[4] G. Alpini[5]; [1]Research & Education, Department of Medicine, Texas A&M University HSC and Scott & White Hospital, Temple, TX, [2]Department of Medical Physiology, Texas A&M University HSC, Temple, TX, [3]Central Texas Veterans Health Care System, Temple, TX, [4]Division of Gastroenterology, Tohoku University School of Medicine, Sendai, Japan, [5]Department of Medical Physiology & Internal Medicine, Texas A&M University HSC, Scott & White Hospital and Central Texas Veterans HCS, Temple, TX

Cholangiocarcinoma is an aggressive biliary tumor, which retains many of the regulatory features controlling normal cholangiocyte proliferation. We have shown that activation of $IP_3/Ca^{2+}$/PKCα-dependent signaling inhibits cholangiocyte growth via downregulation of the cAMP/ERK1/2 pathway. We have previously demonstrated that the cholangiocarcinoma cell line, Mz-ChA-1, expresses all four adenosine receptor (AR) subtypes ($A_1R$, $A_{2A}R$, $A_{2B}R$ and $A_3R$) and that specific adenosine receptor agonists inhibit MzChA-1 growth to varying degrees. AR agonists have been reported to have dual signaling mechanisms via activation of $G\alpha_{i/o}$ resulting in decreased cAMP levels and increased $IP_3$ via stimulation of phospholipase C. The AIM of our study was to further evaluate the signaling mechanisms governing the inhibition of cholangiocarcinoma proliferation via stimulation of $A_3R$. Methods: Proliferation was evaluated by MTS assay. Mz-ChA-1 cells were stimulated with Cl-IB-MECA ($A_3R$ agonist, 1 nM) in the presence/absence of VUF5574 (a $A_3$ receptor antagonist, 1μM) and BAPTA/AM (intracellular $Ca^{2+}$ chelator, 5 μM) for 48 hours and proliferation was evaluated. Intracellular $IP_3$ and cAMP levels were determined by RIA following treatment of Mz-ChA-1 cells with Cl-IB-MECA in the presence/absence of pertussis toxin pretreatment. The effect of Cl-IB-MECA on ERK1/2 and AKT phosphorylation was determined by immunoblotting. Results: Cl-IB-MECA inhibited Mz-ChA-1 cell proliferation (30%), which was blocked by VUF5574 and BAPTA/AM. Cl-IB-MECA increased intracellular $IP_3$ levels, which was inhibited by pertussis toxin pretreatment. Cl-IB-MECA inhibition of cAMP levels was reversed by pertussis toxin. The phosphorylation of both ERK1/2 and AKT was significantly reduced following Cl-IB-MECA treatment. Conclusion: Simulation of $A_3R$ decreased proliferation of Mz-ChA-1 cells via a pertussis toxin sensitive $IP_3$-dependent mechanism with associated downregulation of the cAMP/ERK1/2 and AKT pathways. $A_3R$ agonists may represent a new therapeutic option to regulate cholangiocarcinoma growth.

1417

**Positive Regulation of p53 by Tumor Suppressor pVHL**

J. Roe, H. Youn; Seoul Nat'l Univ. College of Medicine, Seoul, Republic of Korea

The tumor suppressor p53 is activated in response to many types of cellular and environmental insults. The level of p53 is governed largely by its major negative regulator, Mdm2. Also, another tumor suppressor von-Hippel landau(VHL) has emerged as a key factor in cellular responses to oxygen availability. pVHL is required for the oxygen-dependent proteolysis of α subunit of hypoxia-inducible factor-1(HIF-1α). In many renal cell carcinoma patients, it is reported that VHL mutations are directly linked to carcinogenesis. Here we found that α domain of pVHL directly binds to p53 and this interaction prevents Elongin C recruitment to pVHL, so ubiqutin ligase activity of pVHL is disrupted. Also, this interaction is both HIF-1α and Mdm2 independent manner. In contrast to the known role for HIF-1α degradation, pVHL protects p53 from proteasomal degradation and enhances transcriptional activity. These phenomenon is supported by the fact that pVHL assists the recruitment of coactivators like p300 or pCAF. Interestingly, pVHL contributes to p53 dependent cell-cycle arrest at G1-phase and apoptotic cell death induced by DNA damaging agent. Both apoptosis and cell-cycle arrest caused by DNA damage are significantly attenuated in VHL null cell. These results suggest that pVHL participates in p53-medeatied signaling pathways and elucidates cancer formation in pVHL disrupted renal cells.

1418

**Identification of Novel Adipocyte-Secreted Factors Using Microarray Data of Various Metabolic Model Mice**

H. S. Jo, H. W. Jeong, J. B. Kim; Biological Science, Seoul National University, Seoul, Republic of Korea

Since the discovery of leptin in the mid 90's, the list of adipocyte-secreted factors has vastly expanded. An increasing body of evidence suggests that these factors, now referred to as adipocytokines, play critical roles in maintaining whole body energy homeostasis. Tissue specific knockout or overexpression of certain genes in adipocytes, such as IR, PPARγ, GLUT4, G6PD, and FOXC2, leads to aberrant changes in muscle and liver metabolism, affecting insulin sensitivity and susceptibility to the onset of diabetes. These effects are thought to be mediated, in part, by altered adipocytokine expression. To identify novel adipocytokines, we compared microarray data from various mouse models, including the ob/ob and db/db mice, and Rosiglitazone treated mice. We have discovered 11 candidate genes that have been previously cited and 1 gene encoding a hypothetical secreted protein. [This work was supported in part by grants from the National Research Laboratory Program of Korea Science and Engineering Foundation.]

**Regulation of PPARg Protein Expression by Free Fatty Acids in 3T3-L1 Adipocytes**

A. Nguyen,[1] D. D. Sears,[1] H. Satoh,[2] J. M. Ofrecio,[1] J. M. Olefsky[1]; [1]Division of Endocrinology/Metabolism, University of California, San Diego, La Jolla, CA, [2]Fukushima Medical University, Fukushima-City, Japan

Regulation of PPARg Protein Expression by Free Fatty Acids in 3T3-L1 Adipocytes MT Audrey Nguyen[1], Dorothy D. Sears[1], Hiroaki Satoh[2], Jachelle M. Ofrecio[1], Jerrold M. Olefsky[1]. [1]Division of Endocrinology/Metabolism, University of California, San Diego, La Jolla, CA, USA, [2] Fukushima Medical University, Fukushima-City, Japan PPARg is a nuclear receptor whose expression is crucial for adipogenesis and metabolism, and a high-affinity target for the thiazolidinediones or TZDs, a class of powerful antidiabetic drugs. In humans and rodents, PPARg protein level and activity are critical for its beneficial effects as an insulin-sensitizing transcriptional regulator. In this study, we investigated the effect of free fatty acids (FFAs), agents known to decrease insulin sensitivity, on PPARg1 and PPARg2 protein expression in 3T3-L1 adipocytes. Adipocytes were treated with a mixture of saturated and unsaturated FFAs at various concentrations and for various amounts of time, and PPARg protein levels were examined by immunoblotting. FFA treatment led to a decrease in PPARg1 and PPARg2 protein levels in a time and dose-dependent manner. This was paralleled by a time and dose-dependent decrease in PPARg mRNA levels as determined by semi-quantitative RT-PCR. When cells were pretreated with the inhibitor of transcription actinomycin D, the FFA-induced decrease in PPARg mRNA was partially blocked, suggesting involvement of both mRNA stability and transcriptional regulation. When de novo protein synthesis was inhibited with cycloheximide, the FFA-induced decrease in PPARg protein was not prevented. Similarly, inhibition of protein degradation using lactacystin and MG-132 did not block the decrease in PPARg protein, indicating that proteasome-dependent proteolysis is unlikely to contribute to decreased PPARg protein levels. Together the data suggest that FFAs downregulate PPARg protein levels primarily through inhibition of PPARg gene transcription.

1420

**HIV-1 Protease Inhibitors Impair Insulin Signaling and Suppress Nitric Oxide (NO) Production in Vascular Endothelial Cells: Protective Effect of Thiazolidinediones (TZD)**

K. Liu, D. Mondal, M. Ali, K. C. Agrawal; Pharmacology, Tulane University Health Sciences Center, New Orleans, LA

Inclusion of HIV-1 protease inhibitors (PIs) in highly active antiretroviral therapy (HAART) has significantly decreased mortality in HIV-1 infected patients. However, PI therapy can manifest insulin resistance syndrome (IRS), a risk factor for diabetes and atherosclerosis. PI-mediated dysfunctions in vascular endothelial cells (ECs) are not well understood. We have shown that PIs increase oxidative stress in ECs which enhance endothelial-leukocyte adhesion. Since endothelial oxidative stress is regulated by insulin-induced NO production via NO synthase (eNOS), we hypothesized that PIs may suppress NO production by inhibiting eNOS and that insulin sensitization via TZDs may provide protection. Human aortic endothelial cells (HAECs) were exposed (72 hr treatment with fresh PIs added every 24 hr) to PIs [nelfinavir (1-5 μM), atazanavir (1-5 μM), or indinavir (3-15 μM)] and NO production was monitored (DAF-FMDA fluorescence assay). Exposure to PIs, especially nelfinavir, decreased both basal (10-15 %) and insulin-induced (15-40 %) NO production, and coexposure with TZDs [troglitazone or rosiglitazone (0.1-0.25 μM)] inhibited this suppression. Insulin binding to its receptor (IR) activates insulin receptor substrates (IRS-1 and -2), phosphatidylinositol 3-kinase (PI3K) and protein kinase B (PKB or AKT), which leads to increased eNOS expression and activation. We therefore monitored whether nelfinavir affects insulin signaling in HAECs. Immunoblotting of cell lysates from PI-exposed HAECs indicated that nelfinavir exposure decreased phosphorylation of IRβ and IRS-1, and downstream activation of AKT, PI3K (p85) and eNOS. Simultaneous addition of TZDs provided significant ($p<0.05$) protection. These data suggest that TZDs may provide therapeutic benefits towards suppressing the vascular dysfunctions observed in HIV-1 infected individuals receiving PI containing HAART regimen.

**Intrinsic Sorting Signals Required to Target Newly-synthesized IRAP into the Insulin-responsive GLUT4 Storage Compartment**

R. T. Watson, J. Hou, J. E. Pessin; Pharmacological Sciences, SUNY-Stony Brook, Stony Brook, NY

The glucose transporter 4 (GLUT4) and the insulin-responsive aminopeptidase (IRAP) display indistinguishable membrane compartmentalization and insulin-stimulated translocation properties. IRAP is a type II integral membrane protein with a short cytoplasmic region of 109 amino acids that encodes all the information necessary for insulin-responsive compartmentalization. IRAP is therefore an excellent model protein for studying the sorting processes responsible for targeting cargo molecules into the insulin responsive GLUT4 storage compartment. Immediately following biosynthesis, the EGFP-IRAP/WT reporter construct trafficked to the Golgi complex and was efficiently sequestered in perinuclear membrane compartments. At 3-6 h following biosynthesis, EGFP-IRAP/WT did not translocate to the cell surface in response to insulin. However, beginning at 6-9 h following expression, EGFP-IRAP/WT acquired insulin responsive compartmentalization and translocated to the plasma membrane following acute insulin stimulation. In contrast, the EGFP-IRAP/AA(76,77) construct, wherein the dileucine residues at position 76,77 were mutated to alanine, rapidly defaulted to the cell surface following biosynthesis. This trafficking pattern was indistinguishable from a control syntaxin 3 construct that also rapidly defaulted to the cell surface. In addition, coexpression of the VHS-GAT dominant-interfering domains of GGA strongly inhibited the ability of EGFP-IRAP/WT to acquire insulin-responsive compartmentalization at all time points following biosynthesis. However, the VHS-GAT construct did not block the constitutive trafficking of syntaxin 3 or EGFP- IRAP/AA(76,77) to the cell surface. Moreover, the EGFP-IRAP/WT and EGFP- IRAP/AA(76,77) constructs occupied morphologically distinct tubulovesicular carrier compartments in the perinuclear Golgi region. Taken together, the above data indicate that LL76,77 functions at the level of the Golgi complex to target newly-synthesized IRAP protein into the insulin-responsive GLUT4 storage compartment.

1422

**BLX-1028, a Novel Antiadipogenic Compound, Lowers Body Weight Gain in *ob/ob* and Diet Induced Obese Mouse Model**

S. Roy, H. Moon, M. Anamula, A. Sen, A. Nag, P. Neogi, B. Nag, D. Dey; Bexel Pharmaceuticals, Union City, CA

BLX-1028 is a water soluble, orally active, modified amino acid derivative with no structural similarity to any existing antiobesity compounds. It inhibits both PPAR(- and "Dexamethasone-Insulin-IBMX"- mediated adipocyte differentiation in 3T3-L1 fibroblasts. BLX-1028 dose dependently inhibits iNOS expression in both TNFα-induced adipocytes and LPS-induced macrophages. It has been shown that iNOS expression is upregulated in muscle and adipose tissues of both dietary and genetic obesity animal models and targeted disruption of iNOS protects against obesity-linked

insulin resistance in muscle. Since our compound shows a unique antiadipogenic and anti-inflammatory properties, following studies were undertaken to determine the body weight lowering effect of BLX-1028 in different mouse models. Obesity was induced in C57BL/6J mice by exposure to a high fat (60% Kcal fat) diet with free access to water. After 14 days of high fat diet feeding, animals were treated orally, once daily (1 hour before dark cycle) for 30 days with BLX-1028 (5mg/Kg body weight). Compared with placebo treatment, BLX-1028 lowered the body weight gain by 14% without significant changes in food and water intake. Similarly in *ob/ob* (C57BL/6J-Lep$^{ob}$) mice, 10% reduction in body weight was observed in BLX-1028 treated animals in comparison to vehicle treated groups. Oral Glucose Tolerance test performed at day 0 and 30 showed an improvement in glucose tolerance in these mice. Further mechanism of action of BLX-1028 is currently being investigated. These combined results demonstrate the potential of BLX-1028 as a novel compound for the treatment of obesity and related disorders.

1423

**Molecular Mechanisms Underlying Pancreatic β-cell Loss in a Murine Model of Wolfram Syndrome**

H. Ishihara, T. Yamada, D. Takei, Y. Oka; Division of Molecular Metabolism and Diabetes, Tohoku University Graduate School of Medicine, Sendai, Japan

Wolfram syndrome, a rare autosomal recessive disorder characterized by juvenile onset diabetes mellitus, optic atrophy, diabetes insipidus and sensorineural deafness, is caused by mutations in the *WFS1* gene, which encodes an ER resident membrane protein. We have recently established mutant mice with disrupted *wfs1* gene and found that mutant mice exhibited impaired glucose homeostasis due to progressive β-cell loss and impaired stimulus-secretion coupling in insulin secretion. To further investigate mechanisms of β-cell dysfunction, we have conducted studies of cellular physiology and gene expression, especially focusing on ER functions and ER-stress responses, in *wfs1*-deficient cells. ER calcium concentrations, measured using ER-targeted aequorin, were lower in the *wfs1*-deficient cells, which seemed to be attributable to reduced capacitative calcium entry. We also found that increased PERK phosphorylation and XBP-1 expression, indicating that the ER stress responses were enhanced in *wfs1*-deficient islets. The enhanced ER stress responses were accompanied by increased expression of proapoptotic protein CHOP and by an increase in the cleaved form of caspase-3, indicating that ER stress-mediated apoptotic process is initiated in *wfs1*-deficient β-cells. In addition, we found that BrdU incorporation was reduced in the mutant islets. Interestingly, expressions of cell cycle regulators and of the translational control machinery were altered. These data suggest that WFS1-deficiency causes impaired ER calcium homeostasis in β-cells, leading to chronic activation of the ER-stress response, which then eventually results in increased apoptosis and impaired proliferation. Our data thus establish that, as is the case in Wolcott-Rallison syndrome with PERK mutations, ER stress is the pathological basis of Wolfram syndrome.

1424

**Organelle Dynamics during Chronological Aging of Calorie-Restricted Yeast Cells**

A. Goldberg,[1] C. Gregg,[1] T. Guo,[1] T. Boukh-Viner,[1] S. Bourque,[1] P. Kyryakov,[1] M. Noei,[1] R. Noei,[1] A. Brar,[1] R. A. Rachubinski,[2] Y. Gélinas,[3] A. M. English,[3] O. I. Petriv,[1] V. I. Titorenko[1]; [1]Biology Department, Concordia University, Montreal, PQ, Canada, [2]Department of Cell Biology, University of Alberta, Edmonton, AB, Canada, [3]Department of Chemistry and Biochemistry, Concordia University, Montreal, PQ, Canada

Calorie restriction (CR), a dietary regimen low in calories without undernutrition, significantly extends life span and delays most diseases of aging including cancer, atherosclerosis, type II diabetes and neurodegeneration. Even though benefits of CR have been known for many years, the molecular and cellular mechanisms of its action remains unclear. Growing evidence supports the view that the fundamental mechanism of aging is conserved from yeast to humans. We use the yeast *Saccharomyces cerevisiae* as a model system with which to study the molecular and cellular mechanisms of aging. Our research is aimed at understanding how defects in the biogenesis and function of the peroxisome, an organelle known for its role in lipid metabolism, affect life span of yeast. We identified a distinct set of peroxisome-associated proteins that function as global regulators of longevity and stress response in yeast cells placed on the CR diet. Using functional proteomics, we defined a network of protein components whose synthesis and degradation are regulated by these peroxisome-associated proteins. Analysis of mutants that lack individual components of this network demonstrated that many of these components are key determinants of life span and stress resistance of yeast. Using lipidomics, we analyzed the chronological changes in steady-state levels of various lipid species in cells and subcellular organelles of numerous short-living mutants. Our data suggest a model for the hierarchy of events that occur during the remodeling of metabolic pathways and inter-organellar communications in yeast cells placed on the CR diet.

1425

**Generation and Verification of Functional Insulin-producing Cells Derived from Embryonic Progenitor Cells**

J. Zhang,[1] R. Luo,[1] O. L. Kon,[2] F. Xie,[1] S. K. Lim,[3] G. LI[1]; [1]National University Medical Institutes, National University of Singapore, Singapore, Singapore, [2]Division of Medical Sciences, National Cancer Centre, Singapore, Singapore, [3]Stem Cell Biology, Genomic Institute of Singapore, Singapore, Singapore

Transplantation of human pancreatic islets is an efficient therapy for treatment of type 1 diabetes. However, only limited number of patients could benefit from this promising remedy because of the shortage of cadaver pancreas. Therefore, generation of propagational, functional insulin-secreting cells by differentiation of embryonic or adult stem/progenitor cells has become the enthusiastic approach. In this study, progenitor cell lines from early (E6.0-7.5) mouse embryos were differentiated into insulin-producing cells that were characterized by RT-PCR, radioimmunoassay, glucose responsiveness profile, and animal transplantation experiments. These cells could be expanded for >7 months without loss of insulin-producing phenotype or compromise in cell proliferation rate. They expressed mRNA for both proinsulin-1 and -2, but not other islet hormones. Their insulin and C-peptide contents were almost equal (about 7 μg/$10^6$ cells), indicating predominant biosynthesis of insulin. Elevation of glucose levels in the medium from 2.8 to 7-15 mM evoked membrane depolarization, raised cytosolic free $Ca^{2+}$ levels and significantly increased insulin secretion in these cells. Similar to islet beta-cells, such glucose-induced insulin secretion was enhanced by cAMP-elevating agents, but suppressed by diazoxide (hyperpolarization), verapamil (blocking $Ca^{2+}$ entry), or inhibitory hormones (somatostatin or epinephrine). Transplantation of these cells into the kidney subcapsules in streptozotocin-induced diabetic mice was able to ameliorate the hyperglycemia. Such insulin-producing cells are also non-tumorgenic, as they did not induce teratomas when implanted in SCID mice. Our data have demonstrated that the insulin-producing cells derived from mouse embryo progenitor cells exhibit many key properties of primary beta-cells and can be propagated in vitro for a long period. Our findings provide strong evidence for the feasibility of generating functional insulin-secreting cells from human ES cells for type 1

diabetes therapy.

1426

**Morphological Peculiarities of Heart and Coronary Vessels Damage in Patients with Type 2 Diabetes Mellitus**

A. L. Davydov, L. Y. Baranova; Department of Endocrinology, Moscow State Medical Stomatological University, Moscow, Russian Federation

At present great attention is paid to investigation of cardiovascular pathology and vascular complications in type 2 diabetes patents. The aim of the work was to study morphological peculiarities of heart and coronary vessels damage in type 2 diabetes patients with late vascular complications. Materials and Methods: We studied endomiocardial bioptates of 7 patients with type 2 diabetes mellitus (DM) and without coronary atherosclerosis obtained during coronarography and ventriculography. After special treatment the sections of different thickness (thin and ultrathin) were examined under light and electron microscopes. Results: We revealed morphological peculiarities of myocardium and coronary vessels damage in type 2 DM patients without clinical signs of atherosclerosis and ischemic heart disease, in particular, pronounced fatty degeneration of cardiomiocites, accumulation of a - and b-glycogen in them, micromitochondriosis with marked polymorphism, miofibril lysis, sarcoplasmic reticulum defects, mitochondria destruction with crysts loss, apoptosis signs as well as arterioles and small and medium arteries changes, namely, pronounced edema of endotheliocytes, occurrence of fenestrated capillaries that are not normally characteristic of myocardium, and hypertrophy of unstriated muscle cells. These changes were responsible for decrease in useful heart work and disturbed coronary vessels function. Conclusion: The morphological peculiarities of myocardium and coronary arteries damage can be indicative of united pathogenetic mechanisms of development of such diseases as type 2DM, atherosclerosis, ischemic heart disease, and can be responsible for early development of failing heart in type 2 CD patients without coronary atherosclerosis.

1427

**Screening of Differentially Displayed Genes Correlative to Diabetes with and without Chinese Herb Astragalus Membranaceus Treatment**

H. F. Zhao, Y. Wu, S. L. Huang; Department of Biochemistry and Molecular Biology, Shanghai Second Medical University, Shanghai, China

The worst consequence of Diabetes mellitus (DM) at the terminal stage is irreversible renal fibrosis. Several clinical researches have indicated that Chinese herb Astragalus membranaceus (AM) has ability to defer the progression of DM. In this work, we studied the molecular mechanism of AM to defer renal fibrosis. A rat model of type 1 DM with two groups was built: diabetes with (DA group) and without (D group) AM treatment. The total RNA from renal tissues was used for gene chip analysis and some differentially displayed genes were confirmed by real-time PCR. Two hundred and one differentially displayed genes have been found in the chip with 4096 genes, in which 126 genes were up-regulated and 75 genes were down-regulated. One of expression down-regulated genes is *Latent Transforming Factor Binding Protein 1 (LTBP1)*. An interference plasmid of psilencer-shLTBP1 was constructed and transfected into HK2 cells. The changes of gene expression of *LTBP1, TGFβ1, collagenI and collagenIII* were detected by RT-PCR. In psilencer-shLTBP1 transfected HK2 cells, mRNA expression of *LTBP1, TGFβ1, collagenI* and *collagenIII* were down-regulated by 59%, 45%, 50% and 75% respectively. Our results suggest that *LTBP1* can regulate the expression of *TGFβ1* which improves the synthesis of collagen. LTBP1 itself may be a fibrosis associated factor. Our findings provide new insights into the molecular mechanism of AM to defer renal fibrosis via regulating *LTBP1* expression.

1428

**Constitutive Phosphorylation of GSK3-beta by High Extracellular Glucose Impairs CTGF Stimulated Migration in Human Cells**

F. Furlong, J. Crean, L. Thornton, R. O'Leary, M. Murphy, F. Martin; School of Biomolecular and Biomedical Research, Conway Institute, Dublin, Ireland

Diabetic nephropathy (DN) occurs in 30% of diabetic patients and is the leading cause of end stage renal disease. Increasing evidence indicates that hyperglycemia induced cytoskeletal disassembly or mechanical dysfunction contributes to mesangial cell pathology in DN. Our objective was to investigate mesangial cell migration in response to CTGF in glucose stress. Human mesangial cells (HMCs) cultured in high ambient glucose fail to migrate as normal in response to CTGF stimulation in a scratch wound assay. Failure of cell migration under these conditions was associated with failure of cell polarization events, e.g. redistribution of microtubules, in the direction of migration and non-responsiveness of the determining PKC-ζ-GSK3-β signaling axis. This latter intracellular signaling pathway, required for cell polarization, was constitutively activated under conditions of hyperglycemia. We showed that basal PKC-ζ and GSK3-β phosphorylation levels are selectively increased in HMCs exposed to high extracellular glucose for 48 h and that CTGF fails to further increase their levels. Acute exposure to high extracellular glucose (6 h) results in increased PKC-ζ and GSK3-β phosphorylation and this occurs downstream of p42/44 MAPK, PI 3-kinase and PKC-β activity. In normoglucose, CTGF induces HMC migration and the phosphorylation of PKC-ζ and GSK3-β, most likely through cdc-42 activation. However, after exposure to high glucose cdc-42 is also unresponsive to CTGF. Our data indicates that a tightly regulated and localized activation of signaling is essential for HMC migration in response to CTGF. The specific PKC-β inhibitor LY379196 suppressed the high glucose induced GSK3-β phosphorylation and restored CTGF-induced HMC migration in cultures exposed to high extracellular glucose. This hyperactivation of GSK3-β by PKC-β may establish a role for it in the progression of mesangial cell hyporesponsiveness in diabetic nephropathy progression.

1429

**Complete Proteomic Analysis of Purified Adiposomes from CHO K2 Cells**

R. Bartz,[1] J. K. Zehmer,[1] M. Zhu,[1] Y. Chen,[1] R. G. W. Anderson,[1] Y. Zhao,[2] P. Liu[1]; [1]Cell Biology, UT Southwestern Medical Center, Dallas, TX, [2]Biochemistry, UT Southwestern Medical Center, Dallas, TX

Adiposomes, or lipid droplets, are intracellular organelles with a neutral lipid core surrounded by a layer of phospholipid and protein. Recently, mass spectrometry has been used to identify the abundant proteins in the adiposome; however, potentially important low abundance proteins remain to be identified. Therefore, we used mass spectrometry to obtain a more complete picture of the proteins associated with highly purified CHO K2 adiposomes. Adiposome proteins were separated by one-dimensional gel electrophoresis and the gel cut into 34 pieces of equal size. The proteins in each piece were digested and the peptides were identified by mass spectrometry. This approach was supplemented by Western blot analyses of key proteins. We identified 122 proteins that include: 17 Rab GTPases; 14 proteins involved in membrane traffic; 14 cytoskeletal proteins; 16 proteins involved in lipid metabolism and 15 signaling proteins. Surprisingly, ARF1, another major membrane trafficking regulator, its

target protein membrin, and Arf GAP were among the proteins. We also found several proteins usually found in mitochondria, ER and peroxisomes, which is consistent with morphologic studies in yeast and metazoan cells showing an association of these organelles with lipid droplets. The abundance of proteins involved in intracellular trafficking and lipid synthesis support our hypothesis that adiposomes are organelles specialized not only for lipid storage but also intracellular lipid traffic and signal transduction.

1430

**High Content Screening of NPC1 Cells: Identification of Hit Compounds that Reduces Cholesterol Accumulation in Cultured Cells**

N. H. Pipalia, A. Y. Huang, H. Ralph, M. Rujoi, F. R. Maxfield; Biochemistry, Weill Medical College of Cornell University, New York, NY

High content screening of NPC1 cells: Identification of hit compounds that reduces cholesterol accumulation in cultured cells Niemann-Pick disease type C1 (NPC1) is an autosomal recessive genetic disorder that causes an abnormal accumulation of cholesterol and other lipids in many cell types. Despite several attempts to develop treatments for NPC1 disease currently there is no effective therapy to correct this disorder. In order to identify chemicals that would correct the NPC1 phenotype in tissue culture cells, previously we developed a robust high content microscopy based assay to screen a library of combinatorially synthesized compounds (ChemDiv, Inc.). We chose CHO cells with NPC1 defects as our model system and exploited fluorescent property of cholesterol-binding detergent filipin for automated microscopy based high throughput screening. Our primary screen of 14,956 chemicals had identified 14 compounds that reproducibly reduced filipin staining in cells at 10 μM. A secondary screen of an additional 3962 structurally similar compounds to the primary hits identified an additional 6 compounds that are non-toxic and effective at sub-μM concentrations in reducing free cholesterol content as observed by reduction in filipin intensity. The screening results were validated by an alternative biochemical determination of free cholesterol content by gas chromatography. Preliminary results indicate that some of these compounds are also effective in reducing cholesterol accumulation in human fibroblasts obtained from NPC1 patients. We are now screening the secondary library on two human fibroblast lines obtained from NPC1 patients. The molecular mechanism and structure activity relationship for these classes of compounds is also being evaluated. Supported by the Ara Parseghian Medical Research Foundation.

**Study of Cholesterol Pathways Affected by Small Molecules that Partially Revert Niemann-Pick Type C1 Phenotype in Cultured Cells**

M. Rujoi, N. H. Pipalia, A. Y. Huang, H. Ralph, F. R. Maxfield; Biochemistry, Weill Medical College of Cornell University, New York, NY

Niemann-Pick type C1 disease (NPC1) is a fatal neurovisceral multi-lipid-storage disorder. Its hallmark is the defect in cholesterol efflux from lysosomal storage organelles (LSOs). Effective therapeutic treatments are not available. Based on the cholesterol-binding fluorophore, filipin, our lab developed an automated fluorescence microscopy screening method to identify chemicals that correct NPC1 phenotype in cultured cells. From a screen of 14,956 compounds and a follow-up of additional 3,962 we identified 2 sets (S1 and S2) of 14 and 6 hit compounds, respectively that reduce filipin staining of LSOs. Moreover, compounds from S2 decrease the overall cellular cholesterol levels, as confirmed by gas chromatography analysis. The impact of selected compounds on the major intracellular cholesterol pathways in NPC1 cultured cells was analyzed. Cholesterol export from LSOs and transport to extracellular acceptors was monitored before and after compound-treatment using [$^{3}$H]-cholesterol. The majority of compounds (10 chemicals from S1 and 5 from S2) increased cholesterol efflux. A second key pathway is the transport to the ER, where cholesterol gets esterified by acyl-coenzyme A: cholesterol acyltransferase (ACAT). The cholesterol ester formed by ACAT is incorporated in lipid droplets and can then be hydrolyzed by neutral cholesteryl ester hydrolase (NCEH). Incorporation of [$^{14}$C]-oleate into cholesteryl-[$^{14}$C]-oleate was used as a measure of cholesterol esterification by ACAT. Among the 20 selected compounds only one promotes ACAT-mediated esterification. However, quantification by gas chromatography of esterified cholesterol revealed increased ester levels upon treatment with 7 compounds from S1 and 5 from S2. Inhibition of NCEH upon compounds addition could explain the increase in cholesterol ester levels. In conclusion, cholesterol extracellular efflux and/or esterification are the main mechanisms affected by selected compounds to partially correct NPC defect in cultured cells.

**Defective Endocytic Pathways in Lipid Storage Disorders**

S. Muro,[1,2] V. Muzykantov,[1,2] E. Schuchman[3]; [1]Institute for Environmental Medicine, University of Pennsylvania Medical School, Philadelphia, PA, [2]Department of Pharmacology, University of Pennsylvania Medical School, Philadelphia, PA, [3]Department of Human Genetics, Mount Sinai School of Medicine, New York, NY

Lipid storage caused by inherited deficiency of lysosomal hydrolases, cofactors or transporters, impairs intracellular lipid trafficking. Poor uptake of recombinant hydrolases by storage cells suggests that internalization of extracellular ligands may also be impaired. To evaluate whether endocytosis is affected in these diseases, we used fluorescence microscopy to test dextran pinocytosis, clathrin-mediated uptake of transferrin, and caveoli-mediated uptake of cholera-toxin by skin fibroblasts from Gaucher, Fabry, type B and C Niemann-Pick (NPB, NPC) patients, characterized by deficiency of glucocerebrosidase, α-galactosidase-A, acid sphingomyelinase, and NPC1 transporter, respectively. Normal cells internalized 120±14 dextran-positive vesicles (1h-37°C). MDC, filipin, and amiloride, which inhibit uptake by clathrin pits, caveoli, and macropinocytosis, decreased dextran internalization (52±8%, 68±10%, 63±10%). A cocktail of the three drugs abolished uptake (7±4%), indicating that the three pathways contribute to fluid-phase endocytosis. Dextran uptake was reduced in all storage cells (<75±6% of normal cells). MDC did not further inhibit dextran uptake (>92±13% of untreated cells). Inhibition by filipin was less marked for NPB and NPC (>84±11%), and inhibition by amiloride was decreased in NPB (81±11%) and increased in NPC (34±6%). Dextran uptake in EGF-treated cells, inducing macropinocytosis, was decreased in NPB and increased in NPC (80±10% and 155±12% of normal cells). Internalization of cholera-toxin pre-bound to the cell membrane was decreased in NPB and NPC (<63±6% of normal cells). Uptake of pre-bound transferrin was affected in all storage cells (<48±3% of normal cells). These results indicate that: 1-clathrin-mediated endocytosis is affected in Gaucher, Fabry, NPB and NPC; 2-uptake via caveoli is decreased in NPB and NPC; and 3-macropinocytosis is slightly decreased in NPB and increased in NPC. Altered endocytosis may represent a common mechanism contributing to cellular dysfunction in storage disorders, and may add to suboptimal enzyme delivery by therapeutic strategies based on deficient receptors.

**IFN-gamma-inducible Protein (IP-10) Produced By Osteoclast Precursors Mediates Rheumatoid Arthritis**

H. Kwak, D. Yang, H. Ha, H. Kim, J. Lee, H. Kim, H. Kim, Z. Lee; Cell and Developmental Biology, Seoul National University School of Dentistry, Seoul, Republic of Korea

IFN-γ-inducible protein (IP-10), a CXC chemokine important in the activation of T cells, is induced by IFN-γ in a variety of cell types and plays a role in the infiltration of T cells to sites of inflammation. However, the roles of IP-10 in rheumatoid arthritis are mainly unknown. Here we show that the expression of IP-10 was increased in RANKL stimulated osteoclast precursors but not in mature osteoclasts. RANKL induces IP-10 expression through a STAT1-dependnet pathway in osteoclast precursors. IP-10 stimulates the expression of RANKL and TNF-α in $CD4^+$ T cells and induces osteoclastogenesis. We examined the role of IP-10 in a mouse model of collagen-induced arthritis (CIA). ELISA analysis revealed that the expression of IP-10, RANKL, and TNF-α increased in serum of CIA mice. Treatment with the neutralizing anti-IP-10 antibody significantly inhibited infiltration of $CD4^+$ T cells and macrophages into the synovium and attenuated bone destruction in the inflamed joints of CIA mice. Furthermore, the levels of RANKL and TNF-α were inhibited by anti-IP-10 antibody in CIA mice. Also, bone erosion in the knee joint was observed in mice infected with an IP-10-containing retrovirus. Taken together, our findings suggest that IP-10 plays a critical role in the infiltration of $CD4^+$ T cells and macrophage into inflamed joints and causes osteoclastogenesis through production of RANKL and TNF-α. Our result provides the first evidence that IP-10 contributes to the recruitment of inflammatory cells into joint and is involved in rheumatoid arthritis.

**Rhodopsin Resists Oxidative Modification During Light- and Metabolically-Induced Retinal Degeneration**

S. J. Fliesler,[1] M. J. Richards,[2] B. J. Kapphahn,[3] D. A. Ferrington[3]; [1]Ophthalmology and Pharmacol. Physiol. Sci., Saint Louis University, St. Louis, MO, [2]Ophthalmology, Saint Louis University, St. Louis, MO, [3]Ophthalmology, Univ. of Minnesota, Minneapolis, MN

Oxidation of proteins has been implicated in various neurodegenerative processes. This includes covalent modification with lipid-derived adducts, such as 4-hydroxynonenal (HNE), 4-hydroxyhexenal (HHE), and carboxyethylpyrrole (CEP), as well as nitrosylation of tyrosine (NT). Retinal degeneration is exacerbated by exposure to intense constant light ("retinal light damage"). Lipid hydroperoxide accumulation correlates positively with retinal degeneration in both albino rats exposed to light-damage conditions (see Organisciak & Winkler, *Prog. Ret. Eye Res.* 13:1, 1994), and in a rat model of Smith-Lemli-Opitz Syndrome (SLOS; see Fliesler et al., *Arch. Ophthalmol.* 122:1190, 2004). Here, we examined oxidative modification of rhodopsin, the retinal rod visual pigment and predominant outer segment (OS) membrane protein, in these two retinal degeneration models. Pairs of animals were exposed for 24 h to intense green light (1700 lux, 490-580 nm), while the unexposed cohort was kept in darkness. OS membranes were prepared from pairs of retinas for each condition; in parallel, one eye of each animal was taken for morphological analysis. Proteins were resolved by SDS-PAGE, with and without pre-boiling: one gel from each group was silver-stained (SS), while companion gels were blotted and probed with polyclonal antibodies to opsin, HNE, HHE, CEP, or NT. Rhodopsin was not immunopositive to any of these antibodies. Upon boiling, it oligomerized and shifted to the stacker-resolving gel interface, exposing a set of immunopositive bands in the $M_r$ 31-45 kDa region (previously including rhodopsin). We conclude that rhodopsin resists oxidative modifications induced by either intense light or under conditions that mimic SLOS, while other OS-resident proteins do become oxidized. Thus, oxidative damage to opsin is not a primary event in the etiology of these retinal degenerations. [EY07361, EY14176, RPB]

**TRIM37 Is an Ubiquitin E3 Ligase That Interacts with Aryl Sulphotransferase SULT1A2**

J. P. Kallijarvi, R. H. Hamalainen, A. E. Lehesjoki; Dept. Medical Genetics, University of Helsinki and Folkhalsan Institute of Genetics, Helsinki, Finland

Mulibrey nanism (muscle-liver-brain-eye nanism) is a rare growth disorder syndrome of prenatal onset. Mutations in the *TRIM37* gene underlie mulibrey nanism. To date, 11 mulibrey nanism-associated mutations, of which nine are truncating and two are missense mutations, have been described. The pathogenetic mechanisms of mulibrey nanism are unknown. *TRIM37* encodes a member of the TRIM (tripartite motif, RING-B-Box-Coiled-Coil) protein subfamily of zinc-finger proteins, many of which possess ubiquitin ligase activity. We have shown that TRIM37 is subject to RING domain-dependent autoubiquitination, suggesting that it functions as an ubiquitin ligase. A patient mutation causing a Leu76Pro amino acids change, located between the RING and the first B-box domain of TRIM37, abolishes autoubiquitination suggesting that ubiquitin ligase activity is central to the pathogenesis of mulibrey nanism. Here, we used yeast two-hybrid screening to identify proteins that interact with TRIM37. In a screen with a TRIM domain bait we identified a clone containing a putative splice variant of *hast4/SULT1A2* cDNA. GST pull-down experiments confirmed that both the alternative isoform encoded by the yeast clone and the full-length SULT1A2 protein, but not the related enzymes SULT1A3 and SULT1C1, bind to the TRIM domain of TRIM37. SULT1A2 showed a homogenous cytosolic localization when expressed in COS-1 cells. When co-expressed with TRIM37 SULT1A2 localized to cytosolic aggregates. Moreover, co-expression of SULT1A2 and TRIM37 in COS-1 cells resulted in polyubiquitination of SULT1A2. Sulfonation is an important step in the metabolism of many drugs, xenobiotics, neurotransmitters, and steroid hormones. Mulibrey nanism patients display multiple endocrine defects, including hypogonadism, failure of sexual maturation and adrenal hypoplasia. The identification of SULT1A2 as an interaction partner for TRIM37 raises the possibility that dysregulated metabolism of steroid hormones and/or neurotransmitters could play a role in the pathogenesis of mulibrey nanism.

1436

**Unraveling the Cell Biology of 3-Methylglutaconic Aciduria**

M. Huizing,[1] L. Ly,[1] H. Dorward,[1] B. Feldman,[1] Y. Anikster,[2] W. A. Gahl[1]; [1]NHGRI, NIH, Bethesda, MD, [2]Safra Children Hospital, Sheba Medical Center, Tel-Hashomer, Israel

3-Methylglutaconic aciduria (3MGA) comprises a group of urinary organic acid abnormalities, which can result from mitochondrial defects (leucine degradation) or peroxisomal defects (mevalonate shunting). Types I and II 3MGA are caused by defects in mitochondrial proteins, and Type III 3MGA results from abnormalities of OPA3, a protein of unknown function. In addition, a large group of patients exist with unexplained 3MGA (Type IV 3MGA). Since OPA3 contains an N-terminal mitochondrial leader sequence and a C-terminal peroxisomal targeting signal, we studied OPA3 function to gain more insights into 3MGA metabolism. The *OPA3* gene is known to consist of two exons coding for 179 amino

acids. However, we identified a novel *OPA3* transcript consisting of the common exon 1 spliced directly to a 3rd exon (ex 1-3). This transcript is conserved in other species, and exon 3 closely resembles exon 2, suggesting a common evolutionary origin. Molecular analysis of 11 patients with type IV 3MGA did not reveal exon 3 mutations. Normal fibroblasts were electroporated with Green Fluorescent Protein-tagged OPA3 fusion proteins (ex 1-2 and ex 1-3 transcripts) with or without mutated mitochondrial and/or peroxisomal targeting signals. Confocal microscopy clearly demonstrated a mitochondrial localization for both transcripts (ex 1-2 and ex 1-3). However, only the ex 1-2 transcript also localized to peroxisomes. This rare dual localization could help further elucidate the biochemical function of OPA3. To further explore OPA3 function, we created zebrafish models using antisense morpholinos. The mutant fish showed unique features, including small eyes with severely affected optic nerves, delayed development, kinked tails and spastic movements - all resembling human Type III 3MGA symptoms. These zebrafish models promise to further reveal the biochemical function of OPA3 and assist in the development of possible therapies for this group of disorders.

**Fucose Mutarotase, a Novel Component in Fucose Utilization via the Salvage Pathway**

D. Park, K. Kim, D. Choi, C. Park; Department of Biological Sciences, Korea Advanced Institute of Science and Technology, Daejeon, Republic of Korea

Monosaccharides exist as a cyclical pair of isomers, the α- and β- anomers, that differ only in the configuration of the anomeric carbon atom. L-fucose is a monosaccharide normally present in mammals and is utilized presumably for glycosylation. The first step in intracellular fucose utilization through the salvage pathway is known to be a phosphorylation by fucokinase. We discovered a novel component in fucose utilization, which involves the interconversion between the α- and β- anomers of fucose. The mouse and human genes encoding fucose mutarotases belong to the FucU family of proteins, whose prokaryotic homologs have been characterized recently (Ryu *et al.*, 2004, JBC, 279: 25544-8). Using the saturation difference NMR analysis, we were able to demonstrate that the mammalian homologs have similar mutarotase activities. When we overproduced the mutarotase by generating a stable cell line from HepG2, intracellular accumulation of lipid as well as a change in cell morphology was observed. We speculate that this may occur due to a facilitated incorporation of fucose through the salvage pathway, eventually leading to an enhanced glycosylation of various cellular proteins.

1438

**Evaluation of the Glycosylation Status of Alpha-dystroglycan in Hereditary Inclusion Body Myopathy (HIBM)**

P. J. Savelkoul,[1] S. Sparks,[1] G. Rakocevic,[2] R. Klootwijk,[1] C. Ciccone,[1] M. Dalakas,[2] D. Krasnewich,[1] W. A. Gahl,[1] M. Huizing[1]; [1]Section on Human Biochemical Genetics, MGB, NHGRI, NIH, Bethesda, MD, [2]Neuromuscular Disease Section, NINDS, NIH, Bethesda, MD

Hereditary Inclusion Body Myopathy (HIBM) is an adult onset autosomal recessive neuromuscular disorder characterized by slowly progressive myopathic weakness and atrophy. HIBM is caused by mutations in UDP-GlcNAc 2-epimerase (GNE)/N-acetylmannosamine kinase (MNK), the bi-functional and rate-limiting enzyme in sialic acid biosynthesis. We developed individual GNE and MNK enzymatic assays and determined reduced activities in cultured fibroblasts of patients with HIBM harboring missense mutations in either or both GNE and MNK enzymatic domains. To assess the effects of individual mutations on enzyme activity, normal and mutated GNE/MNK enzymatic domains were synthesized in a cell-free *in vitro* transcription-translation system and subjected to the GNE and MNK enzymatic assays. This revealed that mutations in one enzymatic domain affected not only that domain's enzyme activity but also the activity of the other domain. This loss of enzyme activity impairs sialic acid production, which may interfere with proper sialylation of glycoconjugates. We investigated how this would lead to muscle pathology. First, we demonstrated normal iso-electric focusing (IEF) patterns of transferrin in HIBM patients' serum, suggesting normal N-linked glycosylation. Next, we performed immunohistochemistry on HIBM muscle employing antibodies against components of the dystrophin-glycoprotein complex. Beta-dystroglycan and laminin-alpha 2 showed normal patterns, but antibodies recognizing O-linked glycan epitopes of alpha-dystroglycan (α-DG) showed reduced staining. α-DG contains both O-GalNAc and O-mannose linked glycans; the latter are rare in mammals. Finally, we showed normal IEF patterns of apolipoprotein C-III, which contains only O-GalNAc linked glycans, suggesting that O-GalNAc glycosylation is unaffected in HIBM. These findings suggest a defect in O-mannosylation of α-DG in HIBM. Understanding the function and regulation of the O-linked mannose pathway is essential for developing diagnostic tests and therapies for HIBM and other muscular dystrophies with similar pathology.

1439

**Tissue Specificity and Evolutionary Conservation of Vps33 Homologues**

P. Gissen,[1] C. A. Johnson,[1] L. D. Hurst,[2] A. J. Doherty,[3] E. R. Maher[1]; [1]Section of Medical and Molecular Genetics, University of Birmingham, Birmingham, United Kingdom, [2]Department of Biology and Biochemistry, University of Bath, Bath, United Kingdom, [3]UK Genome Damage and Stability Centre, University of Sussex, East Sussex, United Kingdom

Mutations in *VPS33B* cause ARC syndrome, a lethal multi-system disease which affects infants and cause abnormalities of the liver, kidneys, central nervous system and platelets.VPS33B protein is a homologue of yeast class C vacuolar protein sorting (Vps33p) protein, involved in biogenesis and function of vacuoles. Two Vps33 homologues (A and B) are present in most organisms. There are no mouse *VPS33B* knockouts to model ARC, but inactivation of mouse *Vps33a* causes *buff* phenotype, characterized by pigment defects and platelet abnormalities. **Objectives.** Identify functional characteristics of the A and B homologues of Vps33p in different organisms. **Methods.** After performing homology searches, multiple sequence alignment for the vps33p protein homologues was performed using ClustalW. Two phylogenetic trees were then created using MrBayes and also Tree Puzzle, a quartet puzzling maximum likelihood method. Putative functional motifs were modeled using Rasmol. Evolutionary conserved regions in VPS33B and VPS33A were identified by calculating Ka/Ks ratio. Labeled wild-type and truncated constructs of Vps33p homologues were transfected into human renal cells and also mouse melanocytes and the effect of clustering on lysosome related organelles was assessed by immunofluorescence. **Results.** Two homologues of yeast vps33p were identified in the worm, fly, zebrafish, rodent and human genomes. A novel *Drosophila* orthologue of VPS33B was identified, whereas *car* gene product Carnation was found to be an orthologue of VPS33A rather than VPS33B. Conserved functional domains within VPS33B were found and their deletion impaired the clustering effect of the expressed protein. VPS33B induced significantly more clustering of late endosomes and lysosomes than VPS33A in renal cells whilst VPS33A was more efficient at inducing clustering of melanosomes in melanoma cells. This is the first documented evidence of organelle and tissue specificity of the clustering effect.

**Constitutive Clathrin-Mediated Endocytosis of ATP-Sensitive Potassium Channels: the Role of Tyrosine-Based Signals**

A. J. Smith,[1] J. Mankouri,[1] T. K. Taneja,[1] S. Ponnambalam,[2] A. Sivaprasadarao[1]; [1]School of Biomedical Sciences, University of Leeds, Leeds, West Yorkshire, United Kingdom, [2]School of Biochemistry and Microbiology, University of Leeds, Leeds, West Yorkshire, United Kingdom

ATP-sensitive potassium ($K_{ATP}$) channels are involved in numerous physiological processes including the regulation of insulin secretion and the protection of neuronal and cardiovascular cells during periods of metabolic stress. Pancreatic $K_{ATP}$ channels are octomers composed of 4 subunits each of Kir6.2 and SUR1. Because their level of activity is determined not only by the open probability, but also by the density of the channels at the cell surface, we investigated if these channels can undergo endocytosis. For this, we tagged the channels with an extracellular HA epitope in the Kir6.2 subunit, expressed in mammalian cell lines, and examined the mechanism of internalisation using immunofluorescence/confocal microscopy and biochemical approaches. Site-directed mutagenesis was used to alter the sequence of putative motifs required for endocytosis. Our data demonstrate that $K_{ATP}$ channels undergo rapid clathrin-dependent internalisation from the cell surface with subsequent trafficking to perinuclear compartments that are positive for TGN46 and Mannose-6-Phosphate Receptor. Co-localisation with the transferrin receptor positive recycling compartment was found to be limited. Motifs involved in endocytosis seem to be located exclusively in the C-terminal tail of the Kir6.2 subunit. Whilst mutation of the $^{355}$LL$^{356}$ motif has no significant effect on internalisation, mutation of either of the two tyrosine-based motifs ($^{258}$YHVI$^{261}$ and $^{330}$YSKF$^{333}$) inhibited internalisation significantly. Mutation of both tyrosines, however, was required to completely prevent endocytosis, suggesting that multiple signals control internalisation, and hence the surface density of the channels. These findings may have implications for insulin secretion and other $K_{ATP}$-dependent protective mechanisms during ischemia of the heart and the brain. Funded by the MRC-UK.

**Characterization of a Hyaluronidase 1 Deficient Mouse Model**

D. C. Martin, V. Atmuri, R. J. Hemming, B. L. Triggs-Raine; Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, MB, Canada

Hyaluronidases are endoglycosidases that degrade hyaluronan (HA), an abundant component of the extracellular matrix surrounding all vertebrate cells. HA is especially abundant in loose connective tissues and in processes that require rapid proliferation and migration. While six hyaluronidase genes are known in humans, their roles in HA degradation have not been elucidated. A deficiency of one of these enzymes, Hyaluronidase 1 (HYAL1), causes a lysosomal storage disease with a mild clinical phenotype. We obtained an uncharacterized Hyal1 deficient mouse model (Stern et al., *Matrix Biol.* 20(8):499). Our objective is to examine the Hyal1 contribution to HA degradation and the pathology associated with its deficiency. Wild-type (+/+), heterozygous (+/-) and deficient (-/-) animals were generated. We have used Southern blotting and sequencing of PCR products generated from -/- genomic DNA to demonstrate that the neomycin resistance (Neo) cassette is inserted in exon 2 of *Hyal1*. This resulted in a deletion of 750 bp of coding sequence including the predicted active site of the protein. Deficient animals reveal no wild-type *Hyal1* transcript by RT-PCR analysis of liver mRNA. Northern analysis of surrounding genes shows no alteration in their levels of expression due to the incorporation of the Neo cassette. Deficient animals contain no detectable Hyal1 protein or serum hyaluronidase activity by immunoblot and zymographic analysis respectively. Preliminary results of heterozygous breedings suggest an altered male sex ratio. Instead of a 1:2:1 (+/+: +/-: -/-) genotype ratio, a 1:2:2 (n= 45) ratio is observed. Animals display no gross phenotypic abnormalities and are healthy up to 1 year of age. Histological examination of tissues to examine morphology and substrate accumulation is in progress. Our data indicates that this represents a model of complete Hyal1 deficiency and there are no gross morphological changes due to HA accumulation.

1442

**Trafficking of Human Lysosomal Sialidase (neu1) to the Cell Surface**

S. Pattison,[1] J. P. King,[1] H. Kufaishi,[1] D. Aboutouk,[1] R. Truant,[2] B. Trigatti,[2] S. A. Igdoura[1,3]; [1]Biology, McMaster University, Hamilton, ON, Canada, [2]Biochemistry, McMaster University, Hamilton, ON, Canada, [3]Pathology and Molecular Medicine, McMaster University, Hamilton, ON, Canada

Lysosomal sialidase hydrolyzes sialic acid from glycolipids and glycoproteins. The interaction between cathepsin A, β-galactosidase, and sialidase is required for sialidase localization and activity within lysosomes. The role of cathepsin A, is closely tied to targeting of sialidase and catalytic activation. Trafficking of human lysosomal sialidase has been reported to be mediated by binding to immature cathepsin A (CA), and utilizing the CA mannose 6-phosphate receptor signal for transport from the Golgi to the lysosome directly. However, other studies suggested that T-cells have immature complexes of cathepsin A-sialidase at their cell surface, postulating the possibility of an indirect trafficking pathway from the Golgi to the surface membrane to the lysosome. In this study, we created truncated forms of the sialidase and examined their intercellular localization and their association with PPCA. The truncations represented progressively shorter carboxyl termini (p.N261X, p. G321X and p.S355X). Using immunofluorescence and co-localization of the truncated sialidase mutants with Golgi, lysosomal and endosomal markers, we determined the intercellular localization of each truncation mutant. Using a sialidase-monomeric red fluorescent protein fusion construct (Sial-mRFP) and live real time microscopy, we investigated the trafficking pathway of lysosomal sialidase in primary sialidosis fibroblasts and HeLa cells. We combined the sial-mRFP with markers for Golgi and endosomes and determined that Sial-mRFP co-localizes with Golgi elements but not with endosomes. Additionally, treatment with Brefeldin A for 15 minutes revealed a transient appearance at the cell membrane followed by the presence in lysosome-like punctate structures which were not endosomes. We conclude that sialidase follows an indirect pathway to the lysosome via the cell surface; however, that routing mechanism may not require the putative YXXϕ present on its carboxyl terminal.

**The mTOR Pathway is Regulated by Polycystin-1 and Pharmacological Inhibition of mTOR Significantly Improves the Renal Cystic Phenotype in Polycystic Kidney Disease**

J. M. Shillingford,[1] N. S. Murcia,[2] S. Low,[1] R. Hedgepeth,[3] N. Brown,[2] C. A. Flask,[4] A. C. Novick,[3] D. A. Goldfarb,[3] A. Kramer-Zucker,[5] G. Walz,[5] K. B. Pinotek,[6] G. G. Germino,[6] T. Weimbs[1]; [1]Molecular, Cellular and Developmental Biology, University of California, Santa Barbara, CA, [2]Department of Pediatrics, Case Western Reserve University, Cleveland, OH, [3]Glickman Urological Institute, The Cleveland Clinic,

Cleveland, OH, [4]Departments of Radiology and Biomedical Engineering, Case Western Reserve University, Cleveland, OH, [5]Department of Medicine, Nephrology, University Hospital Freiburg, Freiburg, Germany, [6]Department of Medicine, Johns Hopkins University, School of Medicine, Baltimore, MD

The objective of this work was to investigate the contribution of the mammalian target of rapamycin (mTOR) pathway as it relates to the development of renal cysts in polycystic kidney disease (PKD). Herein we show that mTOR and a downstream effector, S6 kinase, are specifically phosphorylated in cyst-lining epithelial cells of renal samples derived from human autosomal dominant PKD (ADPKD) patients and mouse models of PKD but not normal renal samples. Furthermore, using a renal (MDCK) cell culture model engineered to express selective portions of the polycystin-1 (PC1) cytoplasmic tail we have shown that the N-terminal half of the PC1 tail co-localizes with mTOR and tuberin and, by co-immunoprecipitation, directly binds to tuberin. We hypothesized that if the mTOR pathway contributes to renal cyst formation then inhibition of mTOR activity would slow disease progression. To test this hypothesis we treated two genetic mouse PKD models with rapamycin, a specific mTOR inhibitor. These studies revealed that rapamycin treatment significantly improved the renal cystic phenotype as assessed by decreased serum blood urea nitrogen (BUN) levels, kidney weight and cystic index. To demonstrate relevance to human ADPKD we took advantage of the fact that some ADPKD patients retain at least one affected kidney and receive rapamycin treatment in the form of immunosuppressant therapy following renal transplantation. Using predetermined criteria for patient selection and volume analysis of CT scans we documented a significant reduction in ADPKD kidney volume in rapamycin- vs. non-rapamycin-treated patients. In conclusion, we have demonstrated that the mTOR pathway is abnormally and specifically activated in cyst-lining epithelial cells in ADPKD and present data that rapamycin treatment may represent a means of therapeutic intervention in this disease.

### Absence of Flow-induced $Ca^{2+}$ Signaling in Human Autosomal Dominant Polycystic Kidney Disease Cyst Cells

C. Xu,[1] R. L. Bacallao,[2] S. Rosetti,[3] P. C. Harris,[3] A. Wandinger-Ness,[4] S. L. Alper[1]; [1]Medicine, Beth Israel Deaconess Med. Ctr., Harvard Med. School, Boston, MA, [2]Medicine, Indiana Univ. School Med, Indianapolis, IN, [3]Medicine, Mayo Medical School, Rochester, MN, [4]Medicine, University of New Mexico Health Sci. Ctr., Albuquerque, NM

Aberrant function of the primary apical cilium of renal epithelial cells is thought to underlie the pathogenesis of autosomal dominant polycystic kidney disease (ADPKD). The PKD1 gene product polycystin-1 (PC1) and the PKD2 gene product polycystin-2 (PC2) co-localize in cilia of mouse renal epithelial cells, where they are believed to contribute to flow-sensitive mechanosensing. We have found that acetylated α-tubulin-positive cilia of confluent normal human kidney epithelial cells in primary culture contain both PC1 and PC2. However, PC1 is only rarely detected in PC2-positive cilia of cyst cells obtained from an ADPKD patient with a novel heterozygous germline deletion of one amino acid in exon 18 of the PKD1 gene. Confluent normal kidney cells respond to graded increases in laminar shear stress with graded, transient increases in $[Ca^{2+}]_i$ dependent on extracellular $Ca^{2+}$, but laminar flow fails to elicit elevation of $[Ca^{2+}]_i$ in ADPKD cyst cells. Flow-induced $Ca^{2+}$ signaling is blocked by the mechanosensitive channel (MSC) inhibitor GsMTx-IV, by ryanodine and by 2-APB, but not by the phospholipase C inhibitor U73122. Expression at the normal cell surface and primary cilium of a transmembrane fusion protein encoding the C-terminal portion of the PKD1 cytoplasmic tail, PKD1(115-226) partially inhibited flow-induced $[Ca^{2+}]_i$ increase. These data support the hypothesis that normal function of PC1 in the primary cilium in human kidney epithelial cells contributes to mechanosensitive $Ca^{2+}$ influx. (Supported by NIH DK57662 and DK69049).

### Mutant α-Actinin-4 Causes Defects in Cytoskeletal Dynamics and Cell Motility

J. R. Michaud, C. R. J. Kennedy; Ottawa Health Research Institute, Kidney Research Centre, Ottawa, ON, Canada

Mutations in the *ACTN4* gene, encoding the actin filament crosslinking protein α-actinin-4, are associated with a familial form of focal segmental glomerulosclerosis (FSGS). α-Actinin-4 is highly expressed in the foot processes of glomerular podocytes and plays a key role in maintaining the cell's arborized morphology. Though FSGS-associated mutant α-actinin-4 exhibits increased affinity for actin, the downstream effects of this aberrant binding upon cellular dynamics and morphology remain unclear. When overexpressed in mouse podocytes, wildtype α-actinin-4 localized to cortical actin and focal adhesions, with some expression along actin stress fibers. Mutant α-actinin-4 associated predominantly with stress fibers and focal adhesions however, it was excluded from cortical actin. Wildtype and mutant α-actinin-4-expressing cells adhered equally to an extracellular matrix (collagen I) as determined by microplate adhesion assay. When replated onto collagen I-coated coverslips, wildtype but not mutant α-actinin-4-expressing cells spread efficiently. In these newly adherent cells, wildtype α-actinin-4 was localized to the cell membrane, while mutant α-actinin-4 remained condensed within the rounded cell body. Mutant α-actinin-4 also reduced cell motility by 50% as determined by haptotaxis assay. Lastly, wildtype α-actinin-4 favored the formation of long and narrow projections, reminiscent of podocyte foot processes observed *in vivo*. Expression of wildtype α-actinin-4 increased the mean number of processes (5.2 /cell vs. 3.9 /cell for control), while cells expressing mutant α-actinin-4 had fewer processes (2.6 /cell). These data suggest that aberrant sequestering of mutant α-actinin-4 results in significant defects in cell spreading and motility. Furthermore, mutant α-actinin-4 reduces the number of podocyte processes, and may thereby contribute to foot process effacement observed in *ACTN4*-associated FSGS.

### NIMA-Related Kinases Defective in Murine Models of Polycystic Kidney Diseases Localize to Primary Cilia and Centrosomes

M. R. Mahjoub, M. L. Trapp, L. M. Quarmby; Molecular Biology and Biochemistry, Simon Fraser University, Burnaby, BC, Canada

Polycystic kidney disease (PKD) is one of the most common genetic diseases, affecting 12.5 million people worldwide. Several proteins involved in the polycystic pathology are found at primary cilia, basal bodies, and cell-cell junctions. A key feature of the etiology of cyst formation is aberrant cell proliferation, presumably a consequence of dysfunctional regulation of the cell cycle by basal bodies/centrioles and primary cilia [reviewed by Pazour, 2004, J. Am. Soc. Nephrol. 15, 2528-2536]. The NIMA-related kinases (Neks) Nek1 and Nek8 carry the causal mutations of two of the eight established mouse models of PKD [reviewed by Guay-Woodford, 2003, Am. J. Physiol. Renal Physiol. 285, 1034-1049] and members of this kinase family have cell cycle roles [O'Connell et al., 2003, Trends Cell Biol. 13, 221-228]. Here, we report the intracellular localization of endogenous Nek1 and Nek8 in mouse kidney epithelial cell line. Nek1 localizes to centrosomes and Nek8 to the proximal region of the primary cilium. During mitosis, Nek1 remains associated with the centrosome of the mitotic spindle, whereas Nek8 is not observed in dividing

cells. Knockdown of Nek8 results in loss of staining at the cilia, while not affecting ciliary assembly. Taken together with the phenotypes of the mutant mice, our data suggest that Nek1 and Nek8 provide a direct link between cilia, centrosomes, and cell cycle regulation.

**The Injury of Hepatocytes of HBx Transgenic Mice and the Protective Role of Selenium**

Y. Tu,[1] Z. Qi,[1] J. Chen,[2] P. Yang,[1] Y. Pan,[1] S. Yu[3]; [1]Department of Biochemistry and Molecular Biology, Institute of Basic Medical Sciences, Chinese Academy of Medical Sciences, Beijing, China, [2]Department of Pathology, Institute of Basic Medical Sciences, Chinese Academy of Medical Sciences, Beijing, China, [3]Department of Biochemistry and Molecular Biology, Cancer Institute, Chinese Academy of Medical Sciences, Beijing, China

HBx gene product is a pathogenic factor related to human hepatitis B virus (HBV) infection. In order to obtain an animal model for mimicing the chronic injury of hepatocytes caused by HBV and using it to find a protective treatment against the injury of the cells, the HBx transgenic mice (TG) were generated. The TG with or without $Na_2SeO_3$ diet and wild type mice (WT) were maintained and samples were collected for Southern and Northern blot hybridization analysis and pathological examination. The results indicated that the hepatocytes of 2- month old TG were normal. However, 50% of the 8-month old TG showed slight inflammatory cell infiltration and all of the 16-month old TG had serious inflammatory changes of the cells (eg. scattered focal necrosis with distinct inflammatory cell infiltration etc.). Moreover, 50% of 16-month old TG were found experiencing possible precancerous changes. After treatment with 1ppm sodium selenium, the hepatocytes of TG were as normal as controls although those mice were showing an integration and expression of HBx gene in hepatocytes. In summary, the expression of HBx gene in TG can induce a chronic injury of hepatocytes thus the TG as a model have been successfully developed. The selenium can act as a protective reagent against the cellular injury caused by HBx gene expression.

**Inhibition of Ethanol-induced Cytotoxicity in Cultured Hepatocytes by RNAi Silencing of Par-4**

J. Xie, Q. Guo; Department of Physiology, The University of Oklahoma Health Sciences Center, Oklahoma City, OK

The precise mechanisms underlying alcoholic liver disease are not completely understood, although several lines of experimental evidence suggest exposure of hepatocytes to ethanol may induce apoptosis via increased oxidative stress and induction of pro-apoptotic machinery. Par-4 (prostate apoptosis response-4) is a pro-apoptotic protein ubiquitously expressed in many tissues, including the liver. Par-4 contains both a death domain and a leucine zipper domain and its expression is up-regulated in many types of cells induced to undergo apoptosis. Par-4 functions early in apoptotic machinery, upstream of caspase activation and mitochondrial dysfunction. We now report that Par-4 is expressed in primary mouse hepatocyte cultures, and levels of Par-4 are significantly increased in hepatocytes exposed to ethanol. Targeted knockdown of Par-4 by highly specific and effective small interference RNAs (siRNAs) inhibited mitochondrial dysfunction and caspase-3 activation induced by ethanol, and protected hepatocytes from apoptosis. These results identify Par-4 as a novel regulator of ethanol-induced hepatocyte apoptosis, and suggest that targeted inhibition of Par-4 by RNAi may prove to be an effective cytoprotective strategy against alcohol-induced hepatotoxicity.

**The Effect of Mutated Lamin A/C Proteins on the Function of Emerin in Cells Isolated from AD-EDMD Patients**

L. J. Emerson,[1] M. Wehnert,[2] J. A. Ellis[1]; [1]The Randall Division of Cell and Molecular Biophysics, Kings College London, London, United Kingdom, [2]Institute of Human Genetics, Greifswald, Germany

Muscular Dystrophies are a family of progressive skeletal muscle wasting diseases of varying severities caused by defects in a number of different genes. Emery-Dreifuss Muscular Dystrophy (EDMD) also shows a severe cardiac phenotype which can cause sudden cardiac death. There are two forms of EDMD, an X-linked form which is caused by the absence or mutation in the nuclear envelope protein emerin, and an autosomal dominant (AD) form which is caused by mutations in the nuclear lamina proteins lamins A and C which are alternatively spliced from the same gene. Emerin is ubiquitously expressed but shows higher levels of expression in both skeletal and cardiac muscle. It is thought to have a role in maintenance of nuclear membrane structure, cell cycle mediated events and regulation of gene expression. Emerin and lamin A/C proteins have been shown to interact with each other as part of a macro protein complex and are co-localised in myoblasts. The aim of this research is to investigate the effects of EDMD-causing lamin mutations on the function of emerin in cell cycle mediated events using patient skin fibroblast cells lines. These cell lines from EDMD patients each contain a different lamin A/C mutation: R249Q and R377H in the central rod domain, and R401C and R453W in the emerin binding region. Our studies suggest that our AD-EDMD cell lines express less lamin A/C protein, which also exhibit a reduced strength of interaction to nuclear components. Similarly, emerin in these patient cell lines was more soluble. Two of our AD-EDMD cell lines exhibited altered rates of proliferation, suggestive of an extended cell cycle length.

**Genomic Instability in Laminopathy-based Premature Aging**

Z. Zhou; Biochemistry, University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China

Premature aging syndromes often result from mutations in nuclear proteins involved in the maintenance of genomic integrity. LAMIN A is a major component of the nuclear lamina and nuclear skeleton. Truncation in LAMIN A causes Hutchinson-Gilford Progerial Syndrome (HGPS), a severe form of early onset premature aging. Lack of functional ZMPSTE24, a metalloproteinase responsible for the maturation of Prelamin A, also results in progeroid phenotypes in mice and humans. To understand the molecular mechanism underlying HGPS, we investigated DNA damage and repair in mice lacking Zmpste24 and in cells from patients with HGPS. We found that *Zmpste24*-deficient mouse embryonic fibroblasts (MEFs) exhibit increased DNA damage and chromosome aberrations and are more sensitive to DNA-damaging agents. Bone marrow cells isolated from *Zmpste24*$^{-/-}$ mice display increased aneuploidy and the mice are more sensitive to DNA damaging agents. Recruitment of p53 binding protein 1 (53BP1) and Rad51 to sites of DNA lesions is impaired in *Zmpste24*$^{-/-}$ MEFs and in HGPS fibroblasts, resulting in delayed checkpoint response and defective DNA repair. Wild-type MEFs ectopically expressing unprocessible Prelamin A exhibit similar defects in checkpoint response and DNA repair. Our results indicate that unprocessed Prelamin A and truncated LAMIN A act dominant negatively to perturb the DNA-damage response and repair, resulting in genomic instability which might contribute to laminopathy-based premature aging.

**Skeletal Muscle Fibrosis in Duchenne Muscular Dystrophy: Modulation by TGFβ and CTGF in *mdx* Mice**

V. Mezzano, D. Cabrera, E. Brandan; Cell & Mol. Biol., Catholic University of Chile, Santiago, Chile

Duchenne muscular dystrophy (DMD) is a lethal, muscle wasting disease caused by a mutation in the dystrophin gene. The absence of the dystrophin protein leads to degeneration of muscle fibers and eventually fibrotic scarring ensues. The *mdx* mouse model of DMD also lacks dystrophin and its diaphragm reproduces the degenerative changes of DMD. The aim of our work is to understand the fibrotic process which parallels muscle degeneration and, particularly, the involvement of two potent regulators of extracellular matrix (ECM) synthesis: TGFβ and Connective Tissue Growth Factor (CTGF), which has been described as another profibrotic cytokine. We have isolated fibroblasts from *mdx* and control mouse diaphragm, studied their relationship to these factors both regarding their expression and synthesis, and their regulation of ECM molecules. Here we report that CTGF induces fibronectin in fibroblasts of control mice in a concentration dependent manner. Regarding *mdx* fibroblasts we observed that they express and synthezise more CTGF than controls. We, therefore, studied ECM molecules present in these cell cultures and observed an increase in fibronectin and chondroitin sulfate proteoglycans in *mdx* fibroblasts compared to control, increase which is not observed in skin isolated fibroblasts. Interestingly, regarding the ability of proteoglycans to influence the activity/bioavailability of TGFβ, we observed increased binding of TGFβ to TGFβ Receptor III, or betaglycan, a heparan sulfate proteoglycan. These results suggest a constitutive activation of *mdx* fibroblasts obtained from dystrophic muscle in spite of their being isolated from their regenerative/fibrotic niche offering new insights into the understanding of these disorders. **Development of Dual-reporter Transgenic Mice for Readthrough Assay**

M. Shiozuka, K. Shimada, R. Matsuda; Dept. of Life Sci., The Univ. of Tokyo at Komaba, Tokyo, Japan

Negamycin is a naturally-occuring dipeptide antibiotic that causes the RNA translation mechanism in the ribosomes to ignore frequently such a premature termination codon (PTC), i.e. to readthrough it. We previously reported that negamycin rescues dystrophin expression in mdx skeletal and cardiac muscles with less side effects than gentamicin (J. Biochem., 2003). We suggest that negamycin is a therapeutic candidate for not only Duchenne muscular dystrophy but also other genetic disorders caused by nonsense mutations. In order to investigate more potent readthrough stimulator without toxicity and facilitate studies, we have developed a new in vivo dual- reporter assay system for measuring readthrough efficiency. Dual-reporter gene is composed with beta-galactosidase gene and luciferase gene connected with PTC region (27mer which contains the sequence around the PTC of exon 23 of mdx mouse dystrophin) driven by cytomegalovirus/beta-actin hybrid promoter. This dual-reporter allows a simultaneous sensitivity and quantitative accuracy. We have established three transgenic (Tg) mouse strains containing different PTCs (Ochre [TAA], Amber [TAG], Opal [TGA]), that express beta-Galactosidase in skeletal muscle, cardiac muscle and brain. Using these Tg mice, we succeeded in the evaluation of readthrough activity in each tissue in vivo and in real-time in vitro for the first time. Furthermore, we tested the efficacy of cutaneous antibitic ointment in Tg mice. The results showed that treatment regimens that included topical gentamicin provided better rates of readthrough than treatment regimens in which only base preparations were used. We will evaluate this therapeutic potential for variety of other genetic disorders. This work was supported by a Research Grant for Nervous & Mental Disorders and by a grant for Research in Brain Science from the Ministry of Health, Labor and Welfare, Japan.

**Acidic Sphingomyelinase has a Dual Role in Modulating Apoptosis Induced by Reactive Nitrogen Species in Airway Epithelial Cells**

S. Castillo, M. Levy, R. Lanir, C. Wang, J. Vihas, T. Goldkorn; Internal Medicine, University of California at Davis, Davis, CA

Reactive nitrogen species (RNS) are highly reactive molecules that have been implicated in the pathophysiology of inflammatory lung diseases, such as acute respiratory distress syndrome, asthma, and chronic obstructive pulmonary disease. Recently studies have suggested a role for acidic sphingomyelinase (aSMase) and ceramide in lung diseases such as pulmonary edema and emphysema. Previously, we reported that both peroxynitrite (ONOO-) and nitric oxide (NO) generated ceramide in lung epithelial cells, but that only ONOO- induced apoptosis. We found that ONOO- generated ceramide through the activation of acidic sphingomyelinase (aSMase) whereas NO generated ceramide through the activation of ceramide synthase. The objective of the current study was to determine how different RNS modulate apoptosis in lung epithelial cells by examining the regulation of components of the ceramide generating machinery such as aSMase. siRNA impairment of aSMase reduced basal and inducible enzyme activity by 60% and 50% respectively. Furthermore, knockdown of aSMase reduced ONOO- induced apoptosis by approximately 40%. In addition, inhibition of a downstream caspase, caspase-3, also resulted in an inhibition of ONOO- induced apoptosis by ~40%, suggesting that ceramide generation by ONOO- exposure precedes caspase-3 activation. As mentioned previously, despite the fact that ceramide was generated by NO treatment, no apoptosis was observed. We found that upon NO exposure, an increase in the protein-protein interaction between aSMase and caspase-3 occurred, with aSMase sequestering caspase-3 and preventing its cleavage by upstream caspases and thereby blocking an apoptotic response. Knockdown of aSMase resulted in caspase-3 cleavage and the induction of apoptosis after NO treatment. These studies demonstrate a novel way RNS regulate apoptosis in lung epithelial cells by modulating the function of acidic sphingomyelinase to be either a pro-apoptotic mediator or an anti-apoptotic molecule.

**Development and Characterization of the Cystic Fibrosis Airway Epithelial Cell Lines Complemented with wild-type and F508del CFTR cDNA**

R. Maurisse,[1] J. W. Cheung,[1] B. Illek,[2] H. Fischer,[2] T. Shuto,[3] D. C. Gruenert[1]; [1]Research Institute, California Pacific Medical Center, San Francisco, CA, [2]Children's Hospital Oakland Research Institute, Oakland, CA, [3]Faculty of Medical and Pharmaceutical Sciences, Department of Molecular Medicine, Kumamoto, Japan

The development of immortalized airway epithelial cells is critical in elucidation the biochemical and molecular mechanisms underlying cystic fibrosis (CF) pathology and in the development of CF therapies. Different cell systems have been employed in genetic complementation studies and have been used to characterize CF transmembrane conductance regulator (CFTR) -related metabolic pathways. An important feature of CF

cells complemented with wild-type (WT)-CFTR is the reversal of the cAMP-dependent Cl ion transport defect in these cells. Such complementation studies have led to the understanding of the involvement of CFTR function in specific biochemical pathways. Numerous CF cells have been complemented with CFTR cDNA with ~4.7 kB open reading frame (ORF) CFTR cDNA or the entire ~6.2 kB CFTR cDNA comprised of both the ORF and the 3' and 5' untranslated regions (UTR). The studies described here evaluate CF airway epithelial cells that have been complemented with the 4.7 kB, 6.2 kB WT-CFTR, and the 4.7 kB F508del-CFTR under the regulation of a cytomeglovirus (CMV) promoter and cloned into an Epstein Barr Virus (EBV) -derived episomal expression vector. Cell lines that are either homozygous for the F508del mutation or are compound heterozygotes (F508del/Q2X) have been developed and evaluated for their CFTR expression levels and their ion transport characteristics. CF cells complemented with wt 6.2 kB cDNA which exhibit comparable level of WT expression in wt cells line (16HBE14o-) have similar Cl transport activity as the wt cell line. Further studies are underway to more fully correlate the degree of CFTR expression with the ion transport characteristics of the complemented cells.

1455

**Redox Potentials in the Cytosol, ER, Mitochondria and Membrane Surface of CF and CFTR-Corrected Airway Epithelia Measured with roGFP**

C. Schwarzer,[1] H. Fischer,[2] B. Illek,[2] C. Dooley,[3] S. Remington,[4] R. Tsien,[3] T. Machen[1]; [1]Molecular and Cell Biology, Univ California, Berkeley, CA, [2]CHORI, Oakland, CA, [3]UCSD, La Jolla, CA, [4]Univ. Oregon, Eugene, OR

There are many potential contributors to altered redox balance cystic fibrosis (CF) airways: (i) Loss of CFTR and its ability to transport glutathione may lead to oxidation of the airway surface liquid (ASL). (ii) Upregulated Na transport in CF may cause hypoxia and increase mitochondrial production of reactive oxygen species. (iii) Altered CFTR processing in the endoplasmic reticulum (ER) may cause ER stress. We studied the role of CFTR in controlling redox balance in airway epithelial cells by targeting ratiometric, redox-sensitive GFP (roGFP1) to the cytosol, ER, mitochondria and apical surface in the CF nasal cell line JME and also in JME cells in which CFTR had been expressed using an adenovirus. Quantitative measurements were performed using ratio imaging microscopy including calibrations of fluorescence signals in terms of redox potentials measured with a redox-sensitive electrode. Steady state redox potentials were > -50 mV in the ER and at the cell surface, -220 mV in the mitochondria and -250 to -280 mV in the cytosol. These compartments exhibited redox regulation in that their redox potentials recovered, though with quite different time courses depending on the organelle, following brief pulses with either oxidants (H2O2) or reductants (dithiothreitol). As measured using Ussing chambers and electrophysiology, CFTR expression elicited increases in apparent forskolin-stimulated Cl secretion and small decreases in Na absorption, but neither steady state redox potentials nor redox regulation were altered. These data show for JME cells that the ER and membrane surface are oxidized compared to the cytosol and mitochondria, and rates of redox regulation in these compartments are all different from each other. However, CFTR seems not to play a direct role in their redox regulatory properties. Support: CFF, NIH, HHMI

**Integrin Alpha V Beta 5 Regulates Lung Vascular Permeability and Acute Lung Injury by Organizing Signaling Complexes at Endothelial Adherens Junctions**

G. Su,[1,2,3] J. A. Frank,[4,3] M. Hodnett,[5,6] N. Wu,[1] M. Godzich,[5,6] M. A. Matthay,[2,3,5] D. Sheppard,[1,2,3] J. Pittet[5,6]; [1]Lung Biology Center, UCSF, San Francisco, CA, [2]Cardiovascular Research Institute, UCSF, San Francisco, CA, [3]Pulmonary and Critical Care Medicine, UCSF, San Francisco, CA, [4]San Francisco VA Medical Center, San Francisco, CA, [5]Departments of Anesthesia and Surgery, UCSF, San Francisco, CA, [6]Laboratory of Surgical Research, UCSF, San Francisco, CA

Acute lung injury (ALI) is a common, currently untreatable disorder with a high mortality rate. We now show that in two clinically relevant models of lung injury (ischemia- reperfusion and ventilator-induced lung injury), blockade or genetic ablation of integrin alpha v beta 5 dramatically reduces the increase in pulmonary vascular permeability that is the central physiologic feature of ALI. Although integrins are best characterized for their role in attaching cells to the underlying extracellular matrix, in pulmonary endothelial cells, alpha v beta 5 is principally localized to cell-cell junctions, where it is part of a large protein complex that also contains the adherens junction protein, VE-cadherin, the small GTPase RhoA, and the RhoA upstream activator p115rhoGEF. *In vitro* increases in pulmonary vascular permeability induced by three distinct signaling pathways activated by VEGFA, TGFβ and thrombin are each prevented by inhibition of both RhoA and alpha v beta 5. Furthermore, both RhoA and alpha v beta 5 appear to regulate induction of actin stress fiber formation and phosphorylation of VE-cadherin induced by each agonist. These results suggest a novel mechanism by which alpha v beta 5 coordinates increases in pulmonary vascular permeability in response to multiple agonists by regulating endothelial junction protein activation and cell shape changes. We hypothesize that alpha v beta 5 may control local RhoA activation at pulmonary endothelial adherens junctions by coordinating accessibility to activators of RhoA like p115RhoGEF and therefore, might be an attractive target for pharmacologic intervention in ALI.

**QRT-PCR Gene Expression Analysis of Nitric Oxide Synthase in COPD Patients and Normal Individuals Using Formalin-Fixed Paraffin-Embedded Lung Tissues**

N. Novoradovskaya,[1] N. T. Eissa,[2] A. Novoradovsky,[1] J. Braman,[1] F. Kheradmand[2]; [1]R&D, Stratagene, La Jolla, CA, [2]Baylor College of Medicine, Houston, TX

Nitric oxide synthases (NOS) are a family of enzymes that control the production of nitric oxide by converting L-arginine to L-citrulline. It is known that nitric oxide concentrations are elevated in patients with severe asthma, cystic fibrosis, or in patients with chronic obstructive pulmonary disease (COPD). Our prior work (Novoradovsky et al., 1999) demonstrated a modulatory role for endothelial NOS isozyme in destructive lung disease associated with alpha-1antitrypsin deficiency. In this study we compared the gene expression level of neuronal, inducible and endothelial nitric oxide synthases (nNOS, iNOS and eNOS) in the lung tissues of COPD patients and normal individuals. Total RNA was isolated by Absolutely RNA FFPE kit (Stratagene) from formalin-fixed paraffin-embedded (FFPE) lung tissue obtained from four normal and four COPD patients. Gene expression level of nNOS, iNOS and eNOS was evaluated by QRT-PCR using TagMan Probes (ABI) and the Mx3000P Real-time PCR System (Stratagene). β2-Microglobulin (B2M) was used as the normalizing gene. Standard curves were generated using QPCR Universal Human Reference RNA. Relative mRNA quantification was performed using the software application for the "Comparative Quantification"

method on the Mx3000P.The quantity and quality of RNA isolated from FFPE lung tissues by Absolutely RNA FFPE kit were sufficient for QRT-PCR analysis. No difference in gene expression levels of nNOS or iNOS between the two groups were observed. Expression of eNOS was decreased by 2-3 fold in COPD patients compared to healthy controls. Decline in eNOS expression in patients with COPD indicates possible involvement of this izozyme in pulmonary disease. Alternatively, reduced expression of eNOS might result from destruction of endothelial and airway wall tissues in the lung samples from COPD patients.

1458

**Ligation of PAR-1 Enhances αvβ6 Integrin Dependent TGFβ Activation and Promotes Acute Lung Injury**

G. Jenkins,[1] X. Su,[2] G. Su,[3] E. Camerer,[2] G. J. Laurent,[1] G. E. Davis,[4] R. C. Chambers,[1] M. A. Matthay,[2] D. Sheppard[3]; [1]Centre for Respiratory Research, University College London, London, United Kingdom, [2]Cardiovascular Research Institute, University of California, San Francisco, San Francisco, CA, [3]Lung Biology Center, University of California, San Francisco, San Francisco, CA, [4]Department of Pathology and Laboratory Medicine, Texas A&M University System Health Science Center, College Station, TX

Activation of latent TGFβ by the αvβ6 integrin is a critical step in the development of acute lung injury. The αvβ6 integrin must be activated at the onset of acute lung injury, but the mechanisms of activation have not been previously identified. The serine protease, thrombin, is generated early during acute lung injury and is thought to contribute to increased lung permeability via its ability to activate PAR-1. We used two readouts of TGFβ activity, phosphorylation of SMAD2 and a co-culture bioassay, to examine the effects of thrombin and the PAR-1 activating peptide SFLLRN on TGFβ activation by lung epithelial cells. Both agonists increased TGFβ activity in both assay systems and these effects were inhibited by an αvβ6 blocking antibody, demonstrating that ligation of PAR-1 induces αvβ6-dependent TGFβ activation. SFLLRN had no effect on TGFβ activation in PAR-1-/- fibroblasts engineered to express the αvβ6 integrin. Infection of αvβ6-expressing fibroblasts with adenoviral dominant negative RhoA inhibited the response to SFLLRN, whereas constitutively active RhoA enhanced αvβ6 integrin mediated TGFβ activation, even in PAR-1-/- cells. αvβ6 integrin mediated TGFβ activity was also inhibited by the Rho kinase inhibitor Y-27632. To determine the relevance of this pathway in vivo we ventilated mice at high tidal volumes following intratracheal instillation of the PAR-1 agonist TFLLRN or the control peptide FTLRRN. Under the conditions studied, lung permeability was doubled by TFLLRN, an effect that was inhibited by an αvβ6 integrin blocking antibody. The increases in lung permeability and nuclear phosphoSMAD2 staining induced by intratracheal instillation of bleomycin were also significantly reduced in PAR-1-/- mice. These data demonstrate that PAR-1 stimulation leads to αvβ6 mediated TGFβ activation via RhoA and that this pathway is important in the development of acute lung injury.

***"Non-Coding"* Small RNA Bioaptamers as Codes for Epigenetic Phenotype Alterations in Proteinaceous Transfer of Delayed-Type Hypersensitivity and Functions in Wound Healing: RNA-Operated Conformation Phase Pathway-Locked Loops [CPLL] in Epigenomes**

J. H. Wissler,[1] J. E. Wissler,[1] E. Logemann[2]; [1]ARCONS Institute for Applied Research & Didactics, Postfach 1327, Bad Nauheim, Germany, [2]University of Freiburg, Freiburg, Germany

OBJECTIVE: Functions of entitled structure-defined *endogenous* RNA as signals in epigenetic [non-Mendelian] phenotype alterations [EPA] by proteinaceous transfer factors of delayed-type hypersensitivity [TF-DTH] and wound healing. METHODS: Isolation of such RNA from extracellular wound and supernatant fluids of quiescent, lectin- or antigen-activated normal and sensitized cells cultured in serum-free synthetic media. Purification guided by bioassays of cellular differentiation and tissue morphogenesis/ wound healing in terms of non-mitogenic angio-morphogenesis, negative regulation [inhibition] of granulopoiesis and leftward shift reactions [Wissler et al., Protides Biol. Fluids 34:517-536,1986; Materialwiss.Werkstofftech.32:984-1008,2001; Arch.Surg.124:693-698,1989; Ann.NY.Acad.Sci.961:292-297,2002; 991:333-338,2003; 1022:163-184,2004; FASEB J.19:A621,2005; FEBS J.272-s1:N1-06-4P,2005]. RESULTS: From extracellular TF-DTH preparations, bioactive *endogenous* complexes of nucleic acid bioaptamers and protein conformers could be isolated. Some sequence-defined RNA bioaptamers are redox- and metalloregulated, edited and modified "*non-coding*" small RNA [<200 bases] as regulators and messengers of protein structure [folding] at cellular translation and transcription. They address conserved homologous metalloregulated RNA-binding domains in epigenetic regulator proteins [e.g. of angio-morphogens like angiotropin], termed K/R3H-[K/RxxxH], i.e. -t/s/xK/R/q/nxxxH/y/n/q/e/dx$_{7\text{-}9}$h/xx$_{7\text{-}9}$h/xx$_{5\text{-}20}$K/R/q/n/e/h- with accessory basic [R/K]$_n$, R/K-zipper, SR/K/RS and/or HxxxH/y/n/q segments. Sequences and positions may suggest that only some EPA are transmissible or prone to "*bioaptamer disease*" and as upon some protein maturation, copper-binding ATCUN motifs may be formed. CONCLUSIONS: Since not directly retranslatable to heritable genome codes by sequence edition, base modification, redox- and metalloregulation, i.e. code extensions/alterations, entitled *"non-coding"* RNA bioaptamers as products of overwhelming portions [~98%] of transcriptional output apparently represent part of cryptic codes for EPA in DTH transfer and investigated wound healing functions. CPLL orchestrated by *"non-coding"* RNA, redox and metal ions are suggested mechanisms for reprogramming cell fate in EPA of DTH and wound healing reactions.

**Effect of Bioelectromagnetic Fields on Wound Healing in the Sea Urchin, *Lytechinus variegatus***

K. A. Kedrowicz,[1] J. Mckeague,[1] A. Sturycz,[1] D. F. Johnson,[2] L. Winslow[1]; [1]Biology, Northwestern College, St. Paul, MN, [2]Psychology, Northwestern College, St. Paul, MN

All humans emit very low frequency electromagnetic fields known in the literature as bioelectromagnetic fields (BEMFs). Using the sea urchin model, we investigated the effect of BEMFs on wound healing in the sea urchin *Lytechinus variegatus*. Animals were wounded producing a longitudinal 2cm x 0.5 cm incision along one seam of the test. BEMFs were applied by a trained practitioner for 10 minutes each day over five days. Controls maintained in a separate aquarium, were wounded similarly, but did not receive BEMF treatments. Wounds on control and experimental animals were measured daily for longitudinal wound closure. Our data showed that wounds closed faster and more completely in BEMF treated groups than in controls. Measurements of wounds in the BEMF treated group were 1.7cm, 0.75 cm, 0.5 cm on days 2, 4 and 6 respectively, compared with 1.9cm, 1.5cm, 1.3 cm on the same days in the control. This corresponds to a nearly 80% rate of wound healing in the experimental compared to 35% in controls. Student's t Test analysis applied to the data showed statistical significance of $p<.005$. We also observed that animals treated with BEMFs showed remarkably enhanced vitality and longevity over corresponding controls. Immune cell recruitment into the wounds was examined in BEMF treated and untreated animals over five days. BEMF treated animals possess enhanced migration of red

spherule and colorless spherule immune coelomocytes into the wounds by day two after wounding. Similar recruitment of immune cells occurred on day four in controls. We also noticed an increased number of test spicules in BEMF treated animals indicating a stimulation of calcium carbonate secreted by immune effector cells. Taken together, our data indicate that BEMFs significantly enhance immune cell activation and recruitment accelerating wound healing pathways.

**Silver Sulfadiazine and β-sistoserol in Burn Wound Healing: A Comparative Study**

A. R. Jurjus,[1] A. A. Gerges,[2] M. Abou-Jaoudeh,[2] I. Abdallah,[1] R. Tohmé,[1] R. Jurjus,[1] S. Hayek,[1] B. Atyieh[1]; [1]Human Morphology, American University of Beirut, Beirut, Lebanon, [2]Faculty of Pharmacy, Saint Joseph University, Beirut, Lebanon

Healing of cutaneous wounds is a complex process whereby an array of topical agents is frequently used. Antiminobials, have been shown to be cytotoxic to fibroblasts and keratinocytes and to retard wound healing. While others have been considered as promoting wound healing especially when they modulate cytokines. This study was designed to compare the effect of silver sulfadiazine and β-sistosterol creams on burn wound healing in rabbits with thermal burn injury. The rabbit model of Knobl et al., 1999 was adopted . Nine adult male rabbits, average weight 2500g, were divided into 3 groups (G). They were depilated to obtain an absolutely smooth and hairless dorsal skin and anesthetized by ketamine and xylasine. The thermal burn injury was performed on 4 spots of the dorsal skin using a modified soldering iron at a temperature of 80$^{o}$C for a duration of 22 seconds resulting in deep partial thickness burn of 3.8 cm$^{2}$. Lesions biopsies with surrounding healthy skin were excised daily and either fixed in 5% formaldehyde for histological studies or frozen for cytokine studies (b-FGF and TGF-β) by ELISA. G1 was treated with saline, G2 with MEBO and G3 with silver sulfadiazine. The dressings were changed daily. Transepidermal water loss (TEWL) was measured and observations recorded daily. Results showed that the least TEWL was in the MEBO group and the highest was in the silver sulfadiazine group. Histological findings depicted a relatively faster healing (Δ 3 days) in G2 compared to G1 and G3 in addition to a better healing quality (less depression and less surface alterations) compared to the other two groups. Some cytokines were modulated, in particular, bFGF increased in G2. Further quantification of cytokines IL-1, TGF-β are being carried out. (Grant from The MPP, AUB)

**Cholesterol Stabilizes Rab9 on Late Endosomes of Niemann-Pick type C Fibroblasts**

I. G. Ganley, S. Pfeffer; Biochemistry, Stanford University, Stanford, CA

Niemann-Pick type C (NPC) is an intracellular trafficking disorder resulting in the accumulation of cholesterol and glycosphingolipids in late endosomes and lysosomes. It has been reported that overexpression of the small GTPase Rab9 relieves this accumulation (1,2). This suggests that normal Rab9 function may be compromised in NPC cells and/or its overexpression drives a bypass transport pathway out of late endosomes, thus providing an exit route for excess cholesterol. To help understand how Rab9 overexpression rescues cholesterol accumulation, we have investigated endogenous Rab9 in NPC cells. Rab9 levels were elevated 1.8 fold in NPC cells relative to wild type and the half life increased 1.6 fold, suggesting accumulation of Rab9 is due to slower degradation. Increased half life is likely due to stabilization of Rab9 on endosomes as shown by a reduction in GDI-mediated Rab9 extraction from NPC membranes compared to wild type. Why should increased cholesterol stabilize membrane-bound Rab9? It is possible that the Rab9-associated prenyl groups interact with higher affinity with cholesterol-rich bilayers. Alternatively, the Rab may be stabilized by an effector that is itself stabilized on endosomes by increased cholesterol. Salt washing of endosomes, to remove peripheral proteins, or RNAi of TIP47 (a Rab9 effector whose level also increased on cholesterol-laden endosomes) failed to relieve the block in Rab9 extraction. Thus, peripherally associated proteins do not seem sufficient to explain Rab9 stabilization. Evidence for a direct role of cholesterol in stabilizing Rab9 was obtained using liposomes loaded with prenylated Rab9: increasing the cholesterol content of these liposomes resulted in decreased Rab extractability. We conclude that cholesterol contributes directly to the stabilization of Rab9 on membranes of NPC cells. (1) Choudhury et al. (2002) J Clin Invest. 109:1541-50. (2) Walter et al. **A Novel Antiobesity Compound BLX-1028 Inhibits iNOS and Adipocyte Differentiation**

M. Anumula, S. Roy, A. Nag, P. Neogi, B. Nag, D. Dey; Bexel Pharmaceuticals Inc, Union City, CA

Obesity is a condition of excessive fat in the body and the adipocytes are the major sites for the storage of fat. Controlling either increase in the adipocyte cell size or differentiation might be a good strategy to control the weight gain. It is known that iNOS (Inducible Nitric-oxide Synthase) expression is highly elevated in muscle and fat of obesity animal models. We have made several amino acid conjugated small molecules and screened them in both anti-adipogenic and anti-inflammatory assays. We identified BLX-1028 as a unique molecule with both antiobesity and anti-inflammatory properties. Adipogenesis was induced by incubating the cells with rosiglitazone (1uM), a known PPARγ agonist, and co-treated with 0.1, 1 and 10uM concentrations of BLX-1028. Hormone mediated adipogenesis was induced by a mixture of IBMX (3-Isobutyl-1-methylxanthine), dexamethasone and insulin, and treated with different concentrations of BLX-1028. The cells were stained with Oil Red O and visualized under Olympus microscope. Oil Red O was extracted to quantify the amount of triglyceride accumulation. In both experiments BLX-1028 showed dose dependent inhibition of TG accumulation. At 10 uM it showed 90% ($P<0.05$) inhibition of TG. It also inhibited LPS and cytokine induced iNOS expression in different cells. At 10 and 30 uM it showed 70% and 90% inhibition of nitrate in 3T3-L1 adipocytes compared to vehicle, as measured by Griess reagent. In hPBMC cells, compared to vehicle, BLX-1028 lowered TNF-α level by 34, 70 and 84 % at 3, 10 and 30uM concentrations respectively. Based on the above results we conclude that BLX-1028 is a novel molecule with a unique mechanism of targeting adipocytes, which makes it completely different from all the marketed antiobesity drugs. Currently BLX-1028 is being tested in different animal models for obesity.

1464

**Inhibitory Effect of Magnolia Officinalis on Aortic Oxidative Stress and Apoptosis in Hyperlipidemic Rabbits**

W. Chang, Y. Hsu, C. Wu, Y. Yu, P. Yin, S. Chiang; China Medical University, Taichung, Taiwan Republic of China

Twenty hyperlipidemic rabbits were served one of the following: a high-fat and cholesterol diet (cholesterol group, 10% corn oil and 0.5% cholesterol), a high fat and cholesterol diet supplemented with Magnolia officinalis extract (300 mg/kg) or lovastatin (6 mg/kg). The plasma lipids, oxidative stress (measured by free radical, MDA and oxidative DNA damage) and lipid lesions significantly decreased in the Magnolia officinalis

and lovastatin groups when compared with the cholesterol group. Moreover, the expressions of Fas-Ligand, caspase 8 and caspase 9 in the aortic arches were also markedly lowered after Magnolia officinalis and lovastatin supplements. Therefore, the results indicate that anti-atherogenic effect of Magnolia officinalis is involved with a suppression of oxidative stress and with the down-regulation of apoptosis related gene expression in hyperlipidemic rabbits.

## Reprogramming Cell Fate (1465-1467)

1465

### Reprogramming Cell Fate by Nuclear Transfer

J. B. Gurdon; Wellcome Trust/Cancer Research UK Gurdon Institute, University of Cambridge, Cambridge, United Kingdom

The differentiated state of adult somatic cells is very stable. Only very occasionally do cells that have been committed to one pathway of cell fate change directions and enter a different specialization pathway. However, if the nuclei of such determined or differentiated cells are transplanted to eggs or oocytes of amphibia or mammals, a dramatic reversal can take place. In these cases, somatic cell nuclei are rejuvenated to an embryonic pattern of gene expression within only a few hours. As cells differentiate the ease with which they can be reprogrammed by egg cytoplasm declines. In some of these cases somatic cell nuclei retain a memory of their previous pattern of gene expression for numerous cell divisions. The changes that are induced by egg or oocyte cytoplasm fall into three classes. (i) The removal of marks that characterize the differentiated state of a nucleus. These include the demethylation of genomic DNA in the promoter region of genes that undergo reprogramming. Also, modified proteins associated with the inactive state of genes are removed. (ii) The provision by host cells of those transcription factors required to read genes that undergo activation. (iii) The decondensation of chromatin to provide access of transcription factors to the regulatory region of activated genes. The large size and abundance of Xenopus eggs and oocytes facilitates identification of the molecules and mechanisms involved in reprogramming somatic cell nuclei. The long-term aim of this direction of work is to pre-treat somatic cells with reprogramming agents in order to increase the efficiency with which nuclei can be reprogrammed to an embryonic state. The derivation of embryonic stem cells from nuclear transplant embryos could lead to a cell replacement therapy that avoids the need for immunosuppression.

1466

### Regulating Cell Fate by Fusion

H. M. Blau; Baxter Laboratory in Genetic Pharmacology, Stanford University, Stanford, CA

Cell fusion has long been recognized as an experimental means for altering the gene expression profile from that of one cell type to that of another. The plasticity of cell fate observed in such heterokaryons in tissue culture is well known to result largely from the balance of regulators within the cell at any given time. Recently, in response to injury, hematopoietic stem cell (HSC) derivatives have been shown to be capable of fusing with non-hematopoietic tissues in vivo in mice and humans. To contribute function after fusion, reprogramming of the donor nucleus is critical, a process that has been demonstrated to occur to some extent, but which remains inefficient. We are taking several approaches to investigate the molecules and regulatory networks underlying the reprogramming of diverse mammalian somatic cell nuclei for distinct differentiated fates after fusion. (1) Perturbing chromatin remodeling of enhancer/promoter elements in tissue-specific genes by manipulating histone deacetylase activity; (2) Analyzing changes in the methylation state of genomic sequences that influence the degree and rate of nuclear reprogramming; (3) Determining to what extent the stage of differentiation and associated repression of alternative gene expression programs influences the efficiency of nuclear reprogramming. The ultimate goal of this research is twofold. First, the in vivo potential of HSC derivatives to contribute to adult tissues to which they fuse spontaneously may be enhanced which would advance the field of regenerative medicine. Second, the in vitro reprogramming of the nuclei of somatic cells derived from diverse sources to function as differentiated tissue-specific cells could yield determined stem or progenitor cells for transplantation and use as replacement therapy for defective host cells. Ideally, cell fusion would constitute a means of post-natal cloning, by-passing the need for eggs or for directing the differentiation of ES cells.

1467

### Cell Fusion and Mitotic Reduction Divisions in Murine Epithelial Cells

M. Grompe,[1] H. Willenbring,[1] M. Al-Dhalimy,[1] M. Finegold[2]; [1]Department of Medical & Molecular Genetics, Oregon Health and Science University, Portland, OR, [2]Baylor College of Medicine, Houston, TX

Work from several laboratories has shown that hematopoietic stem cells (HSC) can give rise to epithelial cell types in the liver and kidney. Bone marrow derived hepatocytes (BMH) can successfully revert hepatic dysfunction in an animal model of a genetic liver disease, hereditary tyrosinemia type 1 (HT1). Similarly, bone marrow derived cells can reconstitute the tubular epithelium of the kidney in this model. These observations have raised the question whether bone marrow transplantation may have broad utility for the treatment of hepatocellular and renal diseases. However, recent experiments showed that the majority of bone marrow derived epithelial cells (BME) arise by cell fusion, not differentiation of stem cells. BMH express hepatocytic, but not hematopoietic markers and are fully functional in rescuing liver function in vivo. Therefore, the production of HSC derived epithelial cells involves at least partial reprogramming of the nucleus of the hematopoietic fusion partner to the hepatocyte fate. Transplantation of purified subpopulations of hematopoietic cells demonstrated that mature myelomonocytic and not stem cells were the fusion partner. Importantly, cells derived from fusion between hematopoietic donor cells and recipient epithelial cells were able to divide despite being tetraploid. We utilized serial transplantation of BMH to analyze the effects of cell division on the karyotype of synkaryons. Female bone marrow donors were transplanted into male HT1 recipients, followed by serial transplantation of BMH into female secondary recipients. Cytogenetic analysis revealed abundant numbers of male diploid BMH in the female secondary recipients. This observation strongly suggests that the tetraploid synkaryons underwent mitotic reduction divisions. Mitotic reduction divisions of epithelial cells have previously been described in insects but not in mammals. The frequency and significance of this phenomenon are currently unknown.

## Community Building to Promote Careers in Biomedical Science (1468)

1468

### Community Building to Promote Careers in Biomedical Science

C. H. Evans, M. I. Klopf, A. L. French; Department of Human Science, Georgetown University, Washington, DC

We have developed a rural underserved community partner education model to stimulate interest of high school students in biomedical science by working with students, their school, and community mentors. The goals are to 1) increase engagement of individuals from rural areas in the

intellectual and work life of biomedical scientists and health care professionals and 2) test the usefulness of a technologically-driven education model to higher education institutions in drawing rural communities into the intellectually and culturally rich life of institutes of higher learning. 70 high school junior and senior students and adults (52 youth and 18 adults) from the Oglala Lakota Sioux American Indian Pine Ridge Reservation in SD (20 participants), the African-American and Cajun Assumption Parish, LA community (36 participants) and Mexican-American migrant farm worker communities in Florida and Texas (14 participants) traveled to Georgetown University during 2003-5 for 3-week summer science institutes. The on-campus residential experiences featured educational skill evaluation and science classroom and hands on laboratory instruction by Georgetown University faculty, students, and invited experts, as well as career exploration activities. Continuing biomedical science education throughout the year is provided through a biological virtual laboratory that offers students innovative exercises to build qualitative and quantitative science critical thinking and analysis, and communications skills. Validating the effectiveness of this biomedical science education model for increasing individuals in the biomedical and health care related pipeline is being pursued by measuring the success of student participants in entering college and evaluating the biological virtual laboratory as a useful tool for distance interaction, learning and quantitative assessment. Supported by a NIH NCRR Science Education Partnership Award.

## Host-Pathogen Interactions (1469-1471)

1469

### The Biochemistry of HIV Budding

W. I. Sundquist; Department of Biochemistry, University of Utah, Salt Lake City, UT

The HIV Gag protein coordinates viral trafficking, membrane binding, assembly, cofactor packaging, budding, and maturation. Late in the infectious cycle, Gag assembles on plasma and endosomal membranes to form enveloped particles that bud through the membrane. We, and others, have previously shown that the cellular protein, TSG101, binds a conserved PTAP motif within Gag and facilitates virus budding. TSG101 normally functions as part of the multi-protein complex, ESCRT-I, which helps sort ubiquitylated protein cargos into vesicles that bud into late endosomal multivesicular bodies (MVB). These, and other observations support the idea that HIV and other enveloped RNA viruses usurp the machinery of MVB vesicle formation to bud from cells. I will describe our ongoing studies aimed at identifying and characterizing the cellular machinery required for HIV-1 budding, with particular emphasis on the ESCRT-I and VPS4/LIP5 complexes. VPS4/LIP5 is a large ATPase that functions late in MVB vesicle formation and virus budding by binding and releasing the assembled ESCRT machinery. Our structural studies reveal that VPS4 proteins are Type I AAA ATPases with five distinct regions: an N-terminal MIT domain that binds ESCRT-III substrates, a large alpha/beta AAA ATPase domain with a canonical Rossmann fold, a smaller helical AAA ATPase domain, a three-stranded antiparallel beta domain that binds LIP5, and a C-terminal helix of unknown function. Our current biochemical studies are aimed at understanding how VPS4/LIP5 releases/remodels the ESCRT-III machinery during MVB vesicle formation and virus budding.

1470

### Host-pathogen Interactions : The *Listeria* Paradigm

P. Cossart; Institut Pasteur, Paris, France

Bacterial pathogens have evolved a variety of strategies to maximally exploit host cell components and their specific properties, such as the cytoskeleton plasticity, during infection. *Listeria monocytogenes* has emerged as one of the best models to address these issues. During infection, this food pathogen disseminates from the intestinal lumen, to the liver and spleen up to the brain and the placenta after crossing three barriers, the intestinal-, the blood-brain- and the placental barrier resulting in gastroenteritis, meningitis, and materno-fetal infections. In infected tissues, *Listeria* is intracellular owing to its striking property to trigger its own internalization into cells which are normally non phagocytic and in which it replicates, somehow protected from host defenses. At the cell level, entry results in the formation of a vacuole in which the bacterium resides transiently before escaping into the cytosol where it moves using an actin-based motility process. Bacteria then spread directly from cell to cell resulting in their dissemination in infected tissues. Over the last decades, classical genetics, post-genomics and cell biology approaches together with *in vivo* studies using animal models including transgenic mice have led to the identification of listerial factors critical for specific steps of the infectious process, of their cellular ligands and of the signaling cascades resulting from their interactions, revealing how sophisticated are the strategies used by a single organism to exploit host components to its own profit and how tight is are the regulations that lead to a succesful infection. The study of the various underlying mechanisms has significantly contributed to decipher unsolved questions in cell biology such as actin-based motility. Recent results from our laboratory highlight that *Listeria* unexpectedly hijacks the clathrin dependent endocytosis machinery for entry into cells. Whether these results are of general relevance is under investigation.

1471

### Something Old, Something New, Something Borrowed, Something GREEN  The Cell Biology of Apicomplexan Parasites

D. S. Roos; Department of Biology & Genomics Institute, University of Pennsylvania, Philadelphia, PA

The phylum apicomplexa includes *Plasmodium* (which causes malaria), *Toxoplasma* (a leading source of congenital neurological birth defects, and a prominent opportunistic pathogen afflicting immunodeficient patients), and thousands of other protozoan species. Beyond their clinical importance, these intracellular parasites provide fantastic biological probes, manifesting much of the complexity that characterizes eukaryotes, but in a stripped-down package amenable to experimental manipulation both *in vitro* and *in vivo*. Conserved features provide insight into the evolutionary origins and dynamic functions of eukaryotic organelles, while parasite-specific features highlight organellar diversity and suggest strategies for blocking the progress of parasitic disease. Studies on the parasite cytoskeleton -- required for motility, host cell invasion, and replication -- reveals a paucity of filamentous actin, a diverse array of tubulin-based structures, a critical set of intermediate filaments, and a remarkable method of mitotic replication, in which highly polarized daughter cells are assembled within the mother according to a rigorous schedule of organellar duplication and segregation. Subcellular organelles include a specialized secretory apparatus that is required for host cell attachment, invasion, and establishment of the intracellular parasitophorous vacuole, within which parasite replication takes place. Remarkably, these organisms harbor a secondary endosymbiotic organelle, acquired when an ancient protist engulfed (or was invaded by) a eukaryotic alga -- and retained the algal plastid. The 'apicoplast' is an essential organelle, and a promising target for antiparasitic drug development. Studies on the

apicoplast also reveal much about the modular nature of eukaryotic targeting signals, and the evolution of endosymbiotic organelles. The availability of complete genome sequence for numerous apicoplexan parasites enables comparative genomic analysis, and robust systems for molecular genetic manipulation of *T. gondii* provide transgenic parasites for exploring host immune responses.

## Building Sensory Networks (1472-1477)

1472

### Dissecting the Molecular Basis of Photoreceptor Target Selection in the *Drosophila* Visual System

T. R. Clandinin; Neurobiology, Stanford University, Stanford, CA

Understanding how the complex wiring diagram of the central nervous system emerges during development is one of the central challenges in neurobiology. Our work is focused on characterizing the molecular mechanisms that allow neurons to choose specific synaptic partners, using the connections between photoreceptor cells and their primary targets in the Drosophila visual system as a model. Photoreceptor cells that look at the same point in space converge on a common set of target neurons. Remarkably, these precise connections are genetically hard-wired, emerging in the absence of visual input. Using a genetic screen based on a specific visual behavior, we have identified three cell surface molecules, namely two cadherin family members and one receptor tyrosine phosphatase, as playing critical roles in photoreceptor targeting. We are currently characterizing the genetic and biochemical interactions between these molecules. Ongoing experiments have identified additional molecular components. These experiments are likely to define a number of general molecular mechanisms that allow developing neurons to make choices between alternate synaptic partners in a wide range of contexts and animals.

1473

### The Role of Axon-Axon Competition in Retinotectal Map Formation

N. J. Gosse,[1] L. M. Nevin,[2] H. Baier[1,2,3]; [1]Program in Genetics, University of California, San Francisco, San Francisco, CA, [2]Program in Neuroscience, University of California, San Francisco, San Francisco, CA, [3]Department of Physiology, University of California, San Francisco, San Francisco, CA

We have devised a new experimental paradigm for the study of visual map development. In the zebrafish mutant *lakritz*, no retinal ganglion cells (RGCs) are formed, due to a null mutation in the bHLH transcription factor Ath5 (Atoh7). The *lakritz* tectum is therefore devoid of retinal input, but is otherwise normal, as judged by its size, gene expression, and cell-type composition. Wildtype (wt) cells grafted into a *lakritz* host at the blastula stage may give rise, later in development, to a chimera with small clones of wt cells in an otherwise mutant retina. These clones often contain just one RGC, which in turn projects a single axon into the tectum. This configuration has now allowed us to address the role of axon-axon interactions in retinotectal development. We first asked whether a solitary RGC axon would terminate in a topographically accurate location in the tectum, i.e. at the anterior-posterior position predicted by its nasal-temporal origin in the retina. We found that retinal axons in wt->*lakritz* chimeras terminated at approximately the same position as retinal axons in wt->wt chimeras. When all data were combined into a graph plotting tectal arbor position over retinal origin, a smooth map was observed with a slight anterior shift for the solitary axons over the crowded condition. Synaptic competition between neighboring retinal axons has been put forward as a mechanism to restrict arbor size in the tectum. Indeed, we observed that the arbors of solitary axons were twice as large and more complex than in wildtype. We conclude that axon-axon competition plays a surprisingly small role in retinotopic targeting, but strongly influences the elaboration of retinal arbors in the tectum.

1474

### Intraflagellar Transport (IFT) is Required for the Vectorial Movement of TRPV Channels in the Ciliary Membrane

H. Qin,[1] D. T. Burnette,[1] Y. Bae,[2] P. Forscher,[1] M. M. Barr,[2] J. L. Rosenbaum[1]; [1]MCDB Dept., Yale University, New Haven, CT, [2]School of Pharmacy, University of Wisconsin, Madison, WI

The membranes of all eukaryotic motile (9 +2) and immotile primary (9 +0) cilia harbor channels and receptors involved in sensory transduction. These membrane proteins are transported from the cytoplasm onto the ciliary membrane by vesicles targeted for exocytosis at a point adjacent to the ciliary basal body. Here, we use time-lapse fluorescence microscopy and genetics to demonstrate that select GFP-tagged sensory receptors undergo rapid vectorial transport along the entire length of the cilia of *Caenorhabditis elegans* sensory neurons in vivo. Transient receptor potential vanilloid (TRPV) channels OSM-9 and OCR-2 move in ciliary membranes at rates comparable to the intraflagellar transport (IFT) machinery located between the membrane and the underlying axonemal microtubules. OSM-9 and OCR-2 motility is disrupted in certain IFT mutant backgrounds. Surprisingly, motility of transient receptor potential polycystin (TRPP) channel PKD-2, a mechano-receptor, is not detected. Our study demonstrates that IFT, previously shown to be necessary for transport of axonemal components, is also required for the motility of TRPV membrane protein movement along cilia of *C. elegans* sensory cells.

1475

### Neural Ensemble Codes in Fly Olfaction

G. Miesenboeck; Department of Cell Biology, Yale University School of Medicine, New Haven, CT

To understand how information is represented by neuronal assemblies, we study the olfactory system of the fly, Drosophila melanogaster. Our experimental approach relies on genetically encoded optical sensors capable of revealing the activities of distinct neuronal populations in the living brain. Representations of odors and odor blends can thus be visualized in virtual isolation at successive, synaptically coupled stages of intact processing cascades, and the nature of the neural operations performed at and between stages can be deduced.

1476

### Dissecting Neural Networks Using Targeted Cell Class Ablation

S. Nirenberg; Dept. of Neurobiology, UCLA, Los Angeles, CA

Our research focuses on the general question "How do neural networks carry out computations? While a great deal is known about individual cells in the nervous system - in terms of their physiological properties and their patterns of connections - relatively little is known about how they act together in networks to produce specific outputs or carry out computations. Even computations that seem relatively simple, such as determining the

direction of motion of a moving object or the orientation of a line are still not completely understood. One approach to this problem is to dissect the networks using targeted cell class ablation - that is, dissect them by eliminating different classes of cells and evaluating how the network output is perturbed. The focus of my talk will be on a method we developed for this purpose and the results of using it to study network function.

1477

**Enhanced Signaling of a Serotonergic Circuit Regulates Aversive Olfactory Learning of *C elegans***

Y. Zhang, H. Lu, C. I. Bargmann; HHMI, The Rockefeller University, New York, NY

An animal's ability to avoid harmful food is essential for its survival. One robust form of olfactory learning is conditioned avoidance of food associated with noxious stimuli. In its natural soil habitat, *C. elegans* feeds on bacteria, potentially including pathogenic bacteria. Common soil bacteria *Pseudomonas aeruginosa* and *Serratia marcescens* can proliferate in *C. elegans'* intestine and cause death[1]. Learning to avoid pathogens could promote *C. elegans'* survival. Using an olfactory choice assay we found that animals raised on *S. marcescens* or *P. aeruginosa* supplemented with *E. coli* OP50 (standard worm food) avoided the pathogen when it was presented in a choice with OP50, while animals raised on OP50 showed no preference. This experience-based olfactory change is distinct from adaptation and appears to represent a form of associative learning similar to taste aversion. Adult animals exposed to pathogen acquire an aversion within a few hours, indicating that olfactory learning is an acute modification of animals' innate preferences. Different pathogens induce olfactory changes specific to animal's experiences. Using a multiple-choice assay, we found that trained animals acquired both an aversion to the training pathogen and an increased attraction for OP50. To identify modulatory pathways in pathogen-learning, we tested *tph-1* mutants, which are defective in serotonin synthesis. *tph-1* animals are deficient in both attractive and aversive learning. Increased serotonin contents are detected by HPLC in pathogen-trained animals; enhanced serotonin immunoreactivity is specifically detected in serotonergic neurons, ADF. Expression of *tph-1* cDNA in ADF fully rescues aversive learning. We also identified MOD-1, a serotonin-gated chloride channel, functioning in interneurons downstream of ADF to promote aversive learning. We concluded that pathogen exposure enhances serotonergic signaling in ADF neurons, stimulating aversive learning through MOD-1. (1). J.J. Ewbank, *Microbes Infect* 4, 247-56.

## Coordinating Adhesion & Signaling (1478-1483)

1478

**Coordinating Adhesion and Signaling in Colon Cancer Cells by Novel Target Genes of Beta-Catenin-Cadherin Signaling**

A. Ben-Ze'ev,[1] N. Gavert,[1] M. Conacci-Sorrell,[1] P. Altevogt,[2] T. Brabletz[3]; [1]Department of Molecular Cell Biology, Weizmann Institute of Science, Rehovot, Israel, [2]Tumor Immunology Programme, German Cancer Research Center, Heidelberg, Germany, [3]Department of Pathology, University of Erlangen-Nurenberg, Erlangen, Germany

Aberrant β-catenin signaling is prevalent in most colorectal cancer patients. β-catenin, an important cell-cell adhesion component binding cadherin receptors to the cytoskeleton, is also a key co-transcriptional activator of target genes (with LEF/TCF factors) in the nucleus. Hyperactive β-catenin induces genes regulating the cell cycle and the invasion and metastasis of cancer cells. Using human colon cancer cells, we found that sparse cultures mimic cells at the invasive front of tumors displaying low E-cadherin levels, but highly active nuclear β-catenin that transactivates *Slug*, a negative transcriptional regulator of E-cadherin. These cells also expressed abundant ErbB1/2 and active ERK. In contrast, dense cultures had distinct membranal E-cadherin and β-catenin, only limited β-catenin signaling, no Slug, and therefore high E-cadherin levels, but low levels of ErbB1/2 and MAPK signaling. This cell density-regulated phenotypic conversion is reminiscent of the plasticity in β-catenin and E-cadherin in the invasive versus the differentiated colorectal carcinoma tissue. We identified two members of the L1 cell adhesion family (normally expressed in nerve cells), as novel target genes of β-catenin, and found them exclusively in the invasive front of colon carcinoma tissue. Forced expression of L1 and Nr-CAM in fibroblasts induced motility, transformation, conferred tumorigenicity in mice, and liver metastasis in colon cancer cells. Suppression of L1 in colon cancer cells reduced their motility and ECM invasion. We suggest that these "neuronal" adhesion molecules, when aberrantly activated by β-catenin, are exploited opportunistically by colon cancer cells to promote metastasis. Since the extracellular domains of L1 and Nr-CAM are often shedded by metalloproteinases, they could serve as diagnostic markers and anticancer therapy targets. We identified L1 and the metalloproteinase ADAM10 at the invasive front of human colorectal cancer tissue.

1479

**A Central Role for p120ctn in the Regulation of Contact Inhibition of Cell Growth**

G. A. Wildenberg, R. Carnahan, M. Dohn, A. B. Reynolds; Cancer Biology, Vanderbilt University, Nashville, TN

p120ctn binds directly to the juxtamembrane domain of classical cadherins and is essential for proper cadherin function and stability. Overexpression of p120 in fibroblasts induces dramatic branching of cellular processes, apparently due to inhibition of the small GTPase RhoA. Here, we show that siRNA-based p120 ablation in NIH3T3 cells induces constitutive activation of RhoA and a dramatic increase in actin stress fibers. Interestingly, key branches of receptor tyrosine kinase and integrin signaling pathways that regulate the cytoskeleton through inhibition of RhoA are completely blocked, and the cells exhibit cancer-related phenotypes such as focus formation, proliferation in the absence of serum, and loss of contact-mediated inhibition of cell growth. We have found that the failure of contact inhibition occurs because p120 is an essential link in a signaling pathway that allows cadherin-ligation to regulate cell cycle progression. Our data reveal that p120 functions as a potent negative regulator of RhoA via dynamic assembly of novel p120-linked complexes, and these complexes mediate contact inhibition of cell growth.

1480

**A New Role for Desmoplakin in Intracellular Signaling?**

A. P. Miera, I. Gallicano; Cell Biology, Georgetown University, Washington, DC

For 30 years the canonical function for desmoplakin has been to link intermediate filaments to desmosomes. However, recent evidence strongly suggests that desmoplakin may also have nonconical functions. An example is the recent discovery of DP in capillaries and lymphatic vessels. DP has also been linked to the cell adhesion molecule, PECAM, which has a role in adhesion and signal transduction. In fact, the relationship between PECAM and DP led us to investigate if DP may have a role in cell signaling. To do so, we employed a high-throughput proteomics assay whereby

Luciferase-tagged DP cDNA bait was coexpressed with over 500 Flag-tagged prey cDNAs, followed by immunoprecipitation with a flag antibody and detection using the luciferase assay. Using this high throughput assay, we found three guanine exchange factors (GEFs) directly associated with DP. We analyzed the effects caused by GEF/DP interaction focusing on RhoA activity and its downstream targets in human embryonic keratinocytes. Co-immunoprecipitation studies revealed that GEF-1 directly associates with DP in a spatio-temporal manner during early time points of terminal differentiation. Inhibition of this binding by knocking down GEF1 resulted in diminished desmosome formation and diminished RhoA activity. Knocking down DP prior to inducing terminal differentiation and desmosome formation also resulted in diminished RhoA activity, which was restored upon DP siRNA degradation and re-expression of DP protein. Finally, using a fluorescent reporter that measures RhoA activity, we temporally and spatially confirmed the GEF/DP dependent-activation of RhoA at cell junctions during differentiation. Consequently, GEF/DP interaction is needed for normal RhoA activity in keratinocyte differentiation.

**Actin Remodelling during Epithelial Polarization: Distinct Actin Populations and Signalling Events**

V. M. M. Braga,[1] J. K. Zhang,[1] M. E. Betson,[1] J. Erasmus,[1] K. Zeikos,[1] M. Bailly,[2] L. Cramer[3]; [1]Division of Biomedical Sciences, Faculty of Life Sciences, Imperial College London, London, United Kingdom, [2]Institute of Ophthalmology, Imperial College London, London, United Kingdom, [3]MRC-LMCB, Imperial College London, London, United Kingdom

During establishment of cell-cell contacts, a tight coordination between cell adhesion and cytoskeletal remodelling is essential to ensure the morphology and integrity of epithelial sheets. These changes in cytoarchitecture are accompanied by the acquisition of functional and signalling properties that are intrinsic to epithelial function**.** The organization of actin filaments in polarized epithelia has been known for many years. However, during establishment of cell-cell adhesion, the temporal and spatial changes in actin dynamics and remodelling are poorly understood. During keratinocyte polarization, we identified two distinct actin pools: junctional-actin and thin actin bundles. These two actin populations differ in their actin dynamics, mechanism of formation and interestingly, have distinct roles during epithelial polarization. While junctional-actin stabilizes clustered cadherin receptors at cell-cell contacts, peripheral actin bundle reorganization is essential for increase in cell height during polarization. The contribution of Rho GTPases to the formation of each actin population will be discussed in a model that integrates the adhesion-dependent changes in actin dynamics and specific signalling pathways to form a polarized cell shape.

**E-cadherin Engagement Stimulates Proliferation via Rac1**

W. F. Liu,[1] C. M. Nelson,[1] D. M. Pirone,[2] C. S. Chen[2]; [1]Biomedical Engineering, Johns Hopkins University, Baltimore, MD, [2]Bioengineering, University of Pennsylvania, Philadelphia, PA

E-cadherin has been linked to suppression of tumor growth and contact inhibition of cell proliferation in culture, but is also present in tissues where cells continuously proliferate. The mechanism by which E-cadherin regulates proliferation is complex and remains elusive. Here we observed that progressively decreasing seeding density of NRK-52E or MCF10A from maximal confluence released cells from growth arrest, reaching the highest levels of proliferation at intermediate densities. Unexpectedly, further decreasing seeding density so that cells were isolated from their neighbors then decreased proliferation, suggesting that cell-cell contacts were responsible for the increased proliferation rates observed only at intermediate densities. Introducing cell-cell contacts by either increasing the number of cells within multicellular aggregates in three-dimensional cultures, or by examining cells in microwell cultures, also suggested increased proliferation when limited cell-cell contact occurred. The peak level of proliferation observed at intermediate densities was abrogated by expression of a dominant negative mutant of E- cadherin or exposure to blocking antibodies. Rac1 activity and associated lamellepodial ruffling and extension increased with cell-cell contact to maximal levels also at intermediate densities, and were abrogated with expression of dominant negative E-cadherin. Furthermore, inhibition of Rac1 signaling by expression of dominant negative mutants blocked E- cadherin-induced proliferation. The projected area of cell spreading against the underlying substrate correlated directly with proliferation, with highest degrees of spreading at intermediate cell densities, however microfabricated microwell cultures demonstrated that hese changes in cell spreading were not required for the cell-cell contact- induced increases in proliferation. In sum, these findings offer a simple mechanism by which cell-cell contact may stimulate or inhibit proliferation depending on the degree of contact, and demonstrate that dynamic changes in E-cadherin engagement may be used in different settings to trigger different proliferative responses.

**Mechanical Force Mobilizes Zyxin from Focal Adhesions to Actin Filaments and Regulates Cytoskeletal Reinforcement**

M. Yoshigi, L. M. Hoffman, C. C. Jensen, H. Yost, M. C. Beckerle; Huntsman Cancer Institute, University of Utah, Salt Lake City, UT

Organs and tissues adapt to acute or chronic mechanical stress through remodeling their actin cytoskeletons. Cells stimulated by cyclic stretch or shear stress in vitro undergo bi-modal cytoskeletal responses that include rapid reinforcement and gradual reorientation of actin stress fibers, however the mechanism by which cells respond to mechanical cues has been obscure. We report here that application of either unidirectional cyclic stretch or shear stress to cells results in robust mobilization of zyxin from focal adhesions to actin filaments while many other focal adhesion proteins and zyxin family members remain at focal adhesions. The mobilization of zyxin from focal adhesions does not occur in stretched cells plated on poly-lysine, suggesting that integrin-dependent adhesion is required for the response. The redistribution of zyxin upon stretch is preserved in cells treated with gadolinium, thus the response appears not to rely on stretch-activated channels. Mechanical stress also induces rapid, zyxin-dependent mobilization of Vasodilator-Stimulated Phosphoprotein (VASP) from focal adhesions to actin filaments. Thickening of actin stress fibers reflects a cellular adaptation to mechanical stress; this cytoskeletal reinforcement occurs coincident with zyxin mobilization, is abrogated in zyxin-null cells, and is restored upon re-expression of zyxin. Interestingly, the reorientation of cytoskeletal elements in response to uniaxial stretch occurs normally in zyxin-null cells, thus demonstrating that the cytoskeletal reinforcement and reorientation responses are mechanistically distinct. Our findings identify zyxin as a mechanosensitive protein and provide mechanistic insight into how cells respond to mechanical cues.

## Cytoskeletal Molecular Motors (1484-1489)

1484

### Dimerization, but not the Dynein Associated Proteins, is Required for Processive Movement of Yeast Cytoplasmic Dynein

S. L. Reck-Peterson, A. P. Carter, A. Yildiz, A. Gennerich, R. D. Vale; Cellular and Molecular Pharmacology, UCSF, San Francisco, CA

Cytoplasmic dynein is responsible for nearly all minus-end directed microtubule based traffic in most eukaryotic cells and has additional roles in mitosis; however, its mechanism of movement is poorly understood compared to kinesin and myosin. We have developed a method to purify native cytoplasmic dynein and a minimal functional motor domain from *S. cerevisiae.* Using total internal reflection and optical trap microscopy, we find that yeast cytoplasmic dynein is a highly processive motor with a run length of ~8 um and a stall force of ~6 pN. Cytoplasmic dynein processivity requires a dimer of two motor domains. As evidence, we find that monomeric dynein is not processive, but can be induced to move processively by artificial dimerization. By using yeast strains deleted for various dynein associated proteins, we show that the dynein heavy chain is sufficient for processivity, although associated proteins may affect the run length. Finally, to address the stepping mechanism of this motor, we have performed FIONA (Fluorescence Imaging with One Nanometer Accuracy) experiments with dynein molecules labeled on a single motor domain or on the tail domain and have been able to resolve individual steps at low ATP concentration. Based on this data, we propose a model in which dynein moves by a hand-over-hand mechanism with a primary displacement of ~8 nm per cycle although occasional larger steps are observed. Thus, like kinesin and myosin V, cytoplasmic dynein moves processively through the coordination of its two motor domains.

1485

### Myosin VI is a Dimer Due to Actin *in vivo*

H. Park,[1] H. Lee Sweeney,[2] P. R. Selvin[1]; [1]Department of Physics and Biophysics, University of Illinois, Urbana-Champaign, Urbana, IL, [2]Penn. Muscle Institute, University of Pennsylvania, Philadelphia, PA

Myosin VI is a reverse direction actin-based motor capable of taking surprisingly large steps (~30 nm center-of-mass; 60 nm hand-over-hand) when dimerized. However, all dimeric myosin VI molecules that have been examined to date have included a non-native coiled-coil sequences. Reports on full length myosin VI have failed to demonstrate the existence of dimers, and it has been suggested that the predicted coiled-coil sequence within myosin VI may not be capable of dimerization. Here we demonstrate that full-length myosin VI is capable of forming a stable, processive dimer when it binds to actin, moving distances up to 1.1 µm with approximately 30 nm center-of-mass steps in a hand-over-hand fashion. Upon shortening by 203 a.a., removing the cargo-binding domain, the molecule is still processive, with a large fraction (90%) of molecules moving. Upon further shortening by a total of 336 a.a.'s, removing much of the coiled-coil domain, very few myosin VI molecules move, and removing the whole coiled-coil domain makes it non-processive. Furthermore, we present data consistent with the molecule being in an equilibrium between folded and unfolded monomers that are prevented from dimerizing by an inhibitory region within both the motor domains. A model thus emerges that cargo binding likely clusters full length myosin VI molecules, but actin binding is required to induce dimerization by inhibitory regions in both the motor domain and the cargo-binding domain.

1486

### Structural Analysis of Myosin-V Discrimination between Distinct Cargoes

N. Pashkova,[1] Y. Jin,[2] S. Ramaswamy,[1] L. S. Weisman[2]; [1]Biochemistry, University of Iowa, Iowa City, IA, [2]Life Sciences Institute, University of Michigan, Ann Arbor, MI

Myosin V molecular motors function in relatively long-range movement on actin filaments. In a single cell type, a myosin V may move multiple cargoes to distinct places at different times. Indeed the *Saccharomyces cerevisiae* myosin V, Myo2p, moves multiple cargoes including secretory vesicles, the late Golgi, peroxisomes, vacuoles, and the nuclear spindle. The identification of specific mutations that affect the movement of a single cargo has suggested that each cargo binds a distinct region on myosin V. Here we report the crystal structure at 2.2 Å of the myosin V cargo-binding domain. It is comprised of two helical bundles. There are several patches of highly conserved regions distributed on the surface which are candidate attachment sites for cargo-specific receptors. We identified a region of conserved surface residues that is solely required for vacuole inheritance and a second region that is required for secretory vesicle movement, but not vacuole movement. These cargo-binding regions are at opposite ends of the oblong-shaped cargo-binding domain, and moreover are offset by approximately 180° . This large separation of cargo-binding areas strongly suggests that the globular tail of myosin V serves as a scaffold for binding multiple cargoes. That both the vacuole binding region and secretory vesicle region are simultaneously exposed on the surface of the globular tail, suggests that the major targets for the regulation of cargo movement are organelle-specific myosin V receptors.

1487

### Cik1 Targets the Minus-end Kinesin Depolymerase Kar3 to Microtubule Plus-ends

L. R. Sproul,[1] D. J. Anderson,[1] A. T. Mackey,[2] W. S. Saunders,[1] S. P. Gilbert[1]; [1]Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA, [2]Department of Molecular, Cellular, and Developmental biology, Yale University, New Haven, CT

Kar3, a *Saccharomyces cerevisiae* Kinesin-14, is essential for karyogamy and meiosis I, but also has specific functions during vegetative growth. For its various roles during the yeast life cycle, Kar3 forms a heterodimer with either Cik1 or Vik1, both of which are non-catalytic polypeptides. We will present the first biochemical characterization of Kar3Cik1, the kinesin motor which is essential for karyogamy. Kar3Cik1 depolymerizes microtubules from the plus-end and promotes robust minus-end directed microtubule gliding (2.4 µm/min). Immunolocalization studies show that Kar3Cik1 binds preferentially to one end of the microtubule, while the Kar3 motor domain in the absence of Cik1 exhibits significantly higher microtubule lattice binding. Kar3Cik1-promoted microtubule depolymerization requires ATP turnover, and the kinetics fit a single exponential function ($k_{obs}$ = 0.07 $s^{-1}$). The disassembly mechanism is not microtubule catastrophe like that induced by the MCAK Kinesin-13s. Soluble tubulin does not activate the ATPase activity of Kar3Cik1, and there is no evidence of Kar3Cik1-tubulin complex formation as observed for MCAK. These results reveal a novel mechanism to regulate microtubule depolymerization. We propose that Cik1 targets Kar3 to the microtubule plus-end. Kar3Cik1 then uses its minus-end directed force to depolymerize microtubules from the plus-end with each tubulin subunit release event tightly coupled to one ATP turnover. Supported by NIH GM54141 and K02-AR47841 to SPG.

**Self-assembly is Important for the Function of Centralspindlin, a Protein Complex of Mitotic Kinesin and RhoGAP**

M. Mishima,[1,2] M. Glotzer[3,2]; [1]Wellcome/CRUK Gurdon Institute, University of Cambridge, Cambridge, United Kingdom, [2]Research Institute of Molecular Pathology (IMP), Vienna, Austria, [3]Department of Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL

Cytokinesis is essential for cell proliferation and its accurate execution is important for the maintenance of genomic stability. Antiparallel microtubule structures play critical roles in cytokinesis. The central spindle, together with astral microtubules, contributes to specification and promotion of cleavage furrow ingression. The midbody is indispensable for the completion of cytokinesis. Proper assembly of these microtubule structures is dependent on centralspindlin, an evolutionarily conserved protein complex consisting of ZEN-4/Pavarotti/MKLP1 kinesin and CYK-4/RacGAP50C/MgcRacGAP RhoGAP, which has microtubule-bundling activity. It accumulates on the central spindle during anaphase and highly concentrates to the center of the midbody during telophase. The mechanism by which centralspindlin accumulates exclusively on the central spindle and later to the center of the midbody, and not to other microtubule structures, is not known. We have found that centralspindlin undergoes self-assembly into higher order structures. The self-assembly is mediated by a defined region in the putative coiled coil of ZEN-4, the mitotic kinesin subunit in *C. elegans*. A centralspindlin complex whose ZEN-4 subunit is deficient in self-assembly is defective in microtubule bundling. A self-assembly-deficient zen-4 transgene rescued zen-4 null animals less efficiently than wild type zen-4 transgene. These results suggest an important role of self-assembly in the function of centralspindlin.

1489

**Myosin VII and Cell Adhesion**

M. A. Titus, S. A. Galdeen, S. Stephens; Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN

The class VII myosins (M7s) are characterized by the presence of two MyTH4/FERM domains in their tail and are widely expressed throughout phylogeny. Dictyostelium cells lacking M7 are defective in adhesion to substratra and filopod extension. The major Dictyostelium M7 binding partner is talinA, a FERM domain protein with a role in adhesion. TalinA levels are directly linked to M7 levels - overexpression of M7 (either the full-length protein or the tail) results in increased talinA levels and cells lacking M7 have decreased talinA levels. Both proteins are localized to the plasma membrane of Dictyostelium cells, and enriched where actin-based protrusions such as lamellipodia are extended. Deletion studies reveal that removal of a single FERM domain from the M7 tail does not alter localization to the plasma membrane but that deletion of both FERM domains abolishes M7 membrane localization. Two FERM domains linked together, either with or without their preceding MyTH4 domains, fail to localize to the cortex indicating that the FERM domains are necessary but not sufficient for targeting M7 to the plasma membrane. While talinA is not required for M7 localization to the plasma membrane, preliminary IP results reveal additional M7 binding partners in a membrane-cytoskeleton fraction that may play a role in the cortical localization of M7. The role of M7 in adhesion is also being explored in C. elegans. A mutant carrying a deletion in the hum-6 gene encoding the sole M7 is embryonic lethal. The embryos die at the two-fold stage, a time when hypodermis-body wall muscle attachment is critical for continued development, suggesting that M7 may also play a role in cell-cell adhesion in worms.

## Intermediate Filaments (1490-1495)

1490

**A Dominant Vimentin Mutation Causes a Posterior Cataract in Mice**

R. Meier-Bornheim,[1] H. Büssow,[2] D. Bröhl,[2] S. Loch,[1] T. M. Magin[1]; [1]Physiological Chemistry, University of Bonn, Bonn, Germany, [2]Division of Cellular Biochemistry and LIMES, University of Bonn, Bonn, Germany

To gain new insights into the function of the intermediate filament (IF) protein vimentin *in vivo*, we generated transgenic mice which express a mutant vimentin gene controlled by its promoter. The mutation was designed to cause a mutation in the consensus motif in coil1A ($R_{113}C$). Analogous mutations in keratins and GFAP lead to keratinopathies and Alexander disease, respectively. In transgenic mice, $R_{113}C$ acted in a dominant-negative way and displayed cytoplasmic vimentin aggregates in all tissues examined. Vimentin inclusions were most prominent in lens fibre cells and began to form a few days after birth. In due course, lens fibre cells became highly disorganised and were disrupted, culminating in a posterior capsule rupture. Vim$R_{113}C$-expressing lens fibre cells showed premature enucleation, suggesting an involvement of vimentin in this process. Moreover, the mutant caused a strong upregulation of hsp70 but did not interfere with the expression and organisation of the specific lens IF proteins filensin and phakinin. The center of the lens became devoid of aggregated vimentin, demonstrating that aggregates, even in enucleated fibre cells, can be degraded. This was mediated by an upregulation of proteasome activity, which in addition may contribute to lens pathology. In addition, we demonstrated an upregulation of GFAP in the lens epithelium of vim$R_{113}C$-mutant mice, suggesting that the mutant induced a tissue repair process in the regenerating epithelium. Upon expression in cultured fibroblasts, vim$R_{113}C$ induced an increase in the stress-activated kinases ERK1/2. Collectively, our data suggest that vimentin mutations may cause cataracts in humans.

1491

**Novel Roles of Intermediate Filaments in Adhesion and Transcellular Migration**

M. Nieminen,[1] T. Henttinen,[1] M. Merinen,[2] F. Marttila,[2] S. Jalkanen,[2] J. E. Eriksson[1]; [1]Dept. of Biology, University of Turku, Turku, Finland, [2]MediCity Research Unit, University of Turku, Turku, Finland

While the adhesive interactions of leukocytes with endothelial cells are well established, little is known about the detailed mechanisms underlying the actual diapedesis of leukocytes. We have observed that the transmigration commences through two different routes. While polymorphonuclear (PMN) cells (mainly neutrophils) migrate between endothelial cells through junctional areas (paracellular pathway), strikingly peripheral blood mononuclear cells (PBMCs; T and B lymphocytes) were able to pass straight through the endothelial cell (EC) body (transcellular route). The endothelial and the lymphocyte intermediate filaments (IFs) formed a highly dynamic anchoring structure at the site of the EC-PBMC contact. The initiation of this process was markedly reduced in vimentin-deficient (vim -/-) ECs and PBMCs. Furthermore, when compared to wildtype PBMCs, vim -/- PBMCs showed markedly reduced capacity to home to mesenteric lymph nodes and spleen when injected into the mice. These results show that IFs play an active role during lymphocyte adhesion and transmigration, which is a completely novel function for IFs. The dynamic IF structure provides a molecular basis for the transmigratory traction assembly of adhesion molecules. In support of this hypothesis, vim -/- ECs and PMBCs

both showed highly aberrant expression and distribution of surface molecules critical for homing (ICAM-1 and integrin- 1). The molecular mechanisms of IF-adhesion molecule interaction and the role of phosphorylation will be discussed.

**KIF5A is Required for Both Anterograde and Retrograde Movement of Neurofilaments in Axons**

A. Uchida, A. Brown; Center for Molecular Neurobiology, The Ohio State University, Columbus, OH

Neurofilaments are transported bidirectionally along axons in a rapid infrequent manner. The retrograde motor is dynein but the anterograde motor is unknown. Recently the Goldstein lab reported that targeted deletion of KIF5A in mice causes neurofilament accumulation in DRG cell bodies and a reduction in axonal caliber with no apparent effect on organelle transport, suggesting that KIF5A is an anterograde neurofilament motor. To test this hypothesis, we cultured neurons from wild type (WT) and KIF5A-/- mice. Both sympathetic (SCG) and sensory (DRG) KIF5A-/- neurons extended axons that contained neurofilaments. To examine neurofilament transport, we performed time-lapse fluorescence imaging on SCG neurons expressing GFP-tagged neurofilament protein. The frequency of both anterograde and retrograde neurofilament movement was reduced significantly compared to WT ($p<0.001$, K-S test; average reduction=75%). For those neurofilaments that moved, the average anterograde velocity (excluding pauses) was reduced significantly ($p=0.001$, K-S test; average reduction=52%) but the average retrograde velocity was not ($p=0.4$, K-S test). Immunostaining revealed apparently normal dynein/dynactin levels in KIF5A-/- axons and Western blotting revealed normal levels of dynein/dynactin and kinesin light chains in KIF5A-/- brain. Expression of full-length KIF5A in KIF5A-/- SCG neurons rescued the frequency of neurofilament movement in both directions and partially rescued the anterograde velocity. Expression of a “dominant negative” headless KIF5A in WT SCG neurons completely inhibited movement in both directions. Collectively these data indicate that (1) KIF5A is the principal but not exclusive anterograde motor for neurofilaments in SCG neurons, (2) proteins with homology to KIF5A, probably KIF5B and/or KIF5C, may also be capable of moving neurofilaments anterogradely, and (3) KIF5A is necessary for normal retrograde movement of neurofilaments, which suggests a direct or indirect interaction between the dynein and kinesin motors.

1492

**KIF5A is Required for Both Anterograde and Retrograde Movement of Neurofilaments in Axons**

A. Uchida, A. Brown; Center for Molecular Neurobiology, The Ohio State University, Columbus, OH

Neurofilaments are transported bidirectionally along axons in a rapid infrequent manner. The retrograde motor is dynein but the anterograde motor is unknown. Recently the Goldstein lab reported that targeted deletion of KIF5A in mice causes neurofilament accumulation in DRG cell bodies and a reduction in axonal caliber with no apparent effect on organelle transport, suggesting that KIF5A is an anterograde neurofilament motor. To test this hypothesis, we cultured neurons from wild type (WT) and KIF5A-/- mice. Both sympathetic (SCG) and sensory (DRG) KIF5A-/- neurons extended axons that contained neurofilaments. **Interaction of Keratin 17 with 14-3-3 Regulates Protein Synthesis and Cell Growth**

S. Kim, P. Wong, P. A. Coulombe; Biological Chemistry, The Johns Hopkins University School of Medicine, Baltimore, MD

Upregulation of keratin 17 (K17), a type I intermediate filament protein, is a hallmark of stratified epithelia undergoing repair, but its role in this setting has yet to be defined. Here we show that this abundant cytoskeletal protein regulates protein synthesis and epithelial cell growth through its phosphorylation-dependent binding to 14-3-3sigma (stratifin), a multifunctional adaptor protein. Mouse keratinocytes lacking K17 exhibit depressed protein translation and a smaller size correlating with a decrease in the activity of the Akt/mammalian target of rapamycin (mTOR) pathway. Binding of K17 to 14-3-3 is required for the serum-dependent export of 14-3-3 from the nucleus to the cytoplasm, and subsequent stimulation of mTOR activity and protein synthesis. Loss of this function likely accounts for the delay in ectodermal wound closure exhibited by K17 null embryos, a physiological context in which lack of this keratin is associated with a smaller cell size. These findings reveal a novel and unexpected role whereby the intermediate filament cytoskeleton influences cell growth and size by regulating protein synthesis.

1494

**Keratin-8 Mutation Predisposes to Liver Injury by Altering Stress Kinase-mediated Phosphorylation**

N. Ku, M. B. Omary; Medicine, Palo Alto VA Medical Center and Stanford University, Palo Alto, CA

Keratin 8 (K8) G61C mutation is a risk factor for developing end-stage liver disease, as determined by human association studies, but direct evidence for predisposition to liver injury via a natural human K8 mutation is lacking. To investigate the in vivo significance of the human liver disease-associated K8 G61C mutation, we generated transgenic mice that overexpress wild type (WT) or G61C human (h) K8 and compared their susceptibility to stress-induced liver injury. K8 expression was comparable in WT and G61C K8 lines, and there was no significant effect of hK8 transgene expression on endogenous keratin filament organization or on baseline liver histology. However, K8 G61C mice are significantly more susceptible to Fas- or microcystin-LR-induced liver injury as compared to non-transgenic and WT K8 animals. Most deaths occurred within 6-12 hr after drug administration, and histologic assessment after injury supported the mortality data. In mice and transfected cells, K8 G61C decreases dramatically K8 Ser73 phosphorylation by stress-related kinases. K8 G61C is highly insoluble and generates cross-linked keratins in transgenic

mouse livers after administration of Fas or the oxidizing agent paraquat, which may contribute to kinase inaccessibility to K8 Ser73. The importance of K8 Ser73 phosphorylation in protection from liver injury was confirmed by generating mice that overexpress K8 S73A which manifest increased susceptibility to injury similar to G61C mice. These findings provide direct evidence that naturally occurring human K8 mutations predispose to liver injury, and suggest an important role for K8 in protecting hepatocytes from injury by serving as a phosphate sink for stress-activated kinases. This role may extend to keratin-related diseases in other tissues where the K8 S73-containing epitope is conserved.

1495

**The Common Lamin A (LA) Mutation in Hutchison Gilford Progeria (HGPS) Causes a Decrease in Histone Methylation**

D. K. Shumaker,[1] T. Dechat,[1] M. R. Bozovsky,[1] A. E. Goldman,[1] S. Khuon,[1] S. A. Adam,[1] A. Kohlmaier,[2] M. R. Erdos,[3] M. Eriksson,[4] F. S. Collins,[3] T. Jenuwein,[2] R. D. Goldman[1]; [1]Cell Molecular Biology, Northwestern University The Feinberg School of Medcine, Chicago, IL, [2]Research Institute of Molecular Pathology, Vienna, Austria, [3]Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, [4]Department of Medical Nutrition, Karolinska Institutet, Huddinge, Sweden

There is a loss of peripheral heterochromatin in nuclei of HGPS patients' cells expressing the most common LA mutation (LAΔ50). Using a female LAΔ50 patient's cells, we have gained insights into the mechanisms involved in the loss of heterochromatin using the inactive X (Xi) chromosome as a reporter for peripheral heterochromatin. Xi is readily visualized by immunofluorescence using an antibody to the trimethylated K27 on histone H3 (H3K27m3). In mid-passage HGPS cells, H3K27m3 is lost as determined by immunoblotting and there is an apparent loss of Xi by immunofluorescence prior to nuclear envelope lobulation. However, fluorescence *in situ* hybridization (FISH) shows that Xist RNA is retained in these HGPS cells for over 20 passages when nuclei became highly convoluted and LAΔ50 accumulates to high levels. However, in late passage cells the Xist RNA appears to unravel. In contrast, the Xi in cells from the normal female sibling of this patient appears normal for up to 20 passages. To more specifically test whether the accumulation of LAΔ50 causes the loss of H3K27m3, female kidney (HEK293) cells were transfected with pEGFP-LAΔ50 cDNA. Within 12-24 h the Xi in these cells could not be detected with anti-H3K27m3. Controls transfected with pEGFP-LA cDNA showed no loss of Xi staining. In both cases, Xist RNA remained associated with the Xi. There is also a complete loss of peripheral heterochromatin in a stable HeLa cell line expressing GFP-LAΔ50. RTPCR analyses showed that the Ezh2 mRNA which encodes the transmethylase responsible for H3K27 methylation is greatly reduced in mid-late passage HGPS cells. Supported by NIA, PRF and the Ellison Foundation.

## Intersection of Signaling & Trafficking: Small GTPases (1496-1501)

1496

**Disruption of Actin Cytoskeleton Leads to tER-Golgi Splitting in *Drosophila* S2 Cells**

V. Kondylis, B. H. A. Herpers, C. Rabouille; Cell Biology, Cell Microscopy Centre, University Medical Centre Utrecht, Utrecht, The Netherlands

In addition to its central position in intracellular membrane traffic, the Golgi apparatus has been suggested to act as platform for signaling events. Accordingly, there is accumulating evidence showing that several small GTPases of the Ras superfamily and their binding proteins localize on the Golgi membranes, where they could initiate signaling cascades but also maintain/alter the Golgi architecture. The latter seems to be confered by regulating locally the cytoskeleton organization. In *Drosophila* S2 cells, the Golgi apparatus is organized in ~20 individual Golgi stacks closely associated with tER sites (tER-Golgi units). Whereas microtubule depolymerisation does not affect their organization, interference with F-actin dynamics using Cytochalasin D or Latrunculin B results in an approximately 2-fold increase in the number of both the Golgi stacks and tER sites. This has been assessed by immunofluorescence localisation of tethering and Golgi resident proteins, COPII subunits, and cargo receptors, while electron microscopy has revealed that Golgi stacked morphology in these cells remains largely intact. Kinetically, the effect of F-actin depolymerisation on tER-Golgi units takes place within 15-30 min after drug treatment, without significantly affecting anterograde transport to the plasma membrane. The tER-Golgi duplication is protein synthesis and ER-Golgi transport independent, suggesting a splitting rather than a *de novo* mechanism for the formation of the additional organelles. The molecular mechanism involved in tER-Golgi splitting, through F-actin local rearrangements, is currently under investigation. Preliminary results suggest that cdc42- or Rock kinase-mediated changes in F-actin dynamics are not responsible for the effect. Finally, to address the biological significance of this phenomenon, the behaviour of the tER sites and Golgi apparatus during cell cycle is being analyzed.

1497

**Arhgap21, a Novel Rhogap Protein Acting at the Crossroads between Arf1 and Cdc42 Pathways**

P. Chavrier,[1] T. Dubois,[1] N. Ekhatibe,[1] J. Menetrey,[1] M. Perderiset,[1] A. Houdusse,[1] O. Paleotti,[2] M. Franco,[2] A. A. Mironov,[3] M. De Matteis[3]; [1]Cell Biology, Institut Curie, Paris, France, [2]Cnrs umr6097, IPMC, Valbonne, France, [3]Consorzio Mario Negri Sud, Santa Maria Imbaro, Italy

ADP-ribosylation factors (ARFs) are a family of GTP-binding proteins involved in the control of membrane trafficking. ARF1 acts as a master regulator of Golgi complex organization and function through the recruitment of various effectors including coat proteins and lipid modifying enzymes. Members of the Rho family, especially Cdc42, are also known to control Golgi structure through the regulation of Arp2/3 complex/F-actin dynamics on Golgi membranes. We identified ARHGAP21 by yeast two-hybrid as a downstream partner of GTP-bound ARF1. Immuno-localization analysis revealed that ARHGAP21 is predominantly associated with the Golgi complex in an ARF1-dependent manner. ARHGAP21 comprises a RhoGAP domain, which preferentially stimulates Cdc42-mediated GTP hydrolysis in vitro. In addition, ARHGAP21 harbors an amino-terminal PDZ domain and a PH domain. The PH domain, although it does not interact with lipids, is required for interaction with GTP-bound ARF1 and Golgi association. The crystal structure of the complex between GTP-ARF1 and the ARF-binding domain of ARHGAP10 revealed that the interface comprises the PH domain and a carboxy-terminal flanking region. The function of ARHGAP21 on the Golgi complex has been assessed by knocking-down the protein by treatment with short interfering RNAs. Loss of ARHGAP21 was shown to induce fragmentation of the Golgi complex and the accumulation of Arp2/3 complex-containing structures in the cytoplasm. In addition, constitutive activation of ARF1 triggered the formation of F-actin and Arp2/3 complex-based structures, which required Cdc42 activity and was inhibited by expression of the RhoGAP domain. We will also provide evidence that a novel RhoGAP protein closely related to ARHGAP21 is able to bind activated ARF proteins. All together, our results establish a role for ARHGAP21-related proteins in the control of membrane trafficking

downstream of ARF proteins through the regulation Cdc42-mediated actin cytoskeleton reorganization.

**Yeast Oxysterol-Binding Protein Homologues Affect CDC42- and RHO1-Mediated Cell Polarization**

K. G. Kozminski,[1] G. Alfaro,[2] C. T. Beh[2]; [1]Depts. Biology and Cell Biology, University of Virginia, Charlottesville, VA, [2]Dept. Molecular Biology & Biochemistry, Simon Fraser University, Burnaby, BC, Canada

Polarized cell growth requires the establishment of an axis of growth (i.e., cell polarity), which is generally followed by targeted secretion to the cell cortex along this established axis. Disrupting the ordered progression of these processes causes a failure in polarized growth, leading to cells with aberrant cell morphology and impaired function. How polarity establishment and secretion are choreographed is not fully understood, though it is known that Rho and Rab GTPase-mediated signal transduction is required for these events. Superimposed on this regulation are the functions of specific lipids and their cognate binding proteins. Using *S. cerevisiae* to screen for genes that promote polarity establishment by interactions with *CDC42*, which encodes a Rho-family GTPase, we identified *KES1/OSH4*, a yeast homologue of the canonical human oxysterol-binding protein (OSBP). We found that several other yeast *OSH* genes (OSBP homologues) had comparable genetic interactions with *CDC42*, implicating the *OSH* gene family in the regulation of *CDC42*-dependent polarity establishment. We also showed that the entire *OSH* gene family (*OSH1 - OSH7*) is necessary for the maintenance of cell polarity and for the proper localization of proteins involved in polarized growth (i.e., bud formation) such as septins and the Rab GTPase Sec4p. However, many proteins involved in the polarized organization of the actin cytoskeleton localized at the bud site independently of *OSH* gene function. Our data showed that although *OSH* genes promote *CDC42*-dependent polarity establishment, they are antagonistic to *RHO1*-dependent secretion, working in opposition to Sec4p GTPase Activating Proteins (Msb3p and Msb4p). Based on our data, we propose a model in which *OSH* gene function licenses polarized secretion only after cell polarity is established.

**Reversible Intracellular Translocation of KRas in Hippocampal Neurons Regulated by Ca2+/Calmodulin**

M. Fivaz, T. Meyer; Molecular Pharmacology, Stanford University, CA, Stanford, CA

The Ras/MAPK pathway regulates synaptic plasticity and cell survival in neurons of the central nervous system. Here, we show that KRas but not HRas rapidly translocates from the plasma membrane to the Golgi complex and early/recycling endosomes in response to neuronal activity. Translocation is reversible and mediated by the polybasic-prenyl membrane targeting motif of KRas. We provide evidence that KRas translocation occurs through sequestration of the polybasic-prenyl motif by $Ca^{2+}$/Calmodulin ($Ca^{2+}$/CaM) and subsequent release of KRas from the plasma membrane, in a process reminiscent of GDP dissociation inhibitor (GDI)-mediated membrane recycling of Rab and Rho GTPases. KRas translocation was accompanied by partial intracellular redistribution of its activity. We conclude that the polybasic-prenyl motif acts as a $Ca^{2+}$/CaM-regulated molecular switch that controls plasma membrane concentration of KRas and redistributes its activity to internal sites. Our data thus define a novel signaling mechanism that differentially regulates KRas and HRas localization and activity in neurons.

**The DOCK180/Elmo Complex Couples Arf6 Activation to the Downstream Activation of Rac1**

L. C. Santy,[1] K. Ravichandran,[2] J. E. Casanova[1]; [1]Department of Cell Biology, University of Virginia, Charlottesville, VA, [2]Department of Microbiology, University of Virginia, Charlottesville, VA

Cell motility requires extensions of the plasma membrane driven by reorganization of the actin cytoskeleton. Small GTPases, particularly members of the Rho-family, are key regulators of this process. A second class of GTPases, the ADP-ribosylation factors (ARFs) have also been implicated in the regulation of the actin cytoskeleton and motility . ARF6 is intimately involved in the regulation of Rac activity, however the mechanisms by which ARF activation leads to activation of Rac remain poorly understood. We have previously shown that expression of the ARF-specific guanine nucleotide exchange factor ARNO in MDCK cells induces robust activation of Rac, the formation of large lamellipodia and the onset of motility. We report here that this Arf6-induced activation of Rac is mediated by a bipartite Rac GEF, the Dock180/Elmo complex. Both DOCK180 and Elmo colocalize extensively with ARNO in migrating MDCK cells. Importantly, both a catalytically inactive Dock180 mutant and an Elmo mutant that fails to couple to Dock180 block ARNO-induced Rac activation and motility. In contrast, a similar mutant of the Rac GEF Î²-PIX fails to inhibit Rac activation or motility in this context. Together, these data suggest that ARNO and ARF6 coordinate with the Dock180/Elmo complex to promote Rac activation at the leading edge of migrating cells.

1501

**NGF Signaling in Neurite Outgrowth via Regulation of Rab5**

J. Liu,[1] Z. Liang,[1] D. Lamb,[1] M. Chou,[2] Y. Liu,[3] G. Li[1]; [1]Biochemistry and Molecular Biology, University of Oklahoma HSC, Oklahoma City, OK, [2]Cell and Developmental Biology, University of Pennsylvania School of Medicine, Philadelphia, PA, [3]Neurology, University of Pittsburgh School of Medicine, Pittsburgh, PA

NGF induces neurite outgrowth in the differentiation of PC12 cells. This process involves NGF binding to its receptor TrkA and endocytosis of the NGF-TrkA complex into signaling endosomes where the differentiation signal is propagated and sustained. In this study, we find that this process requires inactivation of Rab5 to shut down early endosome fusion, allowing TrkA-containing endocytic vesicles to mature/specialize into signaling endosomes. NGF treatment led to decreases in the cellular level of active GTP-bound Rab5, as shown by pull-down assays with the Rab5 effector Rabaptin5. Importantly, we identified a novel Rab5 GAP (RabGAP5) that was associated with TrkA in co-immunoprecipitation assays and was responsible for the decrease of Rab5-GTP level in the cell. Expression of a GAP-dead RabGAP5 mutant blocked neurite outgrowth in PC12 cells. Furthermore, expression of a dominant negative Rab5 mutant (Rab5:S34N) enhanced NGF-induced neurite outgrowth, while expression of a dominant positive Rab5 mutant (Rab5:Q79L) to force early endosome fusion abolished this differentiation process. We further confirmed these results by establishing stable PC12 cell lines expressing Rab5:S34N. The neurite outgrowth in these cells occurred much earlier than in parental PC12 cells. Taken together, the results suggest that NGF down-regulates Rab5 via RabGAP5 to facilitate neurite outgrowth and cell differentiation. This process is in contrast to EGF-induced cell growth where EGF signals through RIN1, a Rab5 GEF, to activate Rab5.

## Mitosis & Meiosis (1502-1507)

1502

### Studying Spindle Assembly and Chromosome Condensation in *Xenopus* Egg Extracts

R. Heald, R. Deehan, B. S. Freedman, E. Hannak, T. J. Maresca, M. D. Blower, K. S. Brown, T. C. Grammer, R. M. Harland; Department of Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

Accurate segregation of the genetic material during mitosis and meiosis requires a dramatic restructuring of both the chromosomes and the microtubule cytoskeleton to form a dynamic mitotic spindle. We have utilized functional reconstitution approaches in *Xenopus laevis* egg extracts to identify mechanisms underlying the complex events of chromosome condensation and spindle assembly, and to elucidate roles of the individual factors involved. Current projects investigate the contribution of linker histone H1 and the cohesin complex to higher order mitotic chromosome architecture, and explore the role of microtubule associated proteins such as the *Xenopus* CLASP homologue, Xorbit, in coupling microtubule plus end dynamics to kinetochore movement and chromatin-driven microtubule polymerization. To expand our repertoire of in vitro approaches, we have developed the use of egg extracts from a related frog, *Xenopus tropicalis*, a diploid species amenable to genetic approaches and for which genomic sequence data are available to facilitate rapid proteomic analyses. Interestingly, we have found that metaphase spindles formed in *X. tropicalis* extracts are approximately 30% smaller than *X. laevis* spindles, although the same chromosome source (*X. laevis* sperm nuclei) was used in each assembly reaction. This observation suggests that cytoplasmic activities contained within each extract define spindle length. In support of this hypothesis, mixing experiments with the two types of extract yielded intermediate spindle sizes with a linear relationship between the percentage of each extract in a reaction and the final spindle length. Thus, in addition to providing a more molecularly tractable system, experiments with *X. tropicalis* egg extracts may provide novel insight into the regulation of spindle morphogenesis.

1503

### Centromere Pairing and Chromosome Segregation at Meiosis I

M. Stewart, D. Dawson; Department of Molecular Biology/Microbiology, Tufts University School of Medicine, Boston, MA

Our experiments are intended to explore the mechanisms used to partition chromosomes at meiosis I. One of the key differences between meiotic and mitotic chromosome segregation lies in the behavior of homologous chromosomes at meiosis I. Homologous pairs experience recombination (exchanges) prior to metaphase I. These exchanges between the are important for linking the chromosomes, which allows them to attach to the spindle in a bipolar orientation. Exchanges (along with sister chromatid cohesion distal to the exchnage) hold homologs together until the signal for anaphase is received. Mutations that eliminate meiotic recombination result in high levels of meiosis I non-disjunction, and consequently, sterility or reduced fertility. However, in many eukaryotes, single chromosome pairs that fail to experience crossovers do not segregate randomly. This indicates that mechanisms beyond exchange can facilitate meiosis I segregation. Our experiments have focused on examining the mechanisms used to partition non-exchange chromosomes in budding yeast. We expect that these mechanisms probably work in conjunction with crossovers to insure proper segregation of all chromosome pairs. Our experiments revealed that the centromeres of non-exchange chromosomes are actively paired in prophase of meiosis I. This centromere pairing appears to hold non-exchange chromosomes together and orient the kinetochores towards opposite poles. We propose that pairing of non-exchange chromosomes is a default process that occurs after exchange homologs have synapsed. Preliminary results show that centromeric cohesion, the synaptonemal complex, and monopolin all play roles in the centromere pairing of non-exchange chromosomes, and may help play a similar role for exchange chromosomes, helping to orient their centromeres so that they attach properly to the meiosis I spindle.

1504

### A Conserved Checkpoint Monitors Meiotic Chromosome Synapsis in *C elegans*

N. Bhalla, A. F. Dernburg; E.O. Lawrence Berkeley National Lab, University of CA, Berkeley, Berkeley, CA

Meiosis generates haploid gametes from a diploid cell by coupling a single round of replication with two successive rounds of chromosome segregation. During meiotic prophase, the pairing and synapsis of homologous chromosomes and interhomolog recombination are critical events that ensure the proper disjunction of chromosomes. We are studying the mechanisms that monitor these events and contribute to their accuracy. Previous work in *C. elegans* and other organisms has shown that DNA damage that is not repaired during meiotic recombination can target meiotic nuclei for apoptosis. We have now found evidence for a second checkpoint that leads to apoptosis in the germline: errors in synapsis, even in the absence of DNA damage, can act as a direct trigger for cell death. When we analyze mutants where one pair of chromosomes fail to synapse or all chromosomes exhibit asynapsis, we observe elevated levels of germline apoptosis. This activation of apoptosis in response to unsynapsed chromosomes is independent of double-strand break (DSB) formation and the germline DNA damage checkpoint, distinguishing it from the pachytene checkpoint in budding yeast. However, the *C. elegans* homolog of the yeast checkpoint component *PCH2*, is required for synapsis checkpoint activation, suggesting that the molecular mechanism that detects unsynapsed homologous chromosomes is conserved. Our investigations have also revealed that Pairing Centers (PCs), *cis*-acting chromosomal sites that promote homolog synapsis, are required for this meiotic synapsis checkpoint. The essential role of these *cis*-acting sites in both initiating synapsis and detecting defects in this process is evocative of the involvement of centromeres in both microtubule attachment and the spindle assembly checkpoint. We are interested in identifying additional components of this checkpoint to gain a better understanding of how defects in synapsis are monitored and result in apoptosis.

1505

### Condensin is Essential to Prevent Premature Chromosome Decondensation in Anaphase

P. Vagnarelli, D. F. Hudson, W. Earnshaw; Wellcome Trust Centre for Cell Biology, University of Edinburgh, Edinburgh, United Kingdom

The mechanisms underlying the establishment of mitotic chromosome condensation and its maintenance until the end of mitosis remain two of the classic unanswered questions of cell biology. It has recently been proposed that two protein complexes called condensin I and II are important for this condensation, and are essential for topoisomerase II to separate sister chromatids during anaphase. We have used a gene targeting analysis to determine the essential function of condensin in chicken DT40 cells. Our results differ significantly from those predicted by present models of condensin function. Condensin is not essential for mitotic chromosomes to adopt an orderly higher-order structure, for normal cohesin dynamics or

for sister chromatid separation during anaphase. Neither is it essential for topo II function at centromeres or on the chromosome arms. Instead, condensin is essential for vertebrate chromosomes to remain condensed throughout anaphase. In condensin-depleted cells chromatids abruptly decondense while still moving during anaphase B. However, chromatids can remain condensed and segregate normally provided that CDK levels are kept high during mitotic exit. Our results identify a new activity, RCA (regulator of condensation in anaphase), that cooperates with condensin to maintain mitotic chromosome condensation in anaphase.

1506

### A Potential Direct Role for the Chromosomal Passenger Complex in Centromere-Microtubule Attachment in *S cerevisiae*

S. Sandall,[1,2] F. F. Severin,[3] A. A. Hyman,[3] A. B. Desai[1,2]; [1]University of California, San Diego, La Jolla, CA, [2]Ludwig Institute for Cancer Research, La Jolla, CA, [3]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany

Kinetochores function as the primary chromosomal attachment sites for spindle microtubules. The 125 bp sequence-specific *S. cerevisiae* centromere has proven invaluable for characterizing kinetochore composition and function. Over 60 budding yeast kinetochore proteins have been identified, many of which are conserved in higher organisms. Nevertheless, how these proteins form the interface with spindle microtubules is poorly understood. We have utilized an in vitro approach to identify proteins required for the interaction of budding yeast centromeric (CEN) DNA with microtubules. Extracts of wild-type or mutant yeast strains are incubated with fluorescent beads coated with CEN DNA. The bead/extract mix is then passed over microtubules adsorbed to a flow cell surface and microtubule-bound beads are counted using automated image analysis. The attachments are not formed if beads are coated with mutant CEN DNA that is non-functional in vivo. Using this assay in conjunction with activity-based biochemistry, mass spectrometry of a partially purified fraction, and analysis of candidate mutants, we have identified Sli15 and Bir1, two subunits of the chromosomal passenger complex homologous to INCENP and Survivin in higher eukaryotes, as being necessary for CEN DNA-microtubule attachment *in vitro*. From extensive analysis of mutants, these are the only proteins other than subunits of the CEN DNA-binding CBF3 complex that are required for the activity detected in the assay. Previous work has shown that Ipl1, the Aurora B like kinase subunit of the yeast passenger complex, regulates CEN DNA-microtubule attachment in vitro but does not suggest a direct involvement for the chromosomal passenger complex in the attachment. Our results point to a previously unsuspected direct role for this conserved complex in kinetochore-spindle interactions in budding yeast and also suggest potentially distinct functions for different subunits of the complex.

1507

### Cell Cycle Dependent Chromatin Proteomics: Identification and Characterisation of Novel Xenopus and Human Kinetochore Proteins

I. M. Porter,[1] G. A. Khoudoli,[1] J. S. Andersen,[2] J. J. Blow,[1] J. R. Swedlow[1]; [1]Division of Gene Regulation & Expression, University of Dundee, Dundee, United Kingdom, [2]Department of Biochemistry and Molecular Biology, University of Southern Denmark, Odense, Denmark

Many protein factors involved in chromosome segregation are known, but many more factors likely remain to be identified and studied. We have therefore examined the proteome of chromatin and chromosomes at specific stages of the cell cycle. Interphase chromatin and mitotic chromosomes were generated in vitro by incubating sperm nuclei in Xenopus egg cytoplasmic extracts. After isolation of chromatin and chromosomes, associated proteins were eluted and soluble protein fractions were subjected to LC/LC-MS/MS or 2D gel electrophoretic analysis. LC/LC-MS/MS analysis identified over 500 chromatin bound proteins, with approximately 150 specific to mitotic chromosomes. We have used an RNAi-based live HeLa cell secondary screen to characterise the properties of a number of proteins identified in the proteomic analysis that were either entirely novel or poorly characterised. An shRNA-expressing vector (pU6YH) that co-expresses a specific shRNA and H2B-YFP was used to simultaneously identify those cells producing shRNA and monitor any mitotic phenotype by 3D time-lapse fluorescence microscopy. Of 12 uncharacterised proteins, 4 gave strong mitotic phenotypes. One protein has striking sequence similarities to S. cerevisiae Dam1p, a critical kinetochore protein required for proper chromosome attachment and biorientation in yeast. When expressed as a GFP fusion, the human Dam1p homologue localises to spindle poles in G2 and M phase cells and outer kinetochores from prometaphase to anaphase. siRNA against hDam1 in HeLa cells causes a strong biorientation defect, increases the amount of tubulin polymer detected in fixed cells by 4.5x and the amount of chTOG associated with mitotic spindles by 2.5x. We generated a polyclonal antibody that recognises both the human and Xenopus Dam1 proteins, and immunoprecipitates XDam1, XMAP215, and CENP-E from Xenopus CSF extracts. Studies to examine microtubule dynamic after Dam1 depletion and knockdown are underway.

## Organelle Dynamics (1508-1513)

1508

### Physiological Functions of Mitochondrial Fusion in Mice

H. Chen, D. C. Chan; Division of Biology, California Institute of Technology, Pasadena, CA

Mitochondria are dynamic organelles that constantly fuse and divide. These processes control the overall morphology of the mitochondrial population within cells, and likely have important roles in regulation of mitochondrial function. Recent studies have implicated mitochondrial fission in the progression of programmed cell death. In addition, two human neuropathies (Charcot-Marie-Tooth subtype 2A and dominant autosomal optic atrophy) are caused by mutations in mitofusin 2 (Mfn2) and OPA1, proteins essential for mitochondrial fusion. To understand the physiological role of mitochondrial fusion in mammals, we have generated mice carrying null or conditional alleles of Mfn1 and Mfn2. Analysis of mutant mice and cells indicate that mitochondrial fusion controls not only mitochondrial morphology but also mitochondrial heterogeneity and function. The role of mitofusins in membrane fusion will also be discussed.

1509

### Interplay of SNAREs and a dynamin-like GTPase in vacuole fission and fusion

A. Mayer, T. Baars, C. Peters; Department of Biochemistry, University of Lausanne, Epalinges, Switzerland

Membrane traffic consists of cycles of membrane fission and fusion. Fission and fusion must be balanced to guarantee membrane homeostasis - and they are intrinsically antagonistic reactions. Activated fusion machinery might immediately reverse membrane fission of a nascent vesicle, and vice versa, resulting in futile cycles of fission and fusion. This poses the problem if and how these antagonistic activities are coordinated to

guarantee efficient net fusion or fission when needed. Yeast vacuoles undergo regulated cycles of membrane fission and fusion which are linked to the cell cycle. Vacuole fusion can be reconstituted in a cell free system allowing detailed analysis of its mechanisms. It shares many key features with fusion reactions in higher eukaryotic organisms, making it an attractive model. Recently, we have identified a dynamin-like GTPase, Vps1p, as a factor required for vacuole fission. At the same time, however, Vps1p is required for vacuole fusion and interacts functionally and physically with parts of the vacuolar fusion machinery, SNAREs and their activating ATPase Sed18p/NSF. The roles of Vps1 and of SNARE proteins in membrane fusion and fission at the vacuole will be discussed.

1510

**VTC Assembly by Homotypic COPII Vesicle Fusion Involves an Unanticipated Function for Uncomplexed SNAREs in Tether Recruitment**

K. Mullen,[1] D. Xu,[2] J. C. Hay[1]; [1]Division of Biological Sciences, University of Montana, Missoula, MT, [2]EMBL, Heidelburg, Germany

What is the first membrane fusion step in the secretory pathway? In mammals, COPII-coated transport vesicles deliver secretory cargo to VTCs that ferry cargo from ER exit sites to the Golgi. However, the precise origin of VTCs and the membrane fusion step(s) involved have remained experimentally intractable. Here we document in vitro direct tethering and SNARE-dependent homotypic fusion of ER-derived COPII transport vesicles to form larger cargo containers. The assembly did not require detectable Golgi membranes, pre-existing VTCs, or COPI function. Thus, COPII vesicles appear to contain all of the machinery to initiate VTC biogenesis via homotypic fusion. Antibodies that block SNARE complex assembly inhibited homotypic fusion without severely affecting the upstream tethering event, consistent with the well-characterized role of SNARE complexes in fusion. However, inhibition of SNARE complex disassembly by NSF caused a significant decrease in homotypic COPII vesicle tethering as well as fusion, implying an unanticipated role for uncomplexed SNAREs in tethering. Examination of fusion intermediates revealed that COPII vesicles lacking uncomplexed SNAREs failed to recruit the tether GM130 and other regulatory molecules from the cytosol. Our results indicate that uncomplexed SNAREs provide a "signal" that constrains tether assembly to sites containing fusogenic SNAREs. Although it has often been stated that tethering proceeds upstream of and independently of SNAREs, our results indicate that information passes in both directions between tethers and SNAREs. Elucidation of the pathway linking uncomplexed SNAREs to tether recruitment will be described.

1511

**Examining Golgi Maturation in Living Yeast**

E. Losev, C. A. Reinke, J. Jellen, D. E. Strongin, B. S. Glick; MGCB, University of Chicago, Chicago, IL

The Golgi apparatus is made up of biochemically distinct early (*cis*, *medial*) and late (*trans*, TGN) cisternae. The nature of these cisternae has been a subject of debate. The stable compartments model predicts that each Golgi cisterna is a long-lived compartment that retains a characteristic set of Golgi resident proteins. Conversely, the cisternal maturation model predicts that each cisterna matures from early to late by acquiring and then losing specific Golgi resident proteins. We performed a direct test of these two models using 4D video microscopy. The early Golgi was labeled by tagging Vrg4p with GFP, and the late Golgi was labeled by tagging Sec7p with monomeric DsRed. We observed that individual early Golgi cisternae matured into late Golgi cisternae. Alpha-factor pulse-chase experiments, were used to estimate the time required for a secretory protein to transit the Golgi. The kinetics of intra-Golgi transport as measured by pulse-chase match the kinetics of Golgi maturation as measured by video microscopy, confirming that the cisternal maturation model can account for anterograde traffic through the Golgi.

1512

**Centriole Assembly in C elegans**

L. Pelletier,[1] E. T. O'Toole,[2] A. Schwager,[1] A. A. Hyman,[1] T. Mueller-Reichert[1]; [1]Max Planck Institute CBG, Dresden, Germany, [2]The Boulder Laboratory for 3D Electron Microscopy of Cells, Department of Molecular, Cellular, and Developmental Biology, Boulder, CO

Genome-wide RNAi screens and classic genetic analyses in the nematode C. elegans have led to the identification of proteins required for centriole duplication in the early embryo. These proteins include SPD-2, ZYG-1, SAS-4, SAS-5 and SAS-6. Using EM tomography of high-pressure frozen single embryos in combination with GFP-based centriole assembly assays and RNAi, we analyzed the centriole duplication cycle during the first cell division of the C. elegans embryo. Our results show that in wild-type embryos centriole duplication is initiated at the onset of centrosome separation. At this stage a daughter centriole precursor consisting of an inner cylindrical tube of reduced length lacking singlet microtubules can be seen in close proximity to both mother centrioles. During pronuclear migration the inner tube elongates reaching its full length prior to pronuclear rotation. During rotation, the 9 singlet microtubules begin assembling around the inner tube, a process completed prior to metaphase where a fully duplicated centriole pair can be observed at each pole of the mitotic spindle. Using GFP-based mating assays we find that centriole components are recruited to centrioles in two temporarily and spatially distinct steps. Shortly after fertilization, during female meiosis, SPD-2 and ZYG-1 are recruited to the mother centrioles. We further show that SPD-2 is required to localize ZYG-1 to the mother centrioles suggesting that SPD-2 acts upstream of ZYG-1 in this pre-duplication event. Shortly after meiosis, at the time of pronuclear appearance, SAS-4, SAS-5 and SAS-6 become recruited in close proximity of the mother centriole, to what is likely to be the forming daughter centriole. We are currently in the process of reconstituting centriole assembly intermediates by EM tomography upon RNAi of the known centriole components.

1513

**The Cilium/flagellum: A Secretory Organelle?**

K. Huang,[1] D. R. Diener,[1] R. Karki,[1] L. B. Pedersen,[1] S. Geimer,[2] J. L. Rosenbaum[1]; [1]MCDB Department, Yale University, New Haven, CT, [2]Biology/Electron Microscopy, University of Bayreuth, Bayreuth, Germany

The membranes of cilia and flagella are formed from Golgi-derived vesicles targeted for exocytosis at a location ajdacent to the ciliary/flagellar basal bodies. There is no known mechanism for the reclamation of ciliary membranes, so excess ciliary membrane must be discarded. We believe that the cilium/flagellum is not only a sensory and motile organelle, but that it probably also functions as a secretory organelle, by exocytosis of membrane vesicles from its tip. This “secretion,” by pinching off of vesicles, probably balances the addition of membrane at the base of the cilium. We have isolated membrane vesicles from Chlamydomonas medium, and compared them to highly purified membrane vesicles isolated from Chlamydomonas flagella. The vesicles that are “secreted” into the medium contain an enrichment of a subset of the polypeptides found in

membranes obtained from isolated flagella, and include certain intraflagellar transport (IFT) polypeptides, IFT motors, tubulin, 14-3-3 protein, PKD-2 (polycystin-2) and other polypeptides. They do not contain certain axonemal proteins that are being delivered to the flagellar tip by IFT, *eg* radial spoke proteins. By use of fluorescent Con A, which binds to flagellar membrane glycoproteins, dyes that stain membrane lipids, and mutants defective in IFT, we have been able to show that, *in vivo,* membrane lipids and proteins are actively moved to the tip of the flagellum by IFT, and can be followed into the medium. Correlated EM thin sections support this vesicle secretion action at the tip. We presume that this "secretory" activity occurs in almost all cilia, including the solitary sensory primary cilia of vertebrate cells, cilia of the respiratory and reproductive tracts, and the sensory cilia of C. elegans. Supported by NIH grants GM14642.

## Protein Misfolding & Disease (1514-1519)

1514

### Mechanism of alpha -Synuclein toxicity: Inhibition of Endoplasmic Reticulum-Golgi Trafficking

A. A. Cooper,[1] A. Gitler,[2] C. M. Haynes,[1] K. J. Hill,[1] A. Cashikar,[2] S. Lindquist[2]; [1]Division of Cell Biology and Biophysics, University of Missouri-Kansas City, Kansas City, MO, [2]Whitehead Institute for Biomedical Research, MIT, Cambridge, MA

Parkinson's disease (PD) is one of the most common human neurodegenerative disorders, affecting approximately 2% of people after age 65 and about 5% after age 85. Accruing evidence points to a role for the protein alpha-synuclein (αSyn) in the pathogenesis of PD but little is known about its regular cellular function or its contribution to the disease. In *Saccharomyces cerevisiae*, increased αSyn expression is cytotoxic and the underlying cause(s) were examined in an effort to explain the etiology of PD. Here we show that lethality is due to a complete block in endoplasmic reticulum (ER)-Golgi vesicular trafficking. Such a block causes ER stress, a condition also associated with PD, as evidenced by activation of the unfolded protein response. Finally, a direct cause/effect relationship between impaired ER-Golgi trafficking and cytotoxicity was demonstrated by the suppression of αSyn associated cellular defects through over-expression of a subset of ER-Golgi trafficking components. Our finding that the primary defect in cells accumulating αSyn is impaired vesicular trafficking likely explains the particular vulnerability of dopamine producing neurons in PD and will likely open novel avenues for therapeutic intervention.

1515

### Native Amyloid in the Secretory Lysosome Pathway - Lessons for Disease

D. M. Fowler,[1] A. V. Koulov,[2] C. Alory-Jost,[2] M. S. Marks,[3] J. W. Kelly,[1] W. E. Balch[2]; [1]Department of Chemistry and the Skaggs Institute of Chemical Biology, The Scripps Research Institute, La Jolla, CA, [2]Department of Cell Biology and the Institute for Childhood and Neglected Diseases, The Scripps Research Institute, La Jolla, CA, [3]Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, Philadelphia, PA

Proteins are biopolymers that typically adopt a well-defined three-dimensional structure, but can misfold and form aggregates with a specific cross beta-sheet fold called amyloid. This multistep process is linked to a number of diseases, including many resulting in neurodegeneration, whose unifying pathological feature is the presence of protein aggregates with the amyloid structure. Functional, non-pathogenic amyloid has not previously been detected in higher organisms and was unexpected due to the toxicity associated with amyloid formation. We have discovered an abundant, native, intracellular, mammalian amyloid structure that functions in melanosome biogenesis, challenging the current view that intracellular amyloid in mammals is always pathologic. Melanosomes are organelles that contain fibers composed of the protein Pmel. They function to template the synthesis of the tyrosine-based polymer melanin, which protects mammals from UV damage. We have shown that the Pmel fibers in isolated mammalian melanosomes have an amyloid structure based on the binding of dyes that fluoresce upon interacting with a cross beta-sheet structure, and on our ability to reconstitute Pmel amyloid formation *in vitro*. Interestingly, the rapidity of recombinant Pmel fibrilization is unprecedented, consistent with a process optimized by evolution for function and to avoid the toxicity of pathological amyloidogenesis. Our results suggest that variations in the structure and stability of amyloid and the context (environment) in which it is generated by the cell distinguishes function from pathology. The utilization of the amyloid fold for a major cellular activity in mammals demonstrates that sequence and folding pathway evolution can harness this ancient structure for physiological purposes.

1516

### A Molecular Mediator of Neurodegeneration in the Polyglutamine Disease SCA1

H. Orr; Institute of Human Genetics, University of Minnesota, Minneapolis, MN

Spinocerebellar ataxia type 1 (SCA1) is a member of a group of inherited neurodegenerative diseases caused by a CAG trinucleotide expansion that results in the expansion of a polyglutamine tract at the protein level. Here we present data that demonstrate an interaction between wild type Atx-1 (Atx-1) and the retinoid-related orphan nuclear receptor alpha (RORa) and Tip60 a coactivator of RORa.. RORa is a transcription factor highly expressed in Purkinje cells. Loss of RORa is the basis of the cerebellar atrophy seen in staggerer mice. Expansion of the polyglutamine tract in Atx-1 that induces a conformational change and a corresponding decrease in its interaction with RORa and increase in its interaction with Tip60. In SCA1 mice expression of mutant Atx1 resulted in a depletion of RORa and a reduction in expression of genes controlled by the RORa complex. Moreover, loss of one allele of RORa enhanced the pathogenicity of mutant Atx-1 in vivo. These results implicate the loss of RORa as one molecular mechanism of SCA1 pathogenesis that addresses several key aspects of SCA1.

### Inducible Tauopathy in Neuronal Cell Models Shows that the Aggregation of Microtubule-Associated Protein Tau is Toxic to Cells

I. Khlistunova, J. Biernat, Y. Wang, M. Pickhardt, Z. Gazova, E. M. Mandelkow, M. Von Bergen, E. Mandelkow; Structural Molecular Biology, Max-Planck-Institute, Hamburg, Germany

We have generated several models of tau pathology in cells in order to study tau's mechanisms of neurodegeneration in Alzheimer's and other brain diseases. N2a neuroblastoma cell lines were created that inducibly express different variants of tau when exposed to doxycyclin (tet-on system). Three constructs were chosen, based on the repeat domain of full-length tau: The 4R wild-type repeat domain (K18), the 4R repeat domain with the deletion mutation deltaK280 known from frontotemporal dementia and highly prone to spontaneous aggregation, and the 4R repeat domain with

deltaK280 and two further proline point mutations that strongly inhibit aggregation. The comparison of these wild-type, pro-aggregation and anti-aggregation mutants shows: (1) Tau aggregation into paired helical filaments is toxic to cells, (2) the degree of aggregation and toxicity strongly depends on tau's propensity for beta-structure, (3) soluble tau mutants that cannot aggregate are also not toxic; (4) tau phosphorylation in the repeat domain (at KXGS motifs) precedes aggregation but is not correlated with the degree of aggregation; (5) tau aggregates disappear when the tau expression is silenced, showing that aggregation is reversible; (6) Tau aggregation can be prevented by drugs, and even pre-formed aggregates can be dissolved again by drugs. Thus, the cell models open up new insights into the relationship between tau structure, expression, phosphorylation, aggregation, and toxicity that can be used to test current hypotheses on tauopathy and to develop drugs that prevent the aggregation and degeneration of cells. - Supported by ISOA and DFG.

**FAD-Linked Presenilin1 Mutations Show Trafficking Defects from the Endoplasmic Reticulum**

J. Kim,[1] G. Thinakaran,[2] S. S. Sisodia,[2] R. Schekman[1]; [1]Department of Molecular and Cell Biology, University of California-Berkeley, Berkeley, CA, [2]Department of Neurobiology, Pharmacology, and Physiology, University of Chicago, Chicago, IL

Familial Alzheimer's disease (FAD)-linked presenilin (PS) mutations are scattered throughout the PS structural gene. A similar pattern has been found in the genes of other integral membrane proteins linked to human diseases (Sanders and Myers, 2003). These mutated proteins show misassembly and/or trafficking defects in the endoplasmic reticulum (ER). We hypothesized that FAD-linked PS1 mutations cause misfolding of PS1, resulting in aberrant trafficking of PS1 from the ER. Using a cell free assay to directly monitor the exit of cargo proteins from the ER, we show that some of FAD-linked PS1 variants are inefficiently packaged into transport vesicles. An extreme allele, PS1ΔE9, also causes abnormal packaging of APP *in vitro*, and inhibits glycosylation of nicastrin (Nct) *in vivo*, suggesting retention of the γ-secretase complex in the ER. Trimethylamine N-oxide (TMAO), an agent known to influence protein folding, partially rescues abberant trafficking of PS1 and abnormal glycosylation of Nct. TMAO treatment of Neuro 2a cells expressing PS1ΔE9 reduces the ratio of $A\beta_{42}/A\beta_{40}$. Our results suggest that misfolding and/or retention of PS1 in the ER is linked to the generation of toxic $A\beta_{42}$ peptide.

**ER Quality Control Beyond ERAD & the UPR : Autophagy Takes Out the Aggregated Garbage**

K. B. Kruse,[1] A. Dear,[2] E. R. Kaltenbrun,[1] B. E. Crum,[1] J. L. Brodsky,[3] P. M. George,[2] S. O. Brennan,[2] A. A. McCracken[1]; [1]Biology, University of Nevada, Reno, Reno, NV, [2]Molecular Pathology Lab, Christchurch School of Medicine and Health Sciences, University of Otago, Christchurch, New Zealand, [3]Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA

The Z variant of human alpha-1 proteinase inhibitor (A1PiZ) is a substrate for endoplasmic reticulum-associated protein degradation (ERAD) in yeast and mammalian cells. However, we demonstrate here that when A1PiZ is over expressed in yeast, ERAD is saturated and the excess A1PiZ that forms aggregates in the ER is targeted to the vacuole via autophagy. These findings correlate with the pathology of individuals homozygous for A1PiZ. They develop emphysema through a loss-of-function mechanism due to selective removal of the aberrant polypeptide, and a subset of these individuals also experience liver disease through a gain-of-function mechanism when A1PiZ accumulates and aggregates within the ER of their hepatocytes. Interestingly, individuals carrying a mutant variant of the plasma protein fibrinogen present with a similar phenotype, i.e. low plasma levels of fibrinogen, and a subset of individuals who also experience liver disease due to the accumulation of fibrinogen within the ER of their hepatocytes. Because of the similarities between the two disease phenotypes, we hypothesized that the same cellular mechanisms were responsible for the clearance of both A1PiZ and mutant fibrinogen polypeptides. Here we demonstrate that a mutant variant of the fibrinogen gamma chain is degraded through the ERAD pathway, and that when this process is saturated aggregates form within the ER that are cleared by way of autophagy. Together, our findings demonstrate that our yeast system is a valuable model system for the study of autophagy and its link to ER quality control. Further, our findings may have application in the understanding of, and treatment for, individuals with liver disease caused by the accumulation of aggregated polypeptides within the ER of hepatocytes. **Morphogenesis of a Transport Vesicle**

R. W. Schekman; Howard Hughes Medical Institute, Department of Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

Genetics, biochemistry and morphology have been used to understand the mechanism of protein secretion in eukaryotic cells. Membrane and secretory proteins are sorted in the secretory pathway by cytoplasmic coat proteins that assemble on the surface of a donor membrane, bud transport vesicles, and convey cargo proteins to a target membrane. The COPII coat is responsible for all anterograde traffic of cargo from the endoplasmic reticulum to the Golgi complex. COPII assembly is initiated by the recruitment of the GTP-binding protein, Sar1, to the ER membrane through a transient interaction with a guanine nucleotide exchange factor, Sec12, located on the ER. Sar1-GTP extends an amphipathic N-terminal helix that embeds in the ER bilayer and deforms the membrane into a pleiomorphic tubular carrier. Tethered Sar1 recruits Sec23/24p, which binds potential cargo proteins but not resident ER membrane proteins. Cargo-coat complexes are then clustered by Sec13/31p, which acts as a scaffold to concentrate cargo molecules. The N-terminal helix of Sar1p completes the fission process separating cargo-enriched vesicles from resident proteins that remain behind in the ER. Essentially all cargo proteins may be accommodated in small (70nm) transport vesicles. However some particles and structural proteins must be packaged in larger carriers. Collagen fibers and large lipoproteins, such as chylomicrons, are likely to employ an alternative assembly of COPII for their transport from the ER. Sar1p has been implicated in a rare genetic form of a lipid absorption disease known as Anderson's disease or chylomicron retention disease (CMRD). The disease locus corresponds to one of two human SAR1 genes. SAR1b may regulate the traffic of chylomicrons that are unusually large (~500 nm) in relation to the diameter of a typical COPII vesicle. Sar1a and 1b may differ in their influence on the generation of membrane curvature.

## Oncogenes & Tumor Suppressors (1521-1541)

1521

### The Selectivity in Ras Signaling

C. Cheng,[1] B. Onken,[1] M. Philips,[2] E. Chang[1]; [1]Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX, [2]New York University School of Medicine, New York, NY

The Ras G-protein signaling pathways are very complex in humans. There are four Ras proteins. The N-termini of these Ras proteins are over 90% identical in primary sequences, which include the effector-binding domains, and *in vitro* they interact with many effectors with nearly the same efficiency. However, how a given Ras protein selectively activates a particular effector is poorly understood. One leading model suggests that the C-termini of Ras proteins undergo specific post-translational modification, e.g., lipidation, and that such modifications allow Ras to localize and signal from at least two distinct compartments: the plasma membrane and the endomembrane. To unambiguously test this model, we have turned to the fission yeast *Schizosaccharomyces pombe*, which has only one Ras protein, but it is still capable of controlling two highly conserved pathways. Our data show that *S. pombe* Ras selectively activates a MAP kinase pathway to mediate pheromone signaling at the plasma membrane, while it activates Cdc42 at the endomembrane to control cell polarity and mitosis. Ras also appears to act via Cdc42 to transform mammalian cells, and Cdc42 can be found at the endomembrane. Together, these results suggest that Ras in mammalian cells can interact selectively with Cdc42 in the endomembrane. In the current study, we plan to test this idea and to determine if such interaction between Ras and Cdc42 may be important for tumor formation.

1522

### Effects of *Ras* Oncogene on Subcellular Location Patterns in NIH 3T3 Cells

A. T. Hsieh,[1] T. Zhao,[2] T. S. Nowicki,[3] E. Garcia Osuna,[2] R. F. Murphy[4]; [1]Biological Sciences, Carnegie Mellon University, Pittsburgh, PA, [2]Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA, [3]Biology, Dickinson College, Carlisle, PA, [4]Biological Sciences and Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA

A systematic approach to protein location analysis was applied to studying the effects of a cancer-promoting gene. This allows us to gain more insight into the mechanism of cancer, specifically in the change of distribution of proteins in cells. A method was developed in our lab to describe subcellular location patterns from fluorescence microscope images numerically, avoiding personal bias and low reproducibility and accuracy that result from visual inspection. These descriptions are based on numerical features, which capture the essence of subcellular location patterns without being sensitive to the extensive variation that occurs in size, shape, and orientation of the cells in microscope images. *Ras*, which is mutated in 30% of human cancers, serves as the model oncogene in this study. NIH 3T3 cell lines with unique proteins tagged with green fluorescent protein (GFP) were transfected with a retroviral vector containing the *Ras* oncogene. Images were collected for the wildtype and *Ras*-containing pairs so the effects of *Ras* oncogene on subcellular location patterns could be examined. A set of numerical features were calculated for each image, and the Friedman and Rafsky (FR) test was performed to determine the change in subcellular location pattern. Of the 20 pairs of cell lines imaged, 14 were found to have statistically significant differences in subcellular distributions between $Ras^+$ and $Ras^-$. These proteins, having distinct properties compared to their wildtype counterparts, are candidates for screening and possible treatment for cancer.

1523

### p53 Functions as a Multidrug Sensitivity Gene in Childhood Neuroblastoma

C. Xue,[1] C. Flemming,[1] K. V. Gurova,[2] R. B. Lock,[1] K. L. Mackenzie,[1] G. M. Marshall,[1] A. V. Gudkov,[2] M. Haber,[1] M. D. Norris[1]; [1]Children's Cancer Institute Australia for Medical Research, Sydney, Australia, [2]Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, OH

The p53 tumor suppressor pathway is the major cancer preventive mechanism in mammals. p53 exerts its tumor suppressor function by controlling genomic stability in cell populations and by suppressing growth of cells with damaged DNA (Gudkov et al, Nat Rev Cancer, 3:111-29, 2003). For pediatric cancers like neuroblastoma, the most common solid tumor of infancy, p53 mutations are rare at diagnosis, but may be acquired following chemotherapy suggesting a potential role in drug resistance. To address this possibility, we generated p53-deficient variants from a panel of p53 wild type tumor cell lines of neuroblastoma and non-neuroblastoma origin by transduction of p53-suppressive constructs encoding either siRNA or a dominant negative p53 mutant. Analysis of these cells indicated that: (i) in contrast to previous reports, wild type p53 was fully functional in all neuroblastoma cell lines tested, as evidenced by its activation and stabilization in response to DNA damage, nuclear transport, transactivation of target genes and control of cell cycle checkpoints; (ii) inactivation of p53 in neuroblastoma cells resulted in the establishment of a broad drug resistant phenotype; (iii) knockdown of mutant p53 did not revert this phenotype suggesting that it is determined by p53 inactivation rather than gain of mutant p53 function; (iv) in contrast to neuroblastoma, p53 suppression had no effect or caused increased drug susceptibility in several other tumor cell types, including renal cell carcinoma. Thus, p53 inactivation is sufficient for the establishment of a multidrug resistant phenotype in neuroblastoma, suggesting that it may be an important prognostic marker of treatment response in this disease. However, p53 suppression may have opposite effects in other cell types indicating the importance of tissue context for p53-mediated modulation of tumor cell sensitivity to treatment.

1524

### p53 Forms a Disulfide Bond Between Cys275 and Cys277 upon Treatment with Oxidants: A Possible Mechanism for Regulation of DNA Binding Activity

J. J. Leon,[1] H. Wu,[1] C. Vinci,[1] J. Whitelegge,[2] K. Mann,[3] J. Momand[1]; [1]Chemistry and Biochemistry, California State University Los Angeles, Los Angeles, CA, [2]Molecular Sciences, University of California, Los Angeles, CA, [3]Biological Sciences, University of Alaska, Anchorage, AK

Background: p53 tumor suppressor binds to a consensus sequence to regulate transcription of genes. Treatment of p53 with agents that oxidize cysteine thiols prevents it from binding to DNA. Objective: Map the site(s) of oxidation and determine the molecular structure of the oxidized thiol groups. Method: Plasmids expressing *p53* mutants with serine codons substituted for each of nine conserved cysteine codons in the DNA binding domain were transfected into mammalian cells and treated with the p53 oxidizing agent, pyrrolidine dithiocarbamate. Mutants that failed to oxidize were determined. To confirm that p53 could be oxidized at these positions, air oxidized, recombinant wild-type p53 was modified with a

carboamidomethylfluorescein group (CF) at oxidized thiols. Trypsin-released peptides were analyzed by MALDI mass spectrometry to determine if observed masses matched CF-conjugated cysteine-containing peptides. The structure of the oxidized cysteine thiols was determined by microliquid chromatography tandem mass spectrometry (µliquid CTMS) analysis of trypsin-released released peptides. Results: p53 with substitutions at position 275 and 277 were substantially inhibited from oxidation compared to other mutants. CF was bound to Cys275 or Cys277, and Cys182. µliquid CTMS analysis showed evidence for the existence of peptide containing a disulfide bond between Cys275 and Cys277. Conclusion: When p53 is bound to DNA, the Cys277 thiol normally donates a hydrogen bond to the $NH_2$ group on cytosine located in the third position within the p53 consensus response element, (A/T)GPyPyPy. It is proposed that the donating hydrogen bond is removed by disulfide formation between Cys277 and Cys275 and that this oxidation event prevents p53 from binding to its consensus sequence.

**BRCA1 Deficiency Mediates Paclitaxel Resistance through Premature Inactivation of Spindle Checkpoint in Breast Cancer Cells**

C. Chabalier, C. Lamare, C. Racca, M. Privat, A. Valette, F. Larminat; LBCMCP, UMR 5088 CNRS, Toulouse, France

BRCA1 germline mutations predispose women to early onset, familial breast and ovarian cancer. Despite its role in maintenance of genomic integrity, transcriptional regulation and ubiquitination, the exact mechanism of tumor suppression by BRCA1 remains to be defined. A few recent studies have implicated BRCA1 in the cellular response to agents that disrupt the mitotic spindle, including paclitaxel. In this study, we sought to determine the mechanism through which BRCA1 might modulate the paclitaxel response in cancer cells. Since it was recently shown that loss of spindle assembly checkpoint increases paclitaxel resistance (Sudo et al, 2004), we hypothesized that BRCA1 might regulate the mitotic checkpoint machinery. To test this possibility, we significantly reduced BRCA1 protein levels using siRNA in MCF-7 breast cancer cells and investigated the paclitaxel induced-spindle checkpoint activation. Using flow cytometry-based detection of phosphorylated histone H3 for the quantitation of mitotic cells, we showed that suppression of BRCA1 significantly reduces the paclitaxel-induced arrest at mitosis. Next, we showed that BRCA1 deficiency triggers premature cyclin B1 degradation and decrease in Cdk1 activity following paclitaxel treatment in MCF-7 cells, suggesting that BRCA1 downregulation results in premature activation of the anaphase-promoting complex. These findings were confirmed by showing that BRCA1 down-regulation induces premature sister-chromatid separation in MCF-7 cells following spindle damage, as determined by metaphase spreads analysis. Finally, measuring the cell viability, we found that MCF-7 cells transfected with BRCA1 siRNA display a significant increase in resistance to paclitaxel compared with the control cells. All together, our findings support the notion that down-regulation of BRCA1 expression mediates paclitaxel resistance through premature inactivation of spindle checkpoint in breast cancer cells. They link BRCA1 to the mitotic checkpoint which plays an essential role in the maintenance of chromosomal stability.

1526

**BRCA2 Regulates Mitotic Checkpoint upon DNA Damage via BubR1 Acetylation**

H. Lee, E. Choi, D. Hwang, J. Park; Dept. of Biological Sciences, Seoul National University, Seoul, Republic of Korea

Individuals with inherited mutations in BRCA2 are predisposed to early-onset breast cancers. Loss of Brca2 function in mice leads to defects in DNA double-strand break repair and progressive growth impediment. Tumorigenesis in these mice accompanies the inhibition of mitotic checkpoint, suggesting a crucial interplay between DNA repair machinery and mitotic checkpoint function in the maintenance of genetic integrity. Here, we provide the molecular mechanism of how BRCA2 regulates mitotic checkpoint upon DNA damage. BRCA2 acetylates BubR1 after DNA damage and inhibits ubiquitin-dependent proteolysis of BubR1. BubR1 level in BRCA2-deficient cells are significantly lower than wild-type, consistent with the observation that BRCA2-deficient cells possess aneuploidic population. An acetylation-defective BubR1 mutant, K250R, exhibits markedly lower protein level compared to wild-type. Taken together, these results suggest that BRCA2 links DNA repair and mitotic cell cycle arrest by acetylating BubR1 and increasing its stability upon genotoxic injury.

1527

**The Role of Znf217, a Gene Amplified in Breast Cancer, in Neoplastic Progression**

L. E. Littlepage,[1] P. Yaswen,[2] Z. Werb[1]; [1]Anatomy, University of California, San Francisco, San Francisco, CA, [2]Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA

The 20q13 region of the human genome is highly amplified in 20-30% of early stage human breast cancers (as well as in other cancers), and this amplification correlates with poor prognosis. The ZNF217 gene, which is a candidate oncogene in 20q13.2, is found as a component of the corepressor of transcription associated with the human histone deacetylase complex (CoREST-HDAC) and in a complex with the transcriptional co-repressor C-terminal binding protein (CtBP). Previous work has shown that overexpression of ZNF217 leads to immortalization of human mammary epithelial cell lines. To investigate the effect of ZNF217 on neoplastic progression, we cloned mouse Znf217 by PCR and characterized its role as a putative transcription factor. Using Gal4-fusion Znf217 constructs in transcription assays, we find that ZNF217 is a strong transcriptional repressor. We then inserted mouse Znf217 into a retroviral vector. Mouse mammary epithelial SCp2 cells infected with the mouse Znf217 retrovirus express the ZNF217 protein when induced, as determined by western analysis using an antibody raised against human Znf217 that we found cross-reacts with mouse Znf217. Cells overexpressing Znf217 reorganize their actin cytoskeleton and have altered nuclear morphology. Therefore we analyzed cell motility and migration using scratch wound healing assays in culture. SCp2 cells overexpressing Znf217 show increased motility in scratch assays in culture over 24 hours. These data suggest that repression of a transcriptional target by Znf217 might lead to increased motility of epithelial cells. Further characterization of downstream targets and expression patterns will elucidate the pathways that may be affected by ZNF217 in breast cancer progression.

1528

**Study of a Potential Breast Tumor Suppressor Gene, Int6**

J. Suo,[1] J. Sap,[2] E. Chang[1]; [1]Breastcenter, Baylor Colleage of Medicine, Houston, TX, [2]Department of Medicine, Cell Biology and Pharmacology, New York University School of Medicine, New York, NY

The int6 gene was first isolated in a screen using the mouse mammary tumor virus (MMTV) as an insertional mutagen to seek genes that are important for breast cancer formation. Reduction in Int6 expression is also frequently observed in human tumors. While the importance of Int6 and

breast cancer has been established in both mice and humans, its molecular function remains unknown. Our preliminary data derived from the study of an Int6 homolog in the fission yeast Schizosaccharomyce pombe support the hypothesis that Int6 regulates the function of the 26S proteasome, which functions to degrade growth regulatory proteins in a ubiquitin-dependent fashion. We envision that when Int6 functions are inactivated, the proteasome may be weakened to lead to accumulation of regulatory proteins, some of which are key players in the control of cell cycle and chromosome segregation. Therefore Int6 may acts as a tumor suppressor for breast cancer. To test this, we investigate whether altering Int6 functions can influence (1) proteasome functioning and (2) chromosome segregation in human cells, leading to transformation. We have identified several siRNA sequences that can efficiently knock-down int6 expression via direct transfection. For example, they knock down Int6 expression by approximately 80 and 50% in HeLa and MCF10A cells, respectively. Consistent with our yeast data, Int6-knocked-down HeLa cells frequently become multi-nucleated and contain lagging and missegregated chromosomes, suggesting that Int6 is important for chromosome segregation. We have raised a polyclonal antibody against Int6, which can immunoprecipitate Int6 from MCF10A and HeLa cells. We are currently investigating whether Int6 can co-immunoprecipitate proteasome subunits. Furthermore, we are using this and other Int6 antibodies to examine tumor tissues and cell lines by Western blots to determine whether Int6 expression may be altered during tumorigenesis.

1529

**PTEN Expression and Localization Affects Acini Formation of Human Mammary Epithelial Cells in Laminin-Rich Extracellular Matrix**

M. Fournier,[1] K. Martin,[2] K. Giaya,[2] I. Bosch,[2] M. Bissell,[1] P. Yaswen[1]; [1]Lawrence Berkeley National Laboratory, Berkeley, CA, [2]University of Massachusetts, Worcester, MA

**Background:** The growth arrest of non-malignant human mammary epithelial cells (HMEC) in laminin-rich extracellular matrix (lrECM) provides a three-dimensional (3D) model system in which to study a normal process of growth control that is disrupted in cancer. Approximately 50 percent of patients with breast cancer have a mutation in, or loss of, at least one copy of the PTEN gene, which results in the activation of PI3K signaling. It has been shown that inactivation of the PI3K pathway can cause partial or complete reversion of the malignant phenotype in the 3D model system. PTEN and the PI3K pathway are attractive candidates for integrators of signals from soluble growth factors, cell-matrix, and cell-cell interactions. **Hypothesis**: We hypothesize that PTEN and associated pathways perform pivotal roles in integrating the signals from cell-cell and cell-ECM interactions. **Methods and Results**: To systematically probe the molecular changes that lead to growth arrest and acini formation, we have analyzed HMEC expression profiles using microarrays. Transcripts exhibiting greater than 2-fold differences in 2 independent microarray experiments were analyzed by 1-way ANOVA as a function of time. Genes displaying significant ($p<0.05$) differential expression were selected. PTEN was identified by pathway analysis as a key regulatory gene. We observed that PTEN inhibition by shRNA induced significant proliferation, demonstrating that PTEN is required for growth arrest in the 3D. To determine whether endogenous PTEN expression levels and subcellular localization change with disruption of cell-cell contacts, we used E-cadherin function-blocking antibodies in HMEC cultures in 3D. Blocking E-cadherin function inhibited PTEN accumulation at cell-cell contacts, suggesting that disruption of E-cadherin-mediated cell adhesion interferes with the PTEN-dependent growth suppression function.

1530

**The Centrosome-Associated Kinase hMps1 is Highly Expressed in Estrogen Receptor Negative Breast Cancers**

J. M. Colon-Franco,[1] M. A. Zschunke,[2] V. C. Negron,[2] A. Leontovich,[2] E. A. Perez,[3] W. L. Lingle[2]; [1]Tumor Biology, Mayo Clinic, Rochester, MN, [2]Experimental Pathology, Mayo Clinic, Rochester, MN, [3]Medical Oncology, Mayo Clinic, Jacksonville, FL

Human Mps1 is a centrosome-associated kinase that has been reported to function in centrosome duplication. Because centrosome amplification has been implicated in the origin of chromosomal instability during tumor development, we are investigating a possible role of Mps1 in breast cancer and centrosome amplification. We performed quantitative RT-PCR for Mps1 on a total of 95 breast tissues with known estrogen receptor (ER) and lymph node (LN) status. These tissues included 14 normal breast tissues from cosmetic reduction mammoplasties along with 27 ER+/LN-, 23 ER+/LN+, 18 ER-/LN-, and 13 ER-/LN+ tumors. Here, we report the correlation of Mps1 mRNA levels with the ER and LN status of the tumor tissues. The average expression level of Mps1 in ER+/LN- (0.158) and ER+/LN+ (0.201) tumors did not significantly differ from each other or from normal tissue (0.006). However Mps1 expression was significantly greater in ER-/LN+ (1.027) than in ER-/LN- (0.592) tumors, and both groups were significantly greater than normal tissue or ER+ tumors. These results are consistent with quantitative RT-PCR findings for Mps1 in breast cancer cell lines. Mps1 mRNA levels were low in hTERT-hMEC and MCF-7, normal and non-aggressive cell lines, respectively, compared to higher levels present in the more aggressive and invasive T47-D and MDA-MB-231 cell lines. These findings lead us to conclude that Mps1 mRNA is overexpressed in breast cancer cells and tissues with higher invasive potential that lack estrogen sensitivity. Our results suggest a role for Mps1 as a marker for breast cancer aggressiveness and as a potential target for therapy of breast cancers that may not be responsive to anti-estrogen therapies.

1531

**RC-RNase-induced Cytotoxicity in MCF-7 Cells is Modulated by Estrogen Receptor**

M. Hsu,[1] C. Wei,[2] J. Wang[3]; [1]Institute of Biology and Anatomy, NDMC, Taipei, Taiwan Republic of China, [2]Life Sciences, Fu Jen Catholic University, HsinChuang, Taipei, Taiwan Republic of China, [3]College of Medicine, Fu Jen Catholic University, HsinChuang, Taipei, Taiwan Republic of China

Several frog oocyte-derived antitumoral ribonucleases are noted these days, such as onconase from *Rana pipiens* and RC-RNase from *Rana catesbeiana*. RC-RNase belongs to the pancreatic ribonuclease A superfamily, is a pyrimidine-guanine sequence specific ribonuclease, which shares 48.2% amino acid sequence homology to onconase, which is a well-known anti-tumor drug and currently on its phase III trail in USA. RC-RNase processes cytotoxicity for varies tumor cells but rarely to normal cells such as fibroblasts. Our present studies demonstrated that RC-RNase is toxic to estrogen receptor (ER)-positive breast cancer cell lines, MCF-7 and ZR-75-1, but not to ER-negative cells, ZR-75-30 and MDA-MB-231. RC-RNase induced cell death through an apoptotic pathway, and blocked the expressions of ER protein, Bcl-2 and Bcl-$X_L$. We also found that the amount of ER mRNA expression accumulated in MCF-7 cells with a time- and dose-dependent condition. The ER protein expression in a selected RC-RNase-resistant MCF-7 cell line was higher, but, its mRNA level was uninfluenced. These results inferred that RC-RNase induced cytotoxicity of MCF-7 cells could probably act on the translation level to block the ER protein expression, which then is not able to keep the cells

alive. The results that RC-RNase activates caspase-3-like, caspase-8 and caspase-9 in MCF-7 cells indicated that mitochondria-mediated apoptosis mechanism could be involved. Over-expression of ER in MCF-7 cells by transfection of a plasmid, pCMV-sER-neo, rescued RC-RNase induced cytotoxicity. We concluded that RC-RNase-induced cytotoxicity in MCF-7 cells is modulated by ER.

1532

**SURF4 is Overexpressed in Gastric Cancers and Has an Oncogenic Potential During Tumorigenesis**

D. Lee, J. Chang, S. Song, S. Byun, D. Lim; Department of Biological Sciences, KAIST, Daejeon, Republic of Korea

SURF4(Surfeit 4) is located in the surfeit gene cluster, which is a conserved integral membrane protein containing multiple putative transmembrane regions. However, the biological role of SURF4 remains largely undefined. We found SURF4 gene is aberrantly overexpressed in human gastric cancers. SURF4 protein localize to endoplasmic reticulum and its overexpression accelerated G1-S transition. In addition, SURF4 exerted the ability to induce multiple focus formation and sustain anchorage-independent growth of transfected NIH3T3 cells. Moreover, NIH3T3 cells expressing SURF4 formed tumors in athymic nude mice. Therefore, SURF4 was sufficient to support anchorage-independent growth of NIH3T3 cells and tumor formation *in vivo*. Taken together, our observations suggest that overexpression of SURF4 induced tumorigenesis may have positive effects on tumor growth and metastatic progression.

1533

**Eps8 Upregulates the Expression of Focal Adhesion Kinase and Contributes to Human Colon Tumorigenesis**

T. Leu; Pharmacology, National Cheng Kung University, College of Medicine, Tainan, Taiwan Republic of China

Eps8, a common substrate for both receptor and nonreceptor tyrosine kinases, has been characterized as an oncoprotein and participates in Src-mediated transformation in murine fibroblasts. However, to date, its involvement in human cancers is still obscure. In this study, we observe the overexpression of Eps8 in both human colon cancer cell lines and human colorectal tumor specimens. Interestingly, as compared to cells with low Eps8 expression (i.e. SW480), increased growth rate is detected in cells with high Eps8 expression (i.e. SW620 cells), implicating the critical role of Eps8 in colon cancer formation. Indeed, reduced cell proliferation in culture and tumor growth in nude mice is observed in SW620 cells bearing *eps8*-siRNA. Surprisingly, a statistically strong correlation between the expression of Eps8 and FAK is observed in human colon tumor specimens and the capacity of Eps8 to modulate FAK abundance is further confirmed. In agreement with its role in mitogenesis, ectopical expression of FAK in cells with *eps8*-siRNA restored cellular growth. We thus propose that Eps8 overexpression in human colon tumors facilitates proliferation by upregulation of FAK.

1534

**Transcriptional Inhibition of Cyclin D1 by HIPK2: A Novel Tumor Suppressing Mechanism through LEF1/beta-catenin Complex**

G. Wei, S. Ku, G. Ma, A. A. Tang, E. J. Huang; Pathology, UCSF & VA Medical Center, San Francisco, CA

Transcriptional control of cyclin D1 expression plays important roles in cell cycle progression. It is well-established that beta-catenin interacts with TCF/LEF-1 at the enhancer elements of cyclin D1 and positively regulates its transcription. Disruption of such mechanism has been implicated in tumorigenesis in multiple organs. Here we provide evidence that transcriptional corepressor homeodomain interacting protein kinase 2 (HIPK2) is a tumor suppressor that negatively regulates cyclin D1 expression. Loss of HIPK2 leads to a selective increase in the transcription of cyclin D1. As a consequence, HIPK2 null MEFs show rapid G1-S transition, increased BrdU incorporation, and increased colony formation. Conversely, over-expression of HIPK2 inhibits beta-catenin-mediated activation of cyclin D1 transcription and induces growth arrest. The mechanism by which HIPK2 suppresses cyclin D1 transcription does not involve phosphorylation or accelerated degradation of beta-catenin. Rather, HIPK2 regulates cyclin D1 transcription by forming a protein complex with LEF1 and beta-catenin, and presumably by recruiting other transcriptional repressors. Since cyclin D1 is a potent oncogene, the inhibitory effects of HIPK2 leads us to hypothesize that HIPK2 may function as a tumor suppressor. Indeed, our data show that HIPK2 is expressed in transient amplifying cells and a small number of stem cells in the epidermis. In a skin tumorigenesis paradigm, loss of one or both alleles of hipk2 leads to an increased propensity of papilloma formation with most of the tumors progressing into carcinoma. Taken together, our data underscore the important role of HIPK2 as a haploid insufficient tumor suppressor that negatively regulates cell growth and proliferation by inhibiting cyclin D1 transcription. These results further suggest that HIPK2 could be a potential therapeutic target for cancer chemotherapy.

**Differential Effects of Stat3 Inhibition in Sparse vs Confluent Cells**

A. Anagnostopoulou,[1] A. Vultur,[1] R. Arulanandam,[1] J. Turkson,[2] R. Jove,[2] L. Raptis[1]; [1]Pathology and Molecular Medicine, Queens' University, Kingston, ON, Canada, [2]Moffitt Cancer Center, Tampa, FL

We recently demonstrated a dramatic increase in Stat3 phosphorylation at tyr705 (Stat3-ptyr705) and Stat3 activity with cell density in normal cells, which peaked at approximately 1-2 days post confluence and gradually declined as cell death ensued. This observation hints at the possibility that Stat3 might have different targets in sparse vs confluent cultures. To examine such a mechanism, it is important to evaluate the effect of Stat3 inhibition at a precise time-point and this was previously attempted using several approaches: We previously reported that PY*LKTK, the putative Stat3 SH2 domain-binding sequence, coupled to a membrane-translocation sequence can disrupt Stat3:Stat3 dimer formation and subsequent Stat3 DNA-binding activity in intact cells. Our later results also demonstrated that the tripeptides PY*L and AY*L, and peptidomimetics designed using AY*L and PY*L as leads with a substitution of the Y-1 prolyl (or alanyl) residue by aromatic groups, are also strong disruptors of Stat3 DNA binding activity *in vitro* and in cultured cells. We also employed the platinum compounds, $PtCl_4$ and CPA-7, which can be effectively taken up by the cell. To achieve the instant introduction of the peptidimimetics we used a technique of *in situ* electroporation we developed, where an electric pulse is applied as the cells are growing on a conductive and transparent support of indium-tin oxide. In this setup, the electric pulse allows the instant introduction of the material with minimal damage to the cell, presumably because the pores reclose instantly, so that the cellular interior is restored to its original state. Our results using both approaches demonstrate that Stat3 inhibition at precisely the time of its peak activity post-confluence induces apoptosis, which is more pronounced in transformed cells, while Stat3 inhibition in normal, subconfluent cells induces merely a growth retardation.

**Oncogenic Potential of Recombinant hERG: Effects on Growth and Role of Functional hERG Current**

D. M. Pier, J. R. A. Challiss, J. S. Mitcheson; Cell Physiology and Pharmacology, University of Leicester, Leicester, United Kingdom

Human ether-a-go-go related gene product (hERG) is a potassium channel found ubiquitously in embryonic tissue, but only in key excitable tissues in the adult. Cell transformation has been associated with hERG re-expression, and the related EAG channel has been shown to possess oncogenic potential (Pardo *et al*., EMBO J. **18**:5540-5547, 1999). Here we have investigated the effect of stable, recombinant hERG expression in NIH-3T3 cells. At physiological hERG expression levels there was no significant difference ($p=0.77$) in the proliferative rate or serum dependence of growth, compared to mock transfected cells. However, hERG expression increased the ability of confluent cells to overgrow each other resulting in a significant increase ($p=0.015$) in post-confluent cell density compared with wild-type cells. In contrast to the parental cell line, hERG-expressing NIH-3T3 cells grew in soft agar. hERG expression also significantly increased the rate of migration of NIH-3T3 cells into a wound (by 73%; $p=0.005$) compared to wild-type. hERG expression had no effect on the actin cytoskeleton of NIH-3T3 cells in sub-confluent cultures, however, at confluency evidence of cytoskeletal reorganization could be seen, corresponding with a rounding up of the cell to produce a more spindle-like appearance. None of the effects of hERG expression were affected by the presence of the hERG-blocking compound, dofetilide. In conclusion, stable expression of hERG produces some characteristics of a transformed phenotype in NIH-3T3 cells. Pharmacological evidence suggests that this effect on cell phenotype is not dependent on functional channel current. Supported by the British Biotechnology and Biological Sciences Research Council and GlaxoSmithKline.

**Regulation of G1 Transcription by the Evi5 Oncogene**

E. W. Verschuren, A. G. Eldridge, A. Loktev, P. K. Jackson; Pathology, Stanford University, Palo Alto, CA

The timely degradation of cell cycle regulators by ubiquitin-dependent degradation is crucial for irreversible cell cycle progression. At G1/S these mechanisms are superimposed on inactivation of Rb family transcriptional repressor complexes by G1 cyclin/Cdk activity such that E2F-dependent transcription ensues. The Emi1 protein is an E2F target gene that functions to inhibit the anaphase-promoting complex (APC) ubiquitin ligase. Emi1 expression thereby allows for the accumulation of mitotic regulators including cyclins A and B. Upstream of Emi1, we recently identified the Evi5 oncogene as a factor that binds Emi1 and stabilizes Emi1 protein. Here, we studied the effect of Evi5 protein on underlying E2F transcriptional activation. Northern analysis shows that the abundance of Evi5 mRNA is not cell cycle regulated, as opposed to significant increases in Emi1 mRNA in late G1. Notably, Evi5 protein accumulation occurs just before the induction of Emi1 mRNA. Knockdown of Evi5 protein by siRNA treatment from synchronized cells results in a reduction of Emi1, cyclin A2 and cyclin E1 transcript levels as measured by Northern and RT-PCR analysis. These data suggest that Evi5 is a positive regulator of E2F-dependent transcription. We identified several SWI/SNF complex members as Evi5 interacting proteins using a yeast two-hybrid screen. This interaction was confirmed by co-immunoprecipitation of overexpressed as well as endogenous proteins. Interestingly, active Rb-mediated repression of cyclin E, A and D1 promoter is thought to require SWI/SNF remodeling. We are now studying the physiological relevance of Evi5 regulation of E2F transcription on G1/S progression.

**Transforming Growth Factor-β Suppresses Telomerase Expression through the Proximal Region of the hTERT Promoter in a Smad-independent Manner**

A. Lacerte, S. Lemay, J. Lebrun; Hormones & Cancer Research Unit, McGill University, Montreal, PQ, Canada

Tumors develop when barriers that inhibit cell growth are overcome. One such barrier is the length of the telomeres. In 90% of cancers, the telomere length is maintained by the enzyme telomerase. The expression of hTERT, the protein component of telomerase, is closely associated with telomerase activity and is increased in most cancer cells. Transforming growth factor-β (TGFβ), a well-known inhibitor of cell proliferation, has been recently shown to decrease hTERT expression. The aim of the present work is to understand how TGFβ inhibits hTERT expression at the transcriptional level. To test this, we cloned the 2.0kb promoter region of the hTERT gene in front of the luciferase gene. In the keratinocyte HaCaT cancer cell line, we showed that TGFβ inhibits hTERT expression and hTERT promoter activity by 80%. Using an Exonuclease III approach, we truncated the promoter and performed luciferase assays with these deletion mutants. TGFβ repressed hTERT promoter activity through the -252 to +3 region. As TGFβ classically signals through the Smad pathway, we next evaluated its involvement using the inhibitory Smad7 or dominant negative (DN) Smad2 and Smad3 that fail to be phosphorylated. Smad7 overexpression reversed TGFβ-mediated decrease of hTERT promoter activity. Surprisingly, DN Smad2 or DN Smad3 did not reverse TGFβ's inhibition of hTERT promoter. Our data rather indicated that the Erk1/2 and p38 kinases pathways play direct role in TGFβ regulation of the hTERT promoter. Therefore, TGFβ decreases expression of the hTERT gene in addition to its known inhibitory effect on cell division, thus linking two mechanisms that suppress tumor development. Understanding the mechanism by which hTERT gene is upregulated in cancer cells suggests new avenues for the development of cancer therapy.

1539

**Inhibition of Cancer Cell Proliferation by Mutant Template Telomerase RNA Requires the Catalytic Action of Telomerase at Telomeres**

A. Goldkorn, E. H. Blackburn; Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA

Cancer cells contain telomerase activity that sustains their growth. A gene expression construct (MT-hTER/siRNA) was developed that knocks down human endogenous wild type telomerase RNA (wt-hTER) through the use of short interfering RNA (siRNA) and, at the same time, expresses a mutant-template hTER (MT-hTER) to take the place of the endogenous wt-hTER. This combination works synergistically to radically inhibit cancer cell line proliferation (1), but the intracellular mechanism by which this is achieved has not been demonstrated. To elucidate the manner in which the MT-hTER/siRNA construct exerts its inhibitory effects on human cancer cells, three variants of the human telomerase catalytic subunit (hTERT) were ectopically over-expressed via retroviral infection in the LOX human melanoma cell line - wild type (WT-hTERT), "dominant negative" enzymatically inactive (DN-hTERT), and the putative non-telomere-localizing (N125A+T126A-hTERT). MT-hTER/siRNA and vector control were ectopically expressed via lentiviral infection in LOX cells over-expressing each of the three hTERT variants, and the cells were assayed for proliferation and formation of DNA damage foci indicative of telomerase uncapping. Upon ectopic expression of MT-hTER/siRNA,

LOX cells over-expressing WT-hTERT developed significantly greater numbers of DNA damage foci and overall growth inhibition than LOX cells over-expressing the DN-hTERT or N125A+T126A-hTERT variants. Hence, MT-hTER/siRNA requires the presence of WT-hTERT - an enzymatically active, telomere-localizing telomerase catalytic subunit - in order to exert its cellular effects. These results provide direct evidence that supports a model by which MT-hTER/siRNA exerts its toxic effect through combining with endogenous hTERT to form a catalytically active RNP that adds incorrect tandem repeats to the telomere ends. MT-hTER/siRNA's mechanism of action may be exploited for telomerase targeting in cancer therapeutics. 1. Li, S. et al. Cancer Research 2004.

**Substrate Binding of Eukaryotic Chaperonin TRiC/CCT is Mediated by Specificity and Plasticity**

C. Spiess, J. Frydman; Department of Biological Sciences and BioX Center, Stanford University, Stanford, CA

Chaperonins are multimeric cylindrical protein complexes designed to accommodate unfolded proteins in their inner chamber to assist their folding. The eukaryotic Group II chaperonin TRiC/CCT is in contrast to the homo-oligomeric Group I chaperonins, such as the prokaryotic chaperonin GroEL, a hetero-oligomeric complex composed of 8 paralog subunits. Heterogeneity of the subunits raises the question if the chaperonin utilizes this diversity for substrate recognition or mechanistic reasons. We addressed the question of substrate recognition with the Von Hippel Lindau tumor suppressor protein (VHL) as a model substrate. VHL is an obligate TRiC/CCT substrate and the binding determinants are well defined within two short hydrophobic beta-strands (1). Utilizing synthetic peptides spanning the two TRiC/CCT binding motifs of VHL we investigated with a combined cross-linking and mass-spectrometry approach if the paralog subunits show unique and specific binding patterns. We show that a discrete subset of TRiC/CCT subunits binds the same peptide. An identical binding specificity is observed in constructs comprising the isolated substrate binding apical domain of the subunits, showing that the binding specificity is provided independent of the context of other subunits in the complex. This expresses that the subunit heterogeneity of the TRiC/CCT complex is utilized for substrate specificity of the subunits, and allows the eukaryotic chaperonin to expand the mechanism of folding beyond the capabilities of a simpler homo-oligomeric complex. Nevertheless partially overlapping binding specificity suggests that recognition of sequences is still modular and the TRiC/CCT complex shows plasticity to accommodate the same determinant multiple times. (1) Feldman D, et al.(1999) Formation of the VHL-Elongin BC tumor suppressor complex is mediated by the chaperonin TRiC. Mol. Cell 4, 1051-1061.

**Regulation of Nm23-H1 and Macrophage Migration Inhibitory Factor (MIF) by Direct Interaction**

H. Ha, H. Jung, H. Seong, T. N. Lam; Biochemistry, Chungbuk National University, Korea, Cheongju, Republic of Korea

Nm23-H1 is a putative metastasis suppressor and a member of Nm23/nucleoside diphosphate (NDP) kinase gene family. Screening of interacting proteins that potentially modulate Nm23-H1 activity through the yeast two-hybrid assay revealed that macrophage migration inhibitory factor (MIF) could interact with Nm23-H1. MIF was found to form *in vivo* complexes with Nm23-H1 in mammalian cells, as demonstrated by *in vivo* binding assay and coimmunoprecipitation experiments. The use of Nm23-H1 mutants (C4S, C109S, and C145S) and MIF mutants (C57S, C60S, C81S) revealed that this interaction was significantly affected by C145S Nm23-H1 mutant and C60S MIF mutant, but not other Nm23-H1 and MIF mutants, suggesting that a disulfide involving $Cys^{145}$ of Nm23-H1 and $Cys^{60}$ of MIF is responsible for Nm23-H1:MIF complex formation. In addition, this association was dependent on the reducing conditions such as dithiothreitol or β-mercaptoethanol but not in the presence of $H_2O_2$. We show that the interaction of Nm23-H1 with MIF is functional because cotransfection of MIF significantly inhibits Nm23-H1 activities such as autophosphorylation, NDP kinase activity, and phosphotransferase activity, whereas the coexpression of Nm23-H1 stimulates the D-dopachrome tautomerase activity of MIF in a dose-dependent manner. Moreover, Nm23-H1 stimulated p53-dependent transcription and, consistently, down-regulation of the endogenous Nm23-H1 by the transfection of the small-interfering RNA (siRNA) resulted in a decrease of p53-dependent transcription.

**A Model for Epigenetic Therapy for IVF Embryos with Imprinting Errors**

O. Chami, T. Stojanov, D. Leigh, R. P. S. Jansen; R & D, Sydney IVF, Sydney NSW, Australia

Introduction: Manipulation and culture of embryos *in vitro* can lead to stresses different to those found *in vivo*. Recently, a suspected increase in the incidence of the epigenetic form of the Beckwith-Wiedemann syndrome has been associated with embryos produced by IVF. In epigenetic syndromes of this kind the abnormal phenotype is a result of the absence or altered regulation of the imprinted maternal or paternal gene. In this study, we used agents that alter DNA methylation and raise the possibility of their use as potential epigenetic therapies for embryos. Methods: Mouse embryos cultured from the 1 cell stage for 24 to 120 h and undifferentiated human embryonic stem cells developed from blastocyst outgrowths were used. Methylation status was assessed after treatment with 5-aza-2-deoxycytidine or no treatment. Extracted DNA was bisulfite modified using the MethylEasy kit (Human Genetic Signatures, Australia) and then subjected to methylation specific PCR for genes associated with cell cycle regulation, embryonic metabolism and epigenetic syndromes. Results: DNA methylation profiles could routinely be defined using 5-7 cells or from the equivalent of half an embryo. hES cell lines showed a normal methylation pattern for the selected genes. Cell treatment with 5-aza-2-deoxycytidine induced demethylation of the DNA within 48 h in mouse embryos and human ES cells. **Conclusions**: Analysing the methylomic state of preimplantation embryos might enable the determination of both the developmental status and the potential of an embryo. In the medium term, the use of DNA methylation and demethylation agents could assist in reprogramming stem cells or embryos produced by somatic cell nuclear transfer in the development of stem-cell based therapies. In the longer term, it might be possible to safely correct or to optimize embryonic and fetal developmental potential without altering the genetic code.

1543

**Proteomic Screen for Novel Mitotic Substrates of DNA-PK**

L. J. Jeffers,[1] S. Mohommad,[2] O. N. Jensen,[2] S. P. Jackson,[3] C. Morrison[1]; [1]Department of Biochemistry and NCBES, National University of

Ireland, Galway, Galway, Ireland, [2]Department of Biochemistry and Molecular Biology, University of Southern Denmark, Odense University, Odense, Denmark, [3]Welcome Trust and Cancer Research UK Institute of Cancer and Developmental Biology, Cambridge, United Kingdom

The DNA-dependent protein kinase (DNA-PK) is a nuclear serine/threonine kinase and a central player in the maintenance of genomic stability in eukaryotic cells. DNA-PK is primarily involved in the Non Homologous End Joining pathway for the repair of double strand breaks in damaged DNA but also serves in other diverse roles such as telomere capping and apoptosis. The aim of this study is to identify *bona fide* physiological DNA-PK chromosomal substrates. Metaphase chromosomes were isolated from mitotically arrested HeLa S3 cells and incubated with purified human DNA-PK in the presence of radioactive ATP. Mass spectrometry analysis of phosphorylated bands excised from one dimensional polyacrylamide gels identified potential novel chromosomal substrates. Certain putative substrates for DNA-PK were identified from this initial screen and this was followed up by the cloning, expression and *in vitro* phosphorylation of the purified recombinant candidate proteins. Our study identified the proteins Borealin and RuvB as potential *in vivo* phosphorylation targets of DNA-PK by mass spectrometry and *in vitro* analysis. However, site directed mutagenesis on the conserved TQ residues of both proteins did not abrogate the phosphorylation signal and liquid chromatography mass spectrometry did not reveal any specific phospho-peptide residues. Currently, we are continuing the screen for more potential mitotic substrates from the initial mass spectrometry data.

1544

## MAD1 Haplo-insufficiency and Tumor Development in Mice

Y. Iwanaga,[1] A. Miyazato,[1] Y. Chi,[1] K. Haller,[1] J. M. Ward,[2] K. Jeang[1]; [1]NIAID, NIH, Bethesda, MD, [2]NIAID, NIH, Rockville, MD

The mitotic spindle assembly checkpoint monitors attachment of chromosomes to spindle poles and ensures proper chromosome segregation of in mitosis. Mitotic arrest deficient protein 1 (MAD1) locates at kinetochore in prometaphase and is involved in activation of mitotic spindle assembly checkpoint. Down regulation of MAD1 is observed in some human cancer cells; however, the relationship of this to inactivation of the spindle checkpoint, aneuploidy, and tumorgenesis is unclear. We have created a knock out mouse model to examine the physiologic function of MAD1. Complete knock out of MAD1 ($MAD1^{-/-}$) is embryonic lethal. We have examined MAD1 haploinsufficient ($MAD1^{+/-}$) mice in aging studies conducted over 18 months and have observed a higher incidence in tumorgenesis ($p<0.05$) compared to wild type littermates. To ask whether perturbation of spindle assembly checkpoint would provoke tumorgenesis, we treated wild type and $MAD1^{+/-}$ mice with vincristine, a drug that inhibits spindle polymerization. We found a higher proclivity in $MAD1^{+/-}$ mice compared to wild type controls to developing lung adenoma ($p<0.03$) in response to treatment with vincristine. Finally, when we passaged $MAD1^{+/-}$ mouse embryonic fibroblast in athymic nude mice, we observed a markedly elevated incidence of fibrosarcoma, not seen with wild type control MEFs. Altogether, these results hold similarity with previously described $MAD2^{+/-}$ mice, and suggest a parallel function for MAD1 in regulating mitotic checkpoint and tumorgenesis.

1545

## The Role of p63 in Human Corneal Epithelial Cell Proliferation

D. M. Robertson, W. M. Petroll, H. D. Cavanagh; Ophthalmology, UT Southwestern Medical Center, Dallas, TX

PURPOSE: p63 has been reported as a corneal epithelial stem cell marker. This study evaluated p63 expression in human corneal epithelial cells in vivo and in vitro throughout the cell cycle. METHODS: p63 expression was assessed using polyclonal antibodies to p63 in normal human cornea and hTERT-immortalized human corneal epithelial cells by IF and Western blotting. Blocking peptides were used to confirm antibody specificity. To assess changes in p63 with the cell cycle, hTCEpi cells were double-labeled with antibodies to Ki-67 and p63. Whole mount human corneal tissue was used to establish patterns of p63 expression in vivo. All images were obtained with a laser scanning confocal microscope. To assess the regulatory role of p63 in the cell cycle, siRNA directed against p63 was evaluated at days 2 and 4 by double-labeling with p63 and Ki67. RESULTS: In normal human tissue, p63 was seen in all basal and wing cell layers, with a loss of expression seen only in superficial epithelial cells. In organotypic culture, p63 was seen at all stages of stratified epithelial development. Double-labeling with Ki-67 and p63 demonstrated no changes in the levels of p63 expression during mitosis and no changes in cell cycle regulation following 2 and 4 days siRNA. CONCLUSIONS: The localization of p63 in the human cornea in vivo and in vitro suggests that p63 is not a stem cell specific marker, but is present in differentiated cells arising from a stem cell lineage. Ki67 results suggest that p63 is not a cyclin and does not play a direct role in cell cycle regulation. Taken together, these data suggest that p63 is not a specific marker of proliferating cells and is not directly involved in regulating corneal epithelial proliferation.

1546

## Characterization of Early Growth Response Extracted from Human Pulpal Fibroblasts

I. Tamura,[1] B. Chaqour,[2] P. S. Howard,[3] T. Ikeo,[1] E. J. Macarak[3]; [1]Biochemistry, Osaka Dental University, Hirakata, Japan, [2]Anatomy and Cell Biology, State University of New York, Brooklyn, NY, [3]Anatomy and Cell Biology, University of Pennsylvania, Philadelphia, PA

The early growth response (EGR) gene family encodes for transcription factors that are implicated in regulating cell proliferation. There is little information on their expression in oral tissues. We investigated the expression of EGR-1 and -2 mRNAs and proteins in human pulpal fibroblast (PUF) using Western blotting, Northern blotting and FITC-labeled immunocytochemical techniques. Primary cultures of PUFs were obtained from three patients with informed consent. After cultivating PUFs in Dulbecco's modified Eagle medium (DME) for two days without fetal bovine serum (FBS), we incubated them in DME supplemented with 10% FCS for 15, 30, 45, 60 and 120 min. Measurement of 5-bromo 2'-deoxyuridine incorporation was highest in PUFs treated with FBS for 45 min. Expression of EGR-1 mRNA and protein were initially seen beginning 15 min after treatment and then EGR-1 protein subsequently gradually increased. Additionally, phosphorylation of EGR-1 was observed by immunoprecipitation using an antibody to EGR-1. Anti-EGR-1 antibody abundantly localized within the nuclear region 30 min after treatment. Expression of EGR-2 mRNA was greatest at 15 min after treatment while maximal expression of EGR-2 protein was observed at 60 min. By immunocytochemistry, EGR-2 localized in and around the nucleus after 45 min. These results demonstrate that in human pulpal fibroblasts, native and phosphorylated EGR-1 and EGR-2 mRNA and protein expression are strongly stimulated by FBS and that the EGR family plays a potentially important role in the regulation of cell activities such as growth.

1547

**Artificial Control of Cell Proliferation Using an N-terminal Domain of Simian Virus 40 Large T Antigen by Means of PEI-cationization**

H. Murata, J. Futami, M. Futami, M. Kosaka, H. Tada, M. Seno, H. Yamada; Okayama University, Okayama, Japan

Cationization with polyethylenimine (PEI) is a powerful strategy for protein transduction into cells. Protein transduction has an advantage over gene transduction that the expression of the protein function within cells is transient. In this study, we attempted artificial regulation of cell proliferation by protein transuduction of the N-terminal domain (1-132 a.a.) of simian virus 40 large T-antigen (SVLT-N), which specifically inactivates retinoblastoma family proteins (pRb, p107, and p130), but not p53. In order to deliver SVLT-N into cells, we employed an indirect-cationization method as follows. First the SVLT-N was biotinylated and then mixed with PEI-cationized avidin (PEI-avidin). For the biotynylation of the SVLT-N, biotins were conjugated via disulfide bonds (biotin-SS-SVLT-N), which are cleavable in cytosolic reducing environments, because carrier domain of PEI-avidin might interfere the normal function of SVLT-N. To evaluate whether SVLT-N transduced in this way sufficiently drives the growth-arrested cells back into the proliferation stage, quiescent Balb/c 3T3 cells were treated with our new device (PEI-avidin/biotin-SS-SVLT-N) under the confluent condition. As a result, we succeeded to introduce the SVLT-N efficiently in the cells with an accumulation of the protein into their nuclei, in which the protein actually trapped cellular pRb. An assessment of BrdU incorporation also showed that the introduced protein caused a release from contact inhibition of the quiescent cells. In addition, some remarkable change in expression levels of cell cycle-related proteins (up-regulation of cyclin A and down-regulation of p27/Kip1) was detected in parallel with the intracellular contents of the SVLT-N. These results suggest that protein transduction of SVLT-N technology has great potential *in vitro* cell regulation and that may pave a new way for *ex vivo* cell expansion for cell therapy.

1548

**Early p38 Activation in C2C12 Myoblasts Maintains Myoblast Proliferation, While Later p38 Activation is Required for Fusion**

J. M. Churko, P. A. Merrifield; Anatomy and Cell Biology, University of Western Ontario, London, ON, Canada

During myogenesis, multiple signaling pathways regulate the ability of myoblasts to withdraw from the cell cycle, elongate, fuse and express contractile protein isoforms such as myosin heavy chain (MyHC). The p38 mitogen-activated protein kinase pathway has been shown to both promote and inhibit myogenesis in C2C12 myoblasts cultured in vitro. This controversy may be the result of two temporally separated p38 activation events which are involved with different aspects of myogenesis (Weston et al. J Cell Sci. 116, 2885(2003); Cuenda and Cohen. J Biol Chem. 274, 4341 (1999)). To further examine the role of p38 activation in myogenesis, C2C12 myoblasts were initially grown in growth medium and phosphorylated p38 (p-p38) levels examined at 0 h, 1h, 6h, 12h, 24h, 36h, 48h, 60h, and 72h following the addition of differentiation medium. Western blot analysis with p38 and p-p38 specific antibodies demonstrated that p38 followed a biphasic pattern of phosphorylation, with an initial drop in p-p38 levels immediately following the addition of differentiation medium and increasing p-p38 levels after 36h. Inhibition of the alpha and beta isoforms of p38 with 10uM SB220025 in growth media decreased BrdU incorporation and cell counts indicating that p-p38 levels are required for myoblast proliferation. When the inhibitor was removed after 36h, myoblasts fused and expressed MyHC. However, adding the inhibitor after 36h blocked myoblast fusion. These results suggest that p-p38 levels are required to keep myoblasts in a proliferative state and that a subsequent activation of p38 phosphorylation following cell cycle withdrawal is required for myoblast fusion. (Supported by Discovery Grant 105869-02 RGPIN from NSERC).

1549

**Role of Cyclooxygenase-2 Glycosylation in Enzyme Turnover and Cell Proliferation**

M. B. Sevigny,[1] M. Hughes-Fulford[1,2]; [1]Laboratory of Cell Growth, Veterans Affairs Medical Center, San Francisco, CA, [2]University of California, San Francisco, CA

Cyclooxygenase-2 (COX-2) catalyzes the rate-limiting step in the biosynthesis of prostaglandins and thromboxanes by converting fatty acid arachidonic acid (AA) into prostaglandin $H_2$. Consequently, COX-2 plays an important role in various physiological as well as pathophysiological conditions, such as cancer. COX-2 exists as two glycoforms-- 72 and 74 kDa-- with the 74 kDa form resulting from an additional oligosaccharide chain at residue $Asn^{580}$. Since neither the biological significance nor the mechanism behind this differential glycosylation have been fully determined, the objective of this study was three-fold: (1) to determine if COX-2 glycosylation is affected by its substrate AA; (2) to elucidate the effect of glycosylation on COX-2 activity; and (3) to reveal any effects COX-2 glycosylation may have on cell division. Site-directed mutagenesis of the COX-2 gene at $Asn^{580}$ was accomplished, and transient transfection of COS-1 cells with either the mutant or wild-type gene was achieved. COX-2 glycoforms were analyzed via Western blotting, while activity was determined using an ELISA that measured the presence of the downstream product prostaglandin $E_2$. Finally, cell proliferation assays were performed on transfected and nontransfected cells. AA did not affect the expression of either the 72 or 74 kDa glycoforms. Cells transfected with the mutant COX-2 gene accumulated a greater amount of COX-2 protein-- expressed as the 72 kDa glycoform as well as an unexpected 70 kDa form-- and exhibited ~5-fold greater COX-2 activity compared to cells expressing both 72 and 74 kDa glycoforms. Cells unable to express the 74 kDa glycoform also tended to multiply at a significantly slower rate than cells expressing both glycoforms. In conclusion, this study demonstrated that COX-2 enzyme turnover depends upon glycosylation of the 72 kDa glycoform, and this glycosylation may subsequently affect the rate at which cells divide.

**S-nitrosylation Affects Activity of E2F1**

K. Ravi,[1] N. Dyson,[2] G. Enikolopov[1]; [1]Cold Spring Harbor Laboratory, Cold Spring Harbor, NY, [2]Massachusetts General Hospital Cancer Center, Charlestown, MA

Nitric oxide (NO) has been implicated in the regulation of cell division, differentiation, and apoptosis in many cell types and several developmental settings. We have previously shown that during Drosophila development, NO exert part of its antiproliferative action through the Rb-E2F pathway (1, 2). E2F1 transcription factor is an important regulator of the cell cycle, affecting several cell cycle checkpoints; furthermore, it can induce apoptosis (3). We here studied the molecular mechanisms of the NO interactions with the Rb-E2F pathway. We used mouse brain microvascular endothelial (bEnd.3) cells, which produce large amounts of endogenous NO, as a model system to study the action of NO on E2F1. Using the biotin-switch method to detect S-nitrosylation of cysteine residues, we found that E2F1 is S-nitrosylated upon transfection into the bEnd.3 cells,

and that this modification can be suppressed by DTT and by NO synthase inhibitor L-NAME. To identify the residues that are modified by NO in the E2F1 molecule, we mutated each of the E2F1 cysteine residues to serines and found that two out of five residues are S-nitrosylated in bEnd.3 cells. These E2F1 mutants, as well as the double mutant, show altered transcriptional activity in the presence of Rb and DP, indicating the importance of the nitrosylation status of these two cysteine residues. We are now characterizing the interactions between the relevant E2F1 cysteine mutants and the E2F1-binding proteins to gain insights into the functional importance of the E2F1 modifications by NO. 1. Kuzin et al.,.Curr Biol., 10:459-62, 2000. 2. Stasiv et al., Genes&Dev., 18:1812-23, 2004. 3. Dimova and Dyson, Oncogene, 24:2810-26, 2005

**5-Fluorouracil Mediates Apoptosis and $G_1$/S Arrest through a P53-independent Pathway in Laryngeal Squamous Cell Cancers**

H. C. Liu, G. G. Chen, A. C. Vlantis, C. A. van Hasselt; Department of Surgery, The Chinese University of Hong Kong, Hong Kong, China

5-Fluorouracil (5Fu) is commonly used as a chemotherapeutic agent in laryngeal cancer treatment. Cell cycle arrest or apoptosis induced by 5Fu can be either p53-dependent or p53-independent in various cancers but such a situation is unknown in laryngeal squamous cell cancer. In this study, we investigated the cytotoxic effect of 5Fu on laryngeal squamous cancer cell lines and evaluated the role of p53 in 5Fu treatment. We employed two human laryngeal squamous cancer cell lines with different p53 status - one (UMSCC12) has a truncated p53 and the other (UMSCC11A) a mutant but functional p53. Using cytotoxicity assay and Annexin V staining, we proved that 5Fu induced apoptosis of both cell lines in a dose- and time-dependent manner, suggesting that the process was p53 independent. 5Fu induced the accumulation of active pRb and $p21^{WAF1/CIP1}$ in both UMSCC12 and UMSCC11A. However, 5Fu did not activate p53 expression in either UMSCC12 or UMSCC11A cells. In addition, $G_1$/S phase cell cycle arrest was associated with the antiproliferative activity of 5Fu in both cell lines. In order to gain insight into the role of p53 in response to 5Fu in laryngeal squamous cell cancers, we further transfected a wild-type p53 plasmid or an empty pcDNA3.1 vector into UMSCC12 cells and found in both p53-transfected and vector-transfected cells, 5Fu increased p21 and pRb expression without significant accumulation of p53. Our result suggests that apoptosis and $G_1$/S cell arrest mediated by 5Fu in laryngeal cancers may be p53-independent but p21-dependent or p21-Rb-dependent. We also assume that p53 may not be the only target in controlling apoptosis and cell cycle arrest in laryngeal cancer treatment. Further study will need to examine the pathway of p21 and pRb in laryngeal cancer receiving chemotherapy.

**Regulation of *dmyc* Transcription and Cell Cycle Progression by Hfp, Crol and Hay**

N. Mitchell, H. Richardson, L. Quinn; Cell Cycle and Development, Peter MacCallum Cancer Centre, Melbourne, Australia

We have shown that Half pint (Hfp), the *Drosophila* homologue of the mammalian *c-myc* transcriptional repressor (FIR), is required to inhibit cell cycle progression in *Drosophila*. Hfp negatively regulates developmentally coordinated cell cycles in *Drosophila* since (1) *hfp* mutant imaginal tissues undergo ectopic S phases and (2) overexpression of *hfp* inhibits cell cycle progression. Hfp negatively regulates two key cell cycle genes; (1) the *Drosophila* homolog of the *c-myc* cell growth regulator (*dmyc*) at the level of transcription and (2) the *Drosophila* homologue of the critical G2-mitosis regulator Cdc25 phosphatase (Stg) at the protein level. In an effort towards understanding the factors that work downstream of Hfp to regulate *dmyc* transcription and Stg/Cdc25 protein stability we have used a wing phenotype, resulting from overexpression of a *UAS-hfp* transgene with the *en-GAL4* driver, to screen for Hfp interactors. Overexpression of Hfp in the posterior of the wing imaginal disc results in fewer cell cycles and a reduced/disrupted adult wing phenotype, which is amenable to genetic modification. We have identified the Ecdysone responsive transcription factor *crooked legs* and the TFIIH helicase component *haywire* as genes which, when halved in dose, are capable of enhancing the Hfp wing phenotype. We will present evidence that suggests these factors act downstream of Hfp to positively regulate cell cycle progression.

**Role and Regulation of the Cdc25b Phosphatase at the G2/M Checkpoint**

B. Ducommun; LBCMCP, CNRS, Toulouse, France

CDC25 are dual specificity phosphatases that are responsible for the dephosphorylation and the activation of CDK/cyclin complexes at key cell cycle transitions. Our presentation will discuss ongoing projects focusing on the spatial and temporal regulation of CDC25B, one of the three members of this family, and on its involvement in the control of the G2/M transition. We have shown that CDC25B is phosphorylated in vitro and in vivo by a number of protein kinases including Aurora-A, pEg3 and CHK1. The phosphorylated sites have been identified by mass spectrometry. Using specific antibodies, we have shown that these phosphorylated forms first localise at the centrosome level where they play an essential role in the regulation of CDC25B activity and the subsequent control of entry into mitosis. We will present experimental evidences indicating that these regulatory mechanisms are operating in a normal cell cycle and upon activation of the DNA damage activated checkpoint.

1554

**The szy-20 (bs52) Mutation is a Suppressor of zyg-1 and Defines a Novel Regulator of the Cell Cycle**

M. Song; LBG, NIH/NIDDK, Bethesda, MD

The centrosome serves as the primary microtubule-organizing center (MTOC) of the cell and at mitosis plays an important role in establishing a bipolar spindle. Previously a kinase, ZYG-1 was identified as a regulator of centrosome duplication in *C. elegans*. To enhance our knowledge of the biological process of centrosome duplication, we sought to identify additional factors that interact with ZYG-1 and/or are involved in the centrosome duplication process. This should allow us to formulate the genetic pathway(s) that regulate the centrosome during the cell cycle. Toward this end, we carried out EMS mutagenesis on a *zyg-1 (it25)* mutant strain and identified a mutation *bs52* that suppresses the embryonic lethality of the *zyg-1 (it25)* mutation. The bs52 mutation defines a gene that we call *szy-20* (for suppressor of *zyg-1*). *szy-20* encodes a novel coiled-coil protein. In addition to suppressing loss-of-function alleles of *zyg-1*, the *szy-20 (bs52)* mutation itself exhibits a strong temperature-sensitive embryonic lethality. We have begun phenotypic characterization of *szy-20 (bs52)* during the early cell cycles in C. elegans embryos. Immunostaining and video microscopy of *szy-20(bs52)* mutant strain reveals defects in polar body extrusion,cytokinesis and other aspects of cell cycle process. As expected in a double mutant strain of *szy-20 (bs52)* and *zyg-1 (it25)*, we have observed centrosome duplication at restrictive-temperature. We are continuing to analyze this gene molecularly and cytologically, by employing a variety of genetic and molecular tools to determine what the biological function of *szy-20* might be and to understand the nature of its interaction with *zyg-1*.

**Phospho-regulation of Kinetochore Protein-protein Interaction and Chromosome Segregation by the Nek2a Kinase**

J. Yao, X. Cai, S. Pei, Y. Zhang, Z. Guo, J. Zhu, X. Yao, Y. Wang; Cell Cycle Control, University of Science & Technology of China, Anhui, China

Chromosome segregation in mitosis is orchestrated by protein kinase signaling cascades. A biochemical cascade named spindle checkpoint ensures the spatial and temporal order of chromosome segregation during mitosis. Our recent studies show that NEK2A possibly functions as a novel integrator of the spindle checkpoint signaling (J. Biol. Chem. 2004. 279, 20049). The fact that the phosphorylation of kinetochore protein Hec1 by Nek2 kinase is essential for faithful chromosome segregation (J Biol Chem. 2002 277, 49408) propelled us to delineate Nek2A-mediated phospho-regulation of kinetochore function. Using Hec1 as bait, our yeast two-hybrid screen has identified CENP-H as an interacting partner of Hec1 and mapped their interaction domains. The inter-relationship of Hec1-CENP-H was then validated by immunoprecipitation and pull-down assay using bacterial recombinant proteins. Both Hec1 and CENP-H are co-localized to kinetochore of mitotic cells while their interaction defines a stable kinetichore association and faithful chromosome segregation. Mass spectrometric analyses of Hec1 phosphorylated by Nek2A in vitro indicate that Ser165 is a major substrate. Interestingly, phosphorylation of Ser165 modulates Hec1-CENP-H interaction in vitro and chromosome segregation in yeast. The importance of Nek2A kinase in chromosome segregation was validated by a Nek2A depletion experiment in which Nek2A deficiency resulted a chromosome bridge phenotype with sister chromatid inter-connected. Currently, we are evaluating how Nek2A phospho-regulation of Hec1 governs chromosome stability in mitosis using real-time imaging.

1556

**The Mitotic Exit Network Mob1p-Dbf2p Kinase Complex Colocalizes with Cdc14p Phosphatase in the Nucleus and Functions at Kinetochores**

J. Stoepel,[1,2] M. A. Ottey,[1] C. Kurischko,[1] P. Hieter,[2] F. Luca[1]; [1]Dept. of Animal Biology, University of Pennsylvania, Philadelphia, PA, [2]Michael Smith Laboratories, University of British Columbia, Vancouver, BC, Canada

The *Saccharomyces cerevisiae* mitotic exit network (MEN) is a conserved signaling network that coordinates CDK inactivation, cytokinesis and G1 gene transcription. Cdc14p phosphatase plays a pivotal role in MEN signaling and mediates mitotic exit by dephosphorylating Cdk1p substrates and promoting Cdk1p inactivation. Cdc14p is sequestered in the nucleolus prior to anaphase and is transiently released in early anaphase and later in telophase. It was previously established that Cdc14p regulates the localization of chromosomal passenger proteins, which redistribute from kinetochores to the mitotic spindle during anaphase (Pereira and Schiebel, 2003). The role of Cdc14p in passenger protein localization was proposed to be independent of other MEN proteins. Here we present cytological evidence that the MEN protein kinase complex Mob1p-Dbf2p partially localizes to the nucleus during mitosis, associates with kinetochores and colocalizes with Cdc14p. We confirmed the kinetochore associations of Mob1p, Dbf2p and Cdc14p by chromatin immunoprecipitation and established that the kinetochore associations are Ndc10p-dependent. To determine if Mob1p-Dbf2p contributes to passenger protein localization during anaphase, we analyzed the localization of Ipl1p, Sli15p and Bir1p (orthologs of mammalian Aurora kinase, INCENP and survivin) in conditional MEN mutants. Significantly, we found that both Mob1p and the Mob1p-Dbf2p activating kinase Cdc15p are required for maintaining chromosomal passenger proteins on the spindle during anaphase and telophase. Collectively, these data reveal kinetochores as sites for MEN signaling and implicate MEN in coordinating changes in passenger protein localization with mitotic exit.

1557

**Four-Dimensional Imaging of Mitotic Regulatory Proteins of Aspergillus nidulans**

T. Nayak, E. Szewczyk, C. E. Oakley, B. R. Oakley; Molecular Genetics, Ohio State University, Columbus, OH

A γ-tubulin mutation of *Aspergillus nidulans* affects the regulation of mitotic progression independent of microtubule nucleation (Prigozhina *et al.*, 2004, Mol. Biol. Cell 15:1374-1386). We hypothesize that this involves altered binding of mitotic regulatory proteins to the spindle pole body (SPB). In collaboration with the labs of Dr. Michael Hynes and Dr. Stephen Osmani, we have developed a rapid and efficient gene targeting procedure for *A. nidulans* that allows us to create GFP-tagged proteins easily. We have created C-terminal GFP-tagged versions of γ-tubulin, *bimA* (an APC component), and the *A. nidulans* homologs of Mad2, Cyclin B, Cdc14 and Mps1 and, as a first step in determining if their distribution is altered by γ-tubulin mutations, we have begun to 4D image them in a wild-type background. In each case the tagged gene is functional and is controlled by its normal promoter. In interphase, Cdc14 is in the nucleoplasm and at the SPB, but (unlike in *Saccharomyces cerevisiae*) it is largely absent from the nucleolus. As nuclei enter mitosis, Cdc14 disperses, then reappears on the spindle and then, in anaphase, at the SPBs. It becomes dispersed in the nucleoplasm again as the nuclei enter G1. Cyclin B is visible in the nucleoplasm and on the SPB of G2 nuclei. As nuclei enter mitosis, it is briefly located at the SPBs, but it disappears rapidly and is hard to detect by anaphase. Mad2 is found in multiple dots at the nuclear envelope in interphase. As nuclei enter mitosis it moves briefly to the SPB then is seen along the spindle. The nuclear envelope dots re-form as the nuclei exit mitosis. Supported by grant GM31837 from the NIH.

**BubR1: A Checkpoint Protein also Required for Chromosome Congression**

A. Maia, C. E. Sunkel; Molecular Genetics of Mitosis, Institute for Molecular and Cell Biology, Porto, Portugal

During cell division, chromosomes must attach to microtubules and become bioriented to ensure proper segregation of the genome. The fidelity of this process is ensured by the spindle checkpoint. Mutations in genes involved in this surveillance mechanism were predicted to cause chromosome instability and aneuploidy, a hallmark of many cancers. Several proteins, including BubR1, participate in this checkpoint and are able to inhibit the ubiquitin ligase activity of the anaphase-promoting complex or cyclosome (APC/C). This prevents precocious sister chromatid separation and cyclins degradation until correct attachment/biorientation is achieved. Recently, a novel role for *h*BubR1 has been proposed in chromosome congression. Accordingly, we have analyzed this putative function of BubR1 in *Drosophila* S2 cells. We show that indeed depletion of BubR1 by RNAi causes abnormal congression associated with an increased number of chromosomes scattered along the spindle and/or at the poles. Furthermore, we find that blocking the metaphase-anaphase transition in BubR1 RNAi-treated cells with the proteasome inhibitor - MG132 - causes a severe increase in the number of chromosomes scattered along the spindle and at the poles. We conclude that the increase in the frequency

of this phenotype during extended inhibition of the proteasome is likely to be the result of inappropriate retention of Aurora B at kinetochores. An increased activity of Aurora B would then be responsible for the increasing destabilization of kinetochore-microtubule attachments leading to the higher frequency of congression defects observed in the absence of the proteasome inhibitor.

**Emi1 Stably Binds and Inhibits the Core Anaphase Promoting Complex/Cyclosome as a Pseudosubstrate Inhibitor**

J. J. Miller, M. K. Summers, D. V. Hansen, M. V. Nachury, N. L. Lehman, A. Loktev, P. K. Jackson; Department of Pathology, Stanford University Medical School, Stanford, CA

Emi1 serves as an essential regulator of cyclin accumulation by inhibiting the activity of the Anaphase Promoting Complex (APC) from the G1-S transition, through S and G2 phases, and into mitosis. Here we show that Emi1 forms a stable complex with the APC to maintain the APC in the inactive state. To probe the Emi1-APC interaction, we used immobilized Emi1 beads, which efficiently capture the APC from cell extracts. A conserved destruction box and the zinc-binding region of Emi1 both contribute to the binding affinity and the efficiency of APC inhibition. We show that this high affinity interaction allows Emi1 to compete with the binding of D-box containing substrates to the APC. Mutation of the zinc-binding region converts Emi1 into a D-box dependent APC substrate, suggesting that Emi1 acts as a pseudosubstrate inhibitor. We will discuss the mechanism by which Emi1 binding to the APC core is regulated during mitosis, thereby allowing APC activation. We will also consider the role of the mitotic Cdc2 and Plk1 kinases in triggering Emi1 destruction and dissociation from the APC. We propose that combining a conserved degron with a high-affinity E3 binding domain provides a general model for how substrates of ubiquitin ligases can evolve to become regulated inhibitors.

1560

**The Evi5 Oncogene Regulates Cyclin Accumulation by Antagonizing Plk-Mediated Destruction of the Anaphase Promoting Complex Inhibitor Emi1**

A. G. Eldridge,[1] A. V. Loktev,[2] D. V. Hansen,[1] E. W. Verschuren,[2] J. D. R. Reimann,[2] P. K. Jackson[3]; [1]Cancer Biology, Stanford University, Stanford, CA, [2]Pathology, Stanford University, Stanford, CA, [3]Pathology and Microbiology & Immunology, Stanford University, Stanford, CA

The Anaphase Promoting Complex/Cyclosome (APC) inhibitor Emi1 controls progression to S phase and mitosis by stabilizing key APC ubiquitination substrates, including cyclin A. To identify factors upstream of Emi1, we inactivated Emi1-interacting proteins by RNA interference and have identified the Evi5 oncogene as a regulator of Emi1 accumulation. Evi5 antagonizes the polo-like kinase (Plk)- and $SCF^{\beta TrCP}$-dependent ubiquitination and destruction of Emi1 by binding to a site on Emi1 surrounding the DSGxxS degron. By blocking Plk-dependent phosphorylation of Emi1 and βTrCP binding, Evi5 functions as a stabilizing factor maintaining Emi1 levels in S/G2 phase. Evi5 protein is centrosomal, and is itself cell cycle-regulated, accumulating in early G1 following destruction of Plk1 and being triggered for ubiquitin-dependent proteolysis in early mitosis dependent upon Plk1 reaccumulation. Ablation of Evi5 results in precocious degradation of Emi1 by the $Plk/SCF^{\beta TrCP}$ pathway, causing premature APC activation, cyclin A destruction, cell cycle arrest, and uncoupling of the centrosome cycle, leading to mitotic catastrophe. We propose that the balance of centrosomally-localized Evi5 and Polo-like kinase activities determines the timely accumulation of Emi1 and cyclin, ensuring mitotic fidelity.

1561

**Medium Development for Thermostable Alfa-Amylase Production by *Bacillus Stearothermophilus* GRE1 Using Response Surface Methodology**

S. Hossain,[1] G. Haki,[2] S. K. Rakshit[3]; [1]Chemical Engineering, University of Calgary, Calgary, AB, Canada, [2]Debub University, Awassa, Ethiopia, [3]Food Engineering and Bioprocess Technology, Asian Institute of Technology, Pathumthani, Thailand

A culture medium for a newly isolated microorganism identified as *Bacillus stearothermophilus* GRE1 was optimized with regard to thermostable α-amylase production by means of conventional and response surface methods in a batch reactor.1.0 % (w/v) starch and 3.0 % (w/v) lactose were found to be optimal by single factor experiment for enzyme production. Mathematical model developed using response surface methodology also revealed that 1.02% starch and 3.12% lactose produced the best effect on the production of enzyme. A maximum concentration of 11.43 U/ml α-amylase was obtained under these medium constituents. In addition, enzyme production was growth-associated in this study.

1562

**Spatial Organization in Collective Movement of Epithelial Cells on a Collagen Gel Substrate**

H. Haga, K. Hayashi, K. Kawabata; Divsion of Biological Sciences, School of Science, Hokkaido University, Sapporo, Japan

Collective cell movement plays an important role in many physiological events, as it occurs throughout the processes of wound healing and early embryogenesis, such as gastrulation and invagination. However, the mechanism of the collective cell movement has not been elucidated. We had previously found that epithelial cells migrated collectively along one direction on a collagen gel substrate. Furthermore, we also found that there was a role assignment among epithelial cells on the collagen gel. The "leader" cells, which extended large lamellae and being accompanied by many "follower" cells, migrated in the direction of oriented collagen fibers. In the present study, in order to characterize the leader and the follower cells, we transfected MDCK cells with GFP-tagged myosin regulatory light chain (GFP-MRLC), and cultured them on type-I collagen gels. Temporal sequence of GFP-MRLC fluorescent images were captured by confocal laser scanning microscopy equipped with an incubational system. The leader cells had stress fibers and migrated like mesenchymal cells, whereas the typical follower cells did not have stress fibers and showed amoeboid-like migration. We also focused on the spatial distribution of phosphorylation of MRLC. Immunofluorescent observations stained with phosphorylated MRLC revealed that MRLC in a leader cell and the neighboring cells were highly phosphorylated, whereas MRLC in the follower cells were entirely dephosphorylated. These results suggest that mesenchymal-amoeboid transition occur in an epithelial colony on the collagen gels. In the annual meeting, we will present a probable model that the role assignment among epithelial cells may bring harmony into the cell society, and as a result, it may lead to the collective movement of the cells.

## Apoptosis II (1563-1589)

1563

### Induced Expression of a Pro-apoptotic Gene NALP5 Following Neuronal Injuries

C. Lo,[1] X. Ning,[1] C. Gonzales,[1] F. Liu,[1] E. M. Kajkowski,[1] M. M. Zaleska,[1] A. Wood,[1] J. S. Jacobsen,[1] B. A. Ozenberger[2]; [1]Wyeth Neuroscience, Princeton, NJ, [2]NHGRI, NIH, Bethesda, MD

With the emergence of apoptosis pathways as potential points of intervention in neurodegenerative disease, a strategy was developed to investigate the death domain protein repertoire of neurons. Using bioinformatics tools we identified several genes of interest that contain death domain such as CARD or Pyrin. We also sought to limit our searches to those genes that showed brain and/or neuronal localization. NALP5, a member of the NALP (NAcht Leucine-rich repeat Protein) family, represents one of our hits. The predicted protein structure of NALP5 includes a Pyrin domain followed by a nucleotide binding site (NBS) and a leucine-rich repeat. RT-PCR results showed that expression of NALP5 mRNA was induced in two models of neuronal injuries: serum/$K^+$ withdrawal in cerebellar granule neurons (CGN) and transient middle cerebral artery occlusion (MCAO) in rat. A potential function for NALP5 in apoptosis has not been described previously, and we sought to investigate this in recombinant systems. Transient expression of human NALP5 in cell lines (HeLa, HEK293, and 3T3) or in primary neurons (CGN) induced caspase-3 activation and apoptosis, as detected by DEVD-Fmk staining and Hoechst-33342 staining respectively. These data suggest that NALP5 may regulate programmed cell death in injured neurons via a caspase-3 dependent mechanism. This is the first time that NALP5 has been shown to have pro-apoptotic activities, and it is possible that this correlates with the induced gene NALP5 expression in injured neurons. NALP5 represents a novel molecular target for therapeutic intervention in neurodegenerative disorders.

1564

### PNPase Deficiency Compromises Apoptotic Signalling

S. W. French,[1] H. Chen,[1] R. N. Rainey,[2] D. W. Dawson,[1] C. E. Balatoni,[1] J. J. Troke,[1] J. Hong,[1] C. M. Koehler,[2] M. A. Teitell[1]; [1]Pathology, David Geffen School of Medicine at UCLA, Los Angeles, CA, [2]Chemistry and Biochemistry, UCLA, Los Angeles, CA

Mammalian polynucleotide phosphorylase (PNPase) is a 3' to 5' RNA exonuclease that is upregulated in terminally differentiated and senescent cells. However, overexpression of PNPase results in pleiotropic cellular effects that are difficult to reconcile from a presumed role in RNA turnover in the mitochondria matrix. Here, we show that PNPase is imported into mitochondria in the presence of a membrane potential and localizes to the intermembrane space (IMS) as a peripheral membrane protein. Functionally, truncated BID causes partial PNPase release from mitochondria following cytochrome *c* release, where it may encounter and degrade poly(A)+ RNA. PNPase knockdown causes increased cell survival and mitochondria membrane potential stabilization with growth factor withdrawal, indicating roles for PNPase in cell death and respiration. PNPase knockdown also inhibits ATP production and increases lactate levels in serum, further supporting a role for PNPase in oxidative phosphorylation. Combined, efficient cellular mechanisms in apoptosis and metabolism seem to require the novel, IMS-localized PNPase ribonuclease.

1565

### Inducing Endoplasmic Reticulum Stress in Chondrocytes Results in Loss of Differentiation, Cell Growth Arrest and Apoptosis

L. Yang,[1] S. G. Carlson,[2] D. McBurney,[1] W. E. Horton Jr.[1]; [1]Department of Anatomy, Northeastern Ohio Universities College of Medicine, Rootstown, OH, [2]The Lerner Research Institute of The Cleveland Clinic Foundation, Cleveland, OH

In eukaryotic cells, the Endoplasmic Reticulum (ER) is a major storage organelle for calcium and site of synthesis and folding of secretory proteins, cell membrane proteins, and is sensitive to changes in the internal and external environment of the cell. Both physiological and pathological conditions may perturb the function of the ER resulting in ER stress. The chondrocyte is the only resident cell found in cartilage and is responsible for synthesis and turnover of the abundant extracellular matrix and may be sensitive to ER stress. Here we report that glucose withdrawal, tunicamycin and thapsigargin induce ER stress in both primary chondrocytes and a chondrocyte cell line, detected by upregulation of GADD153 and caspase-12. Other agents such as IL-1β or TNFα induced a minimal or no induction of GADD153, respectively. ER stress resulted in decreased accumulation of an Alcian Blue positive matrix by chondrocytes and decreased expression of type II collagen at the protein level. Further, quantitative real time PCR was used to demonstrate a downregulation of steady state mRNA levels coding for aggrecan, collagen II, and link protein in chondrocytes exposed to ER stress-inducing conditions. The Sox9-dependent collagen type II promoter activity was downregulated under ER stress condition. In addition, the ER stress resulted in decreased chondrocyte growth based on cell proliferation assay, upregulation of p21 and decreased PCNA expression. Ultimately, ER stress resulted in chondrocyte apoptosis, as evidenced by DNA fragmentation and Annexin V staining. These findings have potentially important implications regarding consequences of ER stress in cartilage biology.

1566

### Involvement of Ataxia-telangiectasia-mutated (atm) in Calyculin A-induced Apoptosis

X. Tang, Z. Hui, B. Xu; Dept. of Genetics, Louisiana State University Health Science Center, New Orleans, LA

Calyculin A is a natural toxin produced by marine sponge and it is a specific and potent inhibitor of protein phosphatases 1 and 2A (PP1 and PP2A). These phosphatases are essential for cellular signaling network and cell survival, they can also be explored as new targets for developing cancer therapeutic drugs. Exposing cells to calyculin A induces cell death, but the mechanism regulating calyculin A-induced cell death is not well defined. We report here that exposure to calyculin A activates cellular apoptotic response in a variety of cell lines and it is correlated with premature chromosome condensation and global histone H3 phosphorylation. Among the cell lines we tested, Ataxia Telangiectasia Mutated (ATM) -deficient cells displayed resistance to calyculin A-induced cell death detected by MTT assay and colony formation assay. Furthermore, ATM-deficient cells have a pronounced defect in calyculin A-induced apoptosis. These observations indicate that ATM is critical for cellular death induced by calyculin A. Further experiments revealed that ATM is activated in response to Calyculin A treatment and the Structural Maintenance of Chromosomes protein one (SMC1) is phosphorylated in an ATM-dependent manner. Over-expression of a mutated SMC1 (ATM-mediated phosphorylation site mutant) has a dominant negative effect that can abrogate the apoptotic response. These data suggest that ATM phosphorylation of SMC1 is the essential signaling pathway in initiating calyculin A induced apoptosis.

1567

**Programmed Cell Death of the Jacket Cells is Essential for Spermatid Development and Differentiation in *Marsilea vestita***

F. Deeb, S. M. Wolniak; Cell Biology and Molecular Genetics, University of Maryland, College Park, MD

The microspore of the water fern *Marsilea vestita* contains a single cell that is activated to undergo nine rapid division cycles after it is placed in water. The divisions produce seven somatic cells and 32 spermatids. The gametophyte is transcriptionally quiescent during its development and before the divisions commence, certain stored proteins and mRNAs localize in zones that later become the spermatogenous initials. Asymmetric divisions produce somatic jacket cells, and a series of symmetric divisions produce the spermatids. As the spermatids differentiate to become motile gametes, the jacket cells undergo programmed cell death (PCD). We developed RNAi strategies to target mRNA degradation and thereby arrest gametophyte development. These published studies show that the temporal and spatial translation pattern in the gametophyte is highly ordered; certain proteins are required at specific stages of development. In this study, we inhibited PCD in jacket cells with RNAi treatments. dsRNA probes were made from cDNAs encoding two different cell death associated proteins that we isolated from a gametophyte library. These dsRNAs were added to populations of spores and gametophytes were fixed after 8 hours of development. Treated spores had large jacket cells and fewer spermatogenous cells than control gametophytes. Toluidine Blue-O staining of treated spores showed that jacket cells contain more total proteins and mRNAs than the jacket cells in untreated spores. Treated cells were labeled with anti-centrin and anti-β-tubulin antibodies to assess patterns of new translation of stored mRNA and cytoskeletal reorganization, respectively. Unlike normal gametophytes, centrin translation and tubulin localization were no longer limited to the spermatogenous cells. We suspect that impending PCD may underlie the early suppression of translation and development in the jacket cells. (Supported by NSF grant MCB-0234423 to SMW).

1568

**The *S cerevisiae* Protein Bir1p Is a Substrate for Nma111p and Is Able to Inhibit Apoptosis in Yeast**

D. Walter,[1] S. Wissing,[2] F. Madeo,[3] B. Fahrenkrog[1]; [1]M.E. Mueller Institute for Structural Biology, Biozentrum, Basel, Switzerland, [2]Physiologisch-chemisches Institut, University of Tübingen, Tübingen, Germany, [3]Institute for Molecular Biosciences, University of Graz, Graz, Austria

Apoptosis is a form of programmed cell death that is crucial for the development and maintenance of multicellular organisms. Apoptosis is characterized by distinct morphological changes of the cell, and recent findings suggest that a form of programmed cell death also exist in unicellular organisms, such as the yeast *S. cerevisiae*. We have recently shown that the *S. cerevisiae* HtrA-like serine protease Nma111p is able to mediate apoptosis in yeast. In search for substrates of Nma111p that provide insight into the molecular mechanisms of Nma111p's proapoptotic activity, we have now identified Bir1p as a substrate for Nma111p. Bir1p belongs to the family of inhibitor-of-apoptosis proteins (IAPs) that are typically characterized by the presence of one to three baculovirus IAP repeat (BIR) domains that are essential for their anti-apoptotic activity. Bir1p is the solely BIR-protein in yeast and is known to participate in chromosome segregation events, whereas its putative role in yeast apoptosis has not been studied yet. We show here that yeast cells lacking *bir1* are more sensitive to oxidative stress induced by $H_2O_2$ than wild-type cells and undergo apoptosis more frequently. Consistently, overexpression of Bir1p reduces apoptotic-like cell death. This protective effect of Bir1p can be antagonized by simultaneously overexpressing Nma111p. Apoptosis can be induced physiologically by long-term cultivation, known as chronologically ageing. Disruption of *BIR1* significantly accelerates the onset of age-induced cell death, whereas the onset of cell death is delayed in yeast cells overexpressing Bir1p. These results indicate that Bir1p in fact is an inhibitor of apoptotic cell death in yeast, and, like its closest metazoan homologues deterin and survivin, seems to have dual functions: it participates in chromosome segregation and exhibits anti-apoptotic activity.

1569

**Par-4-mediated Recruitment of Amida to the Actin Cytoskeleton Leads to the Induction of Apoptosis**

M. Boosen,[1] S. Vetterkind,[1] A. Koplin,[1] S. Illenberger,[2] U. Preuss[1]; [1]Institute of Genetics, University of Bonn, Bonn, Germany, [2]Cell Biology, Zoological Institute, Technical University of Braunschweig, Braunschweig, Germany

Par-4 (prostate apoptosis response-4) sensitizes cells to apoptotic stimuli, but the exact mechanisms are still poorly understood. Using Par-4 as bait in a yeast two-hybrid screen, we identified Amida as a novel interaction partner, a ubiquitously expressed protein which has been suggested to be involved in apoptotic processes. Complex formation of Par-4 and Amida occurs *in vitro* and *in vivo* and is mediated via the C-termini of both proteins, involving the leucine zipper of Par-4. Expression analysis of Amida in rat fibroblasts revealed a predominantly nuclear localization. Upon coexpression with Par-4, Amida colocalized with Par-4 at actin filaments, resulting in enhanced induction of apoptosis in REF52.2 cells. A similar Par-4-mediated translocation to the microfilament system has previously been demonstrated for Dlk/ZIP kinase, a well characterized interaction partner of Par-4 (S. Vetterkind et al. Exp. Cell Res. 305, 392-408, 2005). Coexpression of Amida and the leucine-zipper point mutant Par-4 L3 resulted in abrogation of both Amida interaction and apoptosis. Furthermore, disruption of the microfilament system decreased apoptosis as well as coexpression of Amida and a Par-4 deletion construct that is impaired in actin binding, indicating that the Par-4-mediated relocation of Amida to the actin cytoskeleton is crucial for the pro-apoptotic function of Par-4/Amida complexes. We postulate that the recruitment of nuclear proteins involved in the regulation of apoptotic processes to the actin filament system by Par-4 represents a potent mechanism how Par-4 can trigger apoptosis.

**Retinal Degeneration in Chronically Hypoglycemic Mice**

R. Barlow,[1] Y. Umino,[1] D. Everhart,[1] T. Nguyen,[1] J. Pan,[1] B. Frio,[1] R. Hafler,[1] B. Knox,[1] E. Solessio,[1] G. Engbretson,[1] K. Cusato,[2] M. Charron[3]; [1]Center for Vision Research, SUNY Upstate Medical University, Syracuse, NY, [2]Ophthalmology, UCSF School of Medicine, San Francisco, CA, [3]Biochemistry, Albert Einstein College of Chemistry, Bronx, NY

Our objective is to determine if metabolic stress in the form of hypoglycemia causes retinal degeneration. We examined the retinas of mice rendered chronically hypoglycemic by a null mutation the glucagon receptor gene, *Gcgr.* Homozygotes have about half normal blood glucose, and heterozygote and wildtype littermates have normal levels. We assessed retinal sensitivity (ERG), anatomy and optomotor responses of Gcgr+/+, Gcgr+/-, Gcgr-/- mice as a function of age. We found that retinas of Gcgr-/- mice begin to degenerate and the animals begin to lose visual acuity at

about 10 months of age and by 14 months the progressive changes are nearly complete, and the mice are functionally blind. Heterozygote littermates and wild-type mice retain normal visual acuity and normal retinal anatomy and sensitivity past 20 months of age. The molecular and cellular mechanisms underlying retinal degeneration are not known. TUNEL staining shows earliest cell death occurs in the inner nuclear layer followed by the outer nuclear and ganglion cell layers. The late-onset retinal degeneration in Gcgr-/- mice results from a null mutation of a gene that does not appear to be expressed in the retina. We suggest that the degeneration results from the metabolic stress caused by hypoglycemia resulting from the null mutation. The late-onset properties of retinal degeneration in these mice may make them useful models for studying causes of some human retinal diseases such as age-related macular degeneration. **Bcl-XL Enhances the Effect of GM-CSF in the in Vitro Development of the Monocyte/Macrophage Lineage**

A. Antignani, R. J. Youle; National Institutes of Health, Bethesda, MD

We have fused GM-CSF, via recombinant DNA, to Bcl-XL and expressed the recombinant fusion protein, GM-CSF-Bcl-XL, using bacteria and yeast. The goal of this chimeric protein is to bind the target human cells population through the GM-CSF receptor and prevent hematopoitetic cell loss during chemio or radiotherapy. Bcl-XL is a member of the Bcl-2 protein family and is able to suppress cell death induced by diverse stimuli in many cell types, including hematopoietic cells. Cytokine are the major mediators of host defense, in that they control hematopoietic cell proliferation, survival and regulate the communication between antigen-presenting cells (APC), lymphocytes and the other host cells. Human granulocyte-macrophage colony-stimulating factor (GM-CSF) is a cytokine that promotes the proliferation and maturation of neutrophils, eosinophilis, and macrophages from bone marrow progenitors. We found that the chimeric protein protects cells from staurosporine induced apoptosis from 24 hours until at least 72 hours, increasing the cell proliferation in monocyte culture. In presence of TyrAg490, an inhibitor of the Jak2 kinase, GM-CSF-Bcl-XL promotes proliferation whereas the cytokine alone is completely inhibited, because of the Bcl-XL portion. The protein is still active even in presence of specific anticancer drugs (cytarabine and daunorubicin). In all condition the antiapoptotic effect was measured and it is higher than the action of the GM-CSF alone. In presence of cytarabine and daunorubicin GM-CSF-Bcl-XL is able also to promote the differentiation of the CD34+ myeloid precursor, with an increase of the population of granulocytes compared to cells treated only with the fusion protein. We conclude that recombinant GM-CSF-Bcl-XL binds the GM-CSF receptor on human monocyte/macrophage cells and bone marrow progenitors and enters into the cells where Bcl-XL blocks cell death increasing the cell proliferation and differentiation.

1572

**Expression of Apoptosis Related Proteins in Villous Cytotrophoblast During Differentiation**

B. Wei, C. Xu, N. S. Rote; Reproductive Biology, Case Western Reserve University, Cleveland, OH

The human placenta is responsible for protection of the fetus during pregnancy. The placental villous surface is composed of 2 major types of cells, villous cytotrophoblast and syncytiotrophoblast. The mononuclear cytotrophoblasts form the inner layer of villi and differentiate to form the outer multinucleate syncytium, syncytiotrophoblast. Syncytiotrophoblasts are non-proliferate and rely solely on intercellular fusion with the underlying cytotrophoblasts for expansion during pregnancy. Although differentiating villous cytotrophoblasts undergo several changes resembling apoptosis, the role of apoptosis in villous cytotrophoblast differentiation is highly debated. To address this question, we studied the expression of a panel of apoptosis-related proteins during forskolin-induced differentiation of a model of villous cytotrophoblast, the choriocarcinoma cell line BeWo. Differentiating BeWo closely mimic differentiating villous cytrophoblasts (e.g., increased hCG production, decreased cellular proliferation, and intercellular fusion into syncytia). We observed that differentiation and syncytialization were not accompanied with activation of caspases-3, -8 or -9, yet the levels of pro-caspases were significantly diminished. By using real-time PCR, we showed that the decreased pro-caspases resulted from reduced transcription rather than activation as proposed by others. Moreover, expression of the pro-apoptotic proteins p53 and Bax were also down-regulated, while those of the anti-apoptotic protein Bcl-2 were up-regulated. Expression of Bcl-xl was unaffected. Expression of p53 protein was decreased within the first 24-hr of differentiation, and changes in Bcl-2, Bax, and the caspases protein levels were not significant until 48-hr of differentiation. Thus, differentiation of the villous cytotrophoblast model BeWo is concurrent with a shift in expression of apoptotic proteins towards a state of decreased apoptotic sensitivity. Whether this shift is related to the villous cytotrophoblast fusion process or whether it is a way of acquiring or maintaining an immune privileged status of the syncytiorophoblasts is under current investigation.

**Wee1 Promotes Apoptosis during the Early Embryonic Development of *Xenopus laevis***

B. N. Wroble, J. C. Sible; Biology, Virginia Tech, Blacksburg, VA

In somatic cells, when endogenous DNA is damaged or unreplicated, checkpoint pathways function to arrest the cell cycle prior to M or S phases through the inhibition of cyclin-dependent kinases (Cdks). In *Xenopus laevis*, early embryonic cellular divisions 2-12 consist of rapid cleavage cycles in which gap phases, cell cycle checkpoint engagement, and an apoptotic program are absent. Upon the completion of the 12$^{th}$ cellular division, the midblastula transition (MBT) begins and the cell cycle lengthens, acquiring gap phases. In addition, cell cycle checkpoint pathways and an apoptotic program become functional. In *Xenopus laevis*, Cdks are inhibited by phosphorylation of tyrosine 15 by the Wee1 kinase. To determine the role of Wee1 in cell cycle checkpoints and the remodeling events of the MBT, exogenous wt-Wee1 was expressed in one-cell stage *Xenopus* embryos. Modest overexpression of wt-Wee1 created a pre-MBT cell cycle checkpoint, characterized by cell cycle delay and inhibitory phosphorylation of Cdks on tyrosine 15. Furthermore, overexpression disrupted key developmental events that normally occur at the MBT, such as the degradation of Cdc25A, cyclin E, and Wee1. Additionally, these embryos possessed a nucleo-cytoplasmic ratio below the critical concentration normally seen at the MBT. Interestingly, overexpression also resulted in post-MBT apoptosis, as determined by gross morphology and activation of caspases. Conversely, overexpression of wt-Chk1 and wt-Chk2, which normally creates a pre-MBT cell cycle checkpoint, inhibits apoptosis. Taken together, these data suggest the importance of Wee1 as not only a Cdk inhibitory kinase, but also as a promoter of apoptosis during the early development of *Xenopus laevis*.

1574

**Role of CK2 in Regulation of TRAIL-induced Apoptosis in Prostate Cancer Cells**

G. Wang, K. A. Ahmad, H. Lindvall, A. Johnson, G. M. Unger, J. W. Slaton, K. Ahmed; Research Service/Lab Med Path, V.A. Medical Ctr/Univ of Minnesota, Minneapolis, MN

Protein kinase CK2 (formerly casein kinase 2 or II) signal is involved in cell proliferation and also in suppression of cell death (apoptosis) (Ahmed et al., Trends Cell Biol 12: 226-230, 2002). Prostate cancer is one of the leading cause of death in the U.S.A. In an attempt to decipher the potential role of CK2 in receptor-mediated apoptosis, here we demonstrate that prostatic carcinoma cells, regardless of their phenotype (such as androgen-insensitive PC-3 or androgen-sensitive ALVA-41), are sensitized to TRAIL-mediated apoptosis by chemical inhibition of CK2 employing the specific inhibitor TBB (4,5,6,7-tetrabromobenzotriazole). Conversely, overexpression of CK2 by using pcDNA6-CK2α expression plasmid affords protection against TRAIL-induced apoptosis. The downstream targets impacted by CK2 in modulating the TRAIL functions are the death inducing signaling complex (caspase activity), DNA fragmentation, and cleavage of downstream target lamin A. Overexpression of CK2 also blocks the mitochondrial apoptosis machinery engaged initially by TRAIL. These findings suggest that while downregulation of CK2 sensitizes prostate cancer cells to TRAIL-mediated apoptosis, the overexpression of CK2 impedes the death receptor-mediated apoptotic execution thus providing insight into the mechanisms involved in CK2 mediated modulation of death receptor-mediated apoptosis. The results hint that novel anti-cancer strategies could be designed targeting CK2 by itself or in combination with TRAIL. [Supported by research grant from NCI and V.A. Medical Research funds].

1575

**Overexpression of Regucalcin Suppresses Apoptotic Cell Death in Cloned Normal Rat Kidney Proximal Tubular Epithelial NRK52E Cells: Change in Apoptosis-Related Gene Expression**

M. Yamaguchi, T. Nakagawa; Laboratory of Endocrinology and Molecular Metabolism, Graduate School of Nutritional Sciences, University of Shizuoka, Shizuoka, Japan

The effect of regucalcin, a regulatory protein in intracellular signaling pathway, on cell death was investigated using the cloned normal rat kidney proximal tubular epithelial NRK52E cells overexpressing regucalcin. NRK52E cells (wild type) and stable regucalcin (RC)/pCXN2 transfectants with subconfluent monolayers were cultured for 72 h in a medium without BS containing various factors. The number of wild-type cells was significantly decreased by culture for 72 h in the presence of TNF-alpha, LPS, Bay K 8644 or thapsigargin. These factor's effect was significantly prevented in transfectants. Agarose gel electrophoresis showed the presence of DNA fragments of adherent wild-type cells cultured with LPS, Bay K 8644 or thapsigargin for 24 h, and this DNA fragmentation was significantly suppressed in transfectants. TNF-alpha-induced decrease in the number of wild-type cells was significantly prevented by culture with caspase-3 inhibitor, while LPS- or Bay K 8644-induced decrease in cell number was significantly prevented by caspase-3 inhibitor or NAME, an inhibitor of NO synthase. Thapsigargin-induced decrease in cell number was not prevented in the presence of two inhibitors. Bcl-2 and Akt-1 mRNA levels were increased in transfectants, while Apaf-1, caspase-3 or G3PDH mRNA expressions were not changed in transfectants. Culture with TNF-alpha, LPS, Bay K 8644 or thapsigargin caused a significant increase in caspase-3 mRNA levels in wild-type cells. LPS significantly decreased Bcl-2 mRNA expression in the cells. Those effects on gene expression of apoptosis-related proteins were not changed in transfectants. This study demonstrates that overexpression of regucalcin has a suppressive effect on cell death and apoptosis induced by various factors which the action are mediated through many intracellular signaling pathways, and that regucalcin modulates the gene expression of apoptosis-related proteins.

**Regulation of Bax Activation and Translocation by Mcl-1 During UV-induced Apoptosis in HeLa Cells**

K. Xiao, L. Zhou, D. C. Chang; Biology, HKUST, Hong Kong, Hong Kong Special Administrative Region of China

A key step to trigger the release of mitochondrial intermembrane proteins during UV-induced apoptosis is the Bax translocation from the cytosol to mitochondria to form small aggregates. The mechanisms for Bax translocation and aggregation, however, have not been fully understood yet. Apparently, other Bcl-2 family proteins play important roles in regulating Bax translocation and aggregation. Among them, Mcl-1 is one of the major regulators. We found that overexpression of Mcl-1 could efficiently prevent Bax translocation, suggesting that Mcl-1 can negatively regulate Bax activation during UV-induced apoptosis in HeLa cells. We observed that Mcl-1 degradation appears to play a significant role in Bax activation, since treatment of MG132, a proteasome inhibitor which prevents Mcl-1 degradation, could prevent Bax translocation. Despite of a transmembrane (TM) domain at its C-terminus, Mcl-1 was found to localize both in cytosol and mitochondria. We produced a cytosolic Mcl-1-ΔTM, in which the TM domain was deleted. We found that overexpression of cytosolic Mcl-1-ΔTM could significantly prevent UV-induced apoptosis, to the same extent as overexpressing full-length Mcl-1. However, Mcl-1-ΔTM could not prevent Bax overexpression-induced apoptosis, while full-length Mcl-1 could. Based on the above and other results, we propose a hypothesis that cytosolic Mcl-1 acts as the primary inhibitory step for Bax activation and translocation, while mitochondrial Mcl-1 prevents Bax forming aggregates at the mitochondrial outer membrane.

**Bre Expression and Interdigital Apoptosis in the Developing Mouse Embryo**

W. M. Wong, K. K. Lee; Department of Anatomy, The Chinese University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China

Brain and reproductive organ expressed (*Bre*) gene is a stress-responsive gene. It is highly expressed in brain, reproductive organs and adrenal gland. When HeLa cells are treated with UV-radiation, DNA-damaging agent or retinoic acid, BRE expression is down-regulated. The human *Bre* gene encodes a 1.8kb mRNA that translates into a 44kDa protein. The human Bre protein shares 99% homology in its peptide sequence with mouse and hamster. Bre has been previously shown to be associated with the juxtamembrane region of p55 tumor necrosis factor receptor-1 (TNFR1) and to down-regulate tumor necrosis factor (TNF) α -induced NFκB activation. It has also been shown to play an anti-apoptotic role in Hela and D122 cell lines. In our study, we have performed in situ hybridization and immunohistochemical staining to analyze the expression patterns of Bre, TNFR1 and NFκB in the mouse embryo in order to elucidate a role of Bre during development. These three genes and their protein products were found to co-express in the brain, heart, neural tube, and especially in the interverterbal and interdigital tissues which normally undergo apoptosis

during development. To further study the role of Bre and understand the relationship between Bre and apoptosis, embryonic limb cells were transfected with a Bre expression plasmid containing a GFP reporter. We demonstrated that over-expression of Bre induced apoptosis and did not alter the morphological appearance in the transfected cells. The differential expression of Bre in the mouse embryo, especially in apoptotic tissues, suggests that this protein may play a key role in the development, through modulation of TNF transduction pathway.

**Anti-apoptotic and Pro-proliferative Effects of Basal Protein Kinase G (PKG) Activity in Vascular Smooth Muscle Cells (VSMCs), Determined Using the New Specific, Cell-permeable PKG Inhibitor DT-2**

C. Y. Wong, R. R. Fiscus; Dept. Physiol. (Fac. Med.) and Mol. Cell. Gerontol., Chinese University of Hong Kong, Shatin, NT, Hong Kong Special Administrative Region of China

Overstimulation of nitric oxide (NO)/cGMP/PKG pathway has pro-apoptotic effects in VSMCs, pancreatic beta-cells and colon cancer cells. Our data, however, indicate that NO at low physiological concentrations, via lower-level cGMP/PKG activation, (and even basal cGMP/PKG activity) has anti-apoptotic effects in many neural cells, female reproductive cells and pancreatic beta-cells. Therefore, NO has dichotomous regulatory roles in physiological and pathological conditions. (Over)stimulation of cGMP/PKG pathway is also reported to be anti-proliferative in VSMCs and vascular remodeling. Our present study determines the role of basal PKG activity, under normal culturing conditions, on apoptosis and proliferation in primary (P0) cultures of VSMCs (i.e. phenotypically normal VSMCs) using a newly-developed PKG inhibitor, DT-2. DT-2 is a highly specific (>10,000-fold selectivity for PKG compared to other protein kinases), potent membrane-permeant peptide blocker of PKG. Cell death detection ELISA was used to determine effects of DT-2 on apoptosis in primaryVSMCs from C57BL/6J mice (2-4 months). In presence of serum, DT-2 had no effect on apoptosis. However, without serum for 72 h DT-2 (250 nM) enhanced pro-apoptotic effect by 2-fold. Thus, basal PKG activity provided anti-apoptotic signal that limited apoptosis during serum deprivation. DT-2 (250 nM and 1 μM, 72 h) also significantly ($p<0.001$) decreased by 40% and 47%, respectively, the rate of cell proliferation stimulated by serum in primary VSMCs from C57BL/6J mice (2-4 months). These results suggested that PKG, at basal activity, plays an anti-apoptotic role and also enhances proliferation rate in primary, phenotypically-normal VSMCs. **New Players that Involved in Mouse Embryonic Interdigital Cell Death**

S. W. Shan, K. K. Lee; Department of Anatomy, The Chinese University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China

Programmed cell death (PCD), or apoptosis, is an essential event in many kinds of biological processes and, the interdigital cell death is a typical example. PCD plays an important role in the shape of emerging limbs. The end result is the formation of free spaces that separate the digits in the hand and the foot. In this study we have used comparative proteomic techniques to identify proteins that may be involved in regulating the survival and death of mouse embryonic interdigital cells. We have identified many proteins that previously are not known to be expressed in the interdigital cells. Among these proteins are Protein Disulfide Isomerase (PDI) and Peroxiredoxin1 (Prdx1) which we found to be differentially expressed in interdigital tissues during PCD. For PDI, it was possible to inhibit interdigital cell death and expression of pro-apoptotic related genes (*bmp4* and *bambi*) by treating interdigital tissues with its enzyme inhibitor (bacitracin). These findings suggest that PDI is involved in the activation and maintenance of interdigital cell death. Conversely, when interdigital tissues were manipulated to survive Prdx1 was strongly expressed, but down-regulated when the cultures were allowed to die. Furthermore, we found that both *bmp4 and Dkk1* genes were down-regulated whereas the expression of another gene, *Wnt 5A*, was found maintained when interdigital tissues were manipulated to survive, these suggest that Wnt 5A may be one of the molecules that leads to the cartilage formation when the interdigital tissues were cultured. In sum, we have identify many new molecules involved in interdigital tissues and this implys that interdigital cell death is not a simple process but involves the interaction of proteins and genes that facilitate cell death and survival.

1580

**cIAP2-Associated Factor (C2AF): A Novel Protein that Controls Anti-apoptotic Function of cIAP2 and Promotes the Sumoylation of cIAP2**

H. S. Jin, H. S. Park, T. H. Lee; Yonsei University, Seoul, Republic of Korea

Cellular inhibitor of apoptosis proteins (cIAP1 and cIAP2) are a family of proteins that suppress apoptosis induced by mitochondria-dependent and -independent pathways by inhibiting caspases. Structurally, the cIAPs contain three baculovirus IAP repeats (BIRs) which are responsible for the inhibition of caspase-3 and -7 as well as a C-terminal RING domain. The RING domains of cIAPs have been shown to possess E3 ubiquitin ligase activities, implying a connection between apoptosis regulation and ubiquitination-proteasome system. Here, we employed a targeted proteomic approach to screen proteins associated with cIAP2. After expression of flag-tagged cIAP2 in 293 cells, the endogenous proteins that are complexed with cIAP2 were purified and displayed on one-dimensional electrophoresis. Protein bands were processed for determining their identities by using mass spectrometic methods. Results reveal that in addition to several proteins previously known to interact with cIAP2, a novel protein was identified as a cIAP2-associated protein, which was named as C2AF. Expression of C2AF suppresses the anti-apoptotic effect of cIAP2 on TNF-induced apoptosis, and triggers a redistribution of cIAP2 from cytosol to the nucleus. We also found that both C2AF and cIAP2 are modified by SUMO conjugation, and C2AF promoted the sumoylation of cIAP2 in the nucleus.

**The Growth Inhibition of MM Cells Induced by Agonist Anti-CD28 Monoclonal Antibody in vitro**

Q. Yu-hua, M. Hong-bing, S. Cheng-hai, S. Li-qin; Department of Immunology, Suzhou Medical College, Suzhou, China

CD28 expressed on T cells mediates necessary co-stimulatory signal promoting T cell activation, proliferation and function. CD28 expressed highly on human multiple myeloma (MM) cells but the significance hadn't been identified till now. Some researcher speculated that co-expression and engagement of CD28 and CD86 on MM cells might mediate a proliferation signals and consequently enhanced the proliferation ability for tumor cells. In this study, human multiple myeloma cell line U266, human T cell lymphoma cell line Jurkat and peripheral blood T cell (PBTC)

were chosen as targets. They were cultured in RPMI1640 medium with 10μg/ml agonist CD28 mAb. The results showed that the mAb had different effects on the different cell: (1) it inhibited growth and proliferation of U266 that highly expressed CD28 molecule and induced the cell apoptosis. Electrophoresis of DNA extract appeared a ladder band. Apoptosis bodies and chromatin marginal change were showed by transmission electron microscope (TEM); (2) it promoted proliferation of Jurkat and PBTC. The following explanation count for: (1) CD28 molecules expressed on different cells had a different configuration, possibly including isomers and mutants with different biological effects. (2) The expression density of CD28 was different on different cells. FCM analysis showed that the average fluorescence intensity of CD28 expressing on U266, Jurkat and PBTC was 462, 110 and 72, respectively. High cross-linking of antigens with the agonist CD28 mAb might inhibit cell membrane mobility, initiate and activate a certain inhibitory signals. The exact biological mechanism is still underlying and deserved to be investigated.

1582

**Visualization in Real Time of the Formation of the Mitochondrial Apoptosis-induced Channel, MAC, Triggered by T-bid by Patch-clamp Techniques**

S. Martinez-Caballero, L. M. Dejean, K. W. Kinnally; Basic Sciences, New York University CD, New York, NY

Bcl-2 family proteins tightly control apoptosis by regulating the permeabilization of the mitochondrial outer membrane and, hence, the release of pro-apoptotic factors from the intermembrane space. MAC is a high-conductance channel that forms early in apoptosis and is the putative cytochrome c release channel. Bcl-2 family proteins regulate apoptosis, in part, by controlling formation of MAC. Activated BH3-only proteins (e.g., t-Bid) trigger the release of cytochrome *c* in isolated mitochondria assayed by ELISA. Patch camp techniques were used directly on isolated mitochondria to verify that t-Bid can catalyze the formation of the MAC channel. The current flow across the outer membrane increased with time after seal formation, consistent with induction of MAC activity, when t-Bid was included in the micropipette. This MAC activity was reversibly blocked by dibucaine. Full length Bid or vehicle alone did not induce MAC formation nor release cytochrome c from isolated mitochondria. Various cell lines that do or do not express the multi-domain pro-apoptotic Bax and Bak are presently being examined. Our preliminary findings support the idea that t-Bid can regulate the formation of MAC in the mitochondrial outer membrane early in apoptosis. Supported by NIH grant GM57249 and NSF grant MCB-0235834 to KWK.

**RNAi-Mediated Gene Silencing to Examine the Biological Function of a Tumor-Associated NADH Oxidase (tNOX) in Transformed Cells in Culture**

S. C. Liu, S. Huang, P. J. Chueh; Institute of Biomedical Sciences, National Chung Hsing University, Taichung, Taiwan Republic of China

Unbalanced cell survival and cell death can result in the development of cancer. In many cancer cells, the survival proteins are up-regulated whereas the pro-apoptotic proteins are down-regulated. Therefore, recent interests have been focused on identifying the anti-survival pathways for the development of cancer therapy. Previous reports have described a tumor-associated NADH oxidase (tNOX) and its constitutive activation in transformed culture cells. Certain anticancer drugs have been shown to inhibit preferentially the tNOX activity and growth of transformed culture cells that correlate with the induction of apoptosis. Here, we utilize RNA interference (RNAi) approach to investigate the biological function of tNOX in transformed cells and its association in apoptosis induction. In this study, the expression of tNOX protein is reduced in RNAi-transfected cells when compared with wild type HeLa cells. The reduction of protein expression is correlated with the decline of growth of RNAi-transfected HeLa cells. To further investigate the effect of tNOX gene silencing, we examine the key regulators of cell cycle by Western blot analyses. In addition, the apoptosis induction is enhanced in tNOX-RNAi cells as shown with flow cytometry using FITC-Annexin V/PI staining. Moreover, the mechanism of apoptosis induction by anticancer drugs is studied. In summery, our data have shown the involvement of tNOX in cell cycle and apoptosis by utilizing RNAi-mediated gene silencing and these fundamental understanding of biological role of tNOX may lead to new anti-cancer strategies. (Supported by NSC93-2311-B-040-001 and NHRI-EX94-9411BC)

1585

**A Role of Zyxin in Apoptosis**

M. Hervy, M. C. Beckerle; Huntsman Cancer Institute, University of Utah, Salt Lake City, UT

Zyxin is an evolutionarily conserved protein that is concentrated at sites of cell adhesion and along actin stress fibers. The protein interacts with a variety of partners and is postulated to serve as a docking site for the assembly of multimeric protein complexes involved in regulating cell motility. Zyxin is also known to shuttle between the cytoplasm and the nucleus. Furthermore *zyxin* gene expression has been reported to be misregulated in a variety of tumors. In an effort to explore zyxin functions that might be relevant in tumorigenesis, we have investigated the involvement of zyxin in apoptosis, a process that is often disturbed in tumor cells. In particular we have compared the effect of UV-C irradiation in wild-type and zyxin-null mouse fibroblasts. We found that, after UV-C treatment, zyxin-null cells had an increased survival rate correlated with slightly lower caspase-3 activation. This observation led us to hypothesize that this effect could be mediated by an interaction of zyxin with regulators of apoptosis. We thus engineered a murine zyxin-null cell line which expressed a tagged version of zyxin allowing for the tandem affinity purification of protein complexes. This approach led us to recover the protein CCAR1 (Cell Cycle and Apoptosis Regulator 1) and further analysis allowed us to identify CCAR1 as a direct partner of zyxin. CCAR1 has recently been described in human breast cancer cells as a mediator of the apoptosis induced by the retinoid CD437, but little is known concerning the function and the mode of action of this protein. The functional significance of the interaction of these two proteins is currently under investigation and could point to a role for zyxin in the regulation of apoptosis.

1586

**RhoB Expression in Kidney Tubules in Response to Ischemia**

M. A. Hallett, N. Ray, S. J. Atkinson; Medicine, Indiana University, Indianapolis, IN

RhoB has been shown to be important for the response to various cellular stresses and is the target of farnesyl transferase inhibitors that induce apoptosis. RhoB may function by antagonizing the Akt survival pathway. We were interested to know if RhoB might be important for apoptosis in kidney tubules that occurs following ischemia. To determine if RhoB expression is changed by ischemia, in situ RTPCR was used to probe rat

kidney sections at 3 and 24 hours after 30 minutes of renal pedicle occlusion. We found that at 24 but not 3 hours post ischemia, RhoB mRNA was elevated. To determine if RhoB protein expression is also increased after ischemia, mouse kidney was made ischemic for 32 minutes, removed quickly, snap frozen in liquid nitrogen and pulverized. A detergent extract was used for a RhoB pull-down assay. We found that RhoB protein expression was elevated at 3 and 24 hours compared to the sham operated control. More of RhoB was active at 3 hours post ischemia than at 24 hours, suggesting that the stabilization of RhoB protein may occur before the increase in RhoB message. The interaction of RhoB with the Akt signaling pathway is our current focus. We suggest that the regulation of RhoB expression may be an important response to kidney ischemia.

1587

**A Mechanochemical Model Linking One-Hit Apoptosis to Cytoskeletal Dynamics**

T. Lomasko, C. J. Lumsden; Medicine, University of Toronto, Toronto, ON, Canada

The constant risk of cell death observed in neurodegenerative diseases may result from a “one-hit mechanism” (OHM) in which a catastrophic event triggers apoptosis (*Nature*,**406**,195). However, the role of the cytoskeleton (CSK) in the OHM has not been thoroughly explored. We have described an idealized mathematical model in which OHM biochemical subunits were distributed along a viscoelastic CSK filament. Filament shortening brings the subunits together and induces apoptosis. Our previous model dealt with a simplified kinetic scheme in which the rate at which stochastic changes in filament length take place is inversely proportional to the size of the changes (*Mol.Biol.Cell*,**15**,135a:748), i.e. the filament fluctuation kinetics resembles a well stirred chemical reaction. Here we treat a more realistic kinetics in which the rates and magnitudes are not locked together. We report simulation results for individual cells and 1-dimensional cell populations when one universal kinetic rate characterizes filament length changes of all sizes. A self-consistent hybrid scheme simulated filament length change as a stochastic variable and the kinetic state of downstream death trigger and intermediate messengers as deterministic nonlinear variables. We determined that for a single model cell, the spontaneous death rate is positively correlated with the magnitude of the stochastic deformations. In our computer models of the cell populations, we observed traveling waves and patches of cell death similar to those reported for diseased retinas (*Bull.Math.Biol.*,**64**,1117). Deletion of apoptotic cells from the population increased the mechanical stress impinging on all remaining cells, further enhancing the feedback from tissue mechanics to death kinetics. Our method is readily generalized to cell populations distributed in two and three dimensions. We conclude that our model simulates key experimentally observed cell death patterns, and therefore help clarify the role of the CSK in degenerative diseases.

1588

**Nongenomic Pathway for Anti-Estrogenic Signaling by Cadmium in Estrogen-Induced Osteoclast Apoptosis**

J. Rink,[1] A. K. Wilson[2]; [1]Northwestern University, Chicago, IL, [2]Biological Sciences, Benedictine University, Lisle, IL

Low-level cadmium exposure has been demonstrated to induce bone loss *in vitro* and *in vivo* by increasing the bone resorbing activity of osteoclasts. Osteoclasts normally undergo apoptosis shortly after they are activated. However, low-level cadmium exposure delays the onset of apoptosis at least 24 hours allowing the osteoclast more time to resorb bone. We investigated the signaling pathways for delaying estrogen-induced apoptosis. Apoptosis was induced in differentiated osteoclasts by the addition of 1μM β-estradiol in the presence or absence of 100 nM cadmium for 24 h. The percentage of apoptotic cells present was determined by morphometric analysis using fluorescent microscopy. β-estradiol and PPT, an estrogen receptor-α agonist, both increased the percent apoptosis approximately two-fold above baseline values. Coincubation with cadmium brought apoptosis values back down to the baseline level. Coincubation with the estrogen receptor antagonist, ICI 182780 at concentrations that diminished estrogen-induced apoptosis approximately 50%, could be further rescued by cadmium to the baseline level suggesting that cadmium is acting through the estrogen receptor. Similar results were obtained after inducing apoptosis with estren, an estrogen agonist that works exclusively in a nongenomic manner. Preincubation with the MEK inhibitor, PD98059 or the PI3K inhibitor, wortmannin did not inhibit estrogen-induced apoptosis. Cadmium was unable to inhibit estrogen-induced apoptosis after preincubation in PD98059 whereas it was able to completely prevent estrogen-induced apoptosis after preincubation in wortmannin. These data suggest that cadmium is interacting with the cell surface estrogen receptor-α but may be using an alternate pathway for cell survival other than MEK/ERK. **Counteracting Effect of Boron on the Structural Changes in Cytochrome C Exposed to Peroxides**

H. Farooqi,[1] S. Ali,[1] F. Ahmad,[2] M. Baig[1]; [1]Biochemistry, Hamdard University, New Delhi, India, [2]Biosciences, Jamia Millia Islamia, New Delhi-110025, India

Mitochondrial cytochrome c is a globular 12 KDa heme protein that is also recognized as an apoptotic inducer protein. Reactive oxygen species such as peroxides, formed *in vivo*, have been reported to inflict damage to this protein, and ultimately cause its release from the mitochondria into cytosol. Cytosolic cytochrome c then triggers various signal transduction pathways culminating in cell death. In the present study, we have shown that under oxidative stress conditions *in vitro* cytochrome c is damaged. The damage has been studied by spectrophotometric, gel filtration and electrophoretic techniques. Boron can counteract this damage as is evident from the results obtained using the above mentioned techniques. This suggests that boron stabilizes the protein structure. This stabilization may be due to interaction of tetrahedral borate anion. $B(OH)^-_4$ , which structurally resembles phosphate ion. Earlier NMR studies have shown that cytochrome c has at least two binding sites for borate. The study has implications in understanding the mechanisims of cell death.

**Isolation and Mapping of Mini-Chromosome-Loss Mutations in Caenorhabditis elegans**

M. Olaf, R. Tooley, S. Keller, M. Howe; Department of Biology, Bucknell University, Lewisburg, PA

Chromosome capture, and movement during mitosis are processes essential to chromosome segregation, and each requires kinetochore-spindle interactions. We have developed a sensitized genetic screen to identify proteins that mediate kinetochore-spindle interactions. In *C. elegans* chromosomes are holocentric allowing extrachromosomal transgenes to segregate as mini-chromosomes during mitosis. Chromosomal fragments

and transgenes regularly segregate as mini-chromosomes at mitosis and meiosis, because they, too, assemble kinetochores. We have shown that transmission of these mini-chromosomes is more sensitive to a mutant form of the kinetochore protein, HIM-10, than are whole chromosomes. Using free duplications or transgenes, marked with a GFP reporter construct, we have screened for mutations, like *him-10*, that cause mini-chromosome loss. Specifically, we screened for mosaic expression of the GFP reporter using the *him-10* mutant as a positive control. Six candidate mutations were isolated that cause mosaic GFP expression. Secondary analysis of these mutations involves determining that GFP expression from the duplication and transgene is mosaic and transmission of mini chromosomes is reduced in the germ line. We are developing assays to directly visualize the mini chromosomes in embryonic and germ-line cells. One mutation, *qa5300*, exhibits high frequency loss of the transgene. Transmission of the transgene through the germ line in this mutant was reduced by 18-20% when compared with the parent strain and similar to transmission in a *him-10* control strain. Similarly, DAPI staining of the germ line suggested that the frequency of transgene in diakinesis oocytes was reduced by 18-20% in the *qa5300* worms when compared to the parent strain. The mutation was mapped to the third chromosome using traditional methods. The map position of *qa5300* is being refined using SNP markers. In summary our result suggest that mini-chromosome loss is an effective primary assay for mutations affecting mitotic segregation.

1591

**Characterization and Mapping of Mini-Chromosome-Loss Mutant *qa5301* in *C elegans***

S. Eggert, M. Howe; Bucknell University, Lewisburg, PA

The overall aim of our research is to understand the molecular machines that segregate chromosomes at mitosis. Specifically we are identifying proteins that mediate kinetochore-spindle interactions using a sensitized genetic screen for mutations that cause mini-chromosome loss in *C. elegans*. We have identified a candidate mutation, *qa5301*, that causes mosaic expression of a GFP reporter construct carried on a transgenic mini chromosome. The mosaic phenotype of *qa5301* is similar to the phenotype observed in our positive control, a mutant version of the conserved kinetochore protein HIM-10. The mini chromosome is more sensitive to mitotic mutations than the intact chromosomes, allowing us to isolate homozygous viable mutant alleles such as *qa5301*. DAPI staining of diakinesis oocytes suggest that *qa5301* causes a low level of nondisjunction of the mini-chromosome sister chromatids in germ-line mitosis. There was a 10-fold increase in the number of oocytes with two mini-chromosomes in the mutant relative to the parental strain. Finally, though *qa5301* was not isolated as a temperature-sensitive mutation, it causes some sterility and larval arrest at elevated temperatures. These phenotypes are associated with other mitotic mutants in *C. elegans*, and they are consistent with chromosome segregation defects. Current efforts are focused on mapping the *qa5301* allele using a single nucleotide polymorphism technique with two reproductively isolated strains of *C. elegans*. The results thus far indicate that the *qa5301* allele is strongly linked to a marker on the right end of the X chromosome. Our results suggest that mapping and characterization of the gene impaired by the *qa5301* mutation will identify a factor important to proper mitotic chromosome segregation.

**Chk2 Function During DNA Damage Induced Mitotic Catastrophe**

H. Varmark,[1] J. Nordberg,[2] W. Theurkauf[1]; [1]Molecular Medicine, University of Massachusetts, Worcester, MA, [2]Cell Biology, University of Massachusetts, Worcester, MA

The G2/M damage checkpoint delays progression into mitosis to allow time for repair, and thus helps prevent mitotic propagation of potentially deleterious mutations. When checkpoint control fails and cells enter mitosis with DNA lesions, mitosis is aborted through a poorly understood process termed mitotic catastrophe. It is unclear if division failure is a non-specific consequence of damage or the result of a genetically programmed damage response. We have previously shown that the Chk2 kinase is required for damage induced division failure in *Drosophila* embryos (Takada et al. Cell 2003). Chk2 transduces DNA damage signals to downstream targets that regulate cell cycle progression, DNA repair and apoptosis, and chk2 mutations in humans are linked to cancer predisposition. The mitotic functions for human Chk2, however, are not well understood. We have used chromosomal mutations in chk2 and several other checkpoint genes in human HCT116 colorectal cancer cells to examine the function of this conserved kinase during mitosis. Using FACS, live cell imaging, and immunofluorescence, we examined cell cycle progression and mitosis in cells treated with DNA damaging drugs. In the presence of DNA damage, a fraction of parental and checkpoint compromised p21-/- HCT116 cells progress into mitosis, delay in M-phase, and then exit mitosis without cytokinesis. During mitotic delay, spindles are abnormal and chromosomes are not properly aligned at the metaphase plate. By contrast, chk2-/- cells treated with DNA damaging agents do not delay in mitosis. Rather, anaphase figures are observed and cytokinesis is often completed. These observations indicate that human Chk2 is required to delay mitotic exit and block cytokinesis in response to DNA damage. One of the structures disrupted during this damage response is the mitotic spindle, suggesting that Chk2 links cytoskeletal organization to genome integrity during the mammalian mitotic catastrophe response.

**Role of DNA Repair Proteins Involved in the Formation of Anaphase Bridges**

C. Acilan, W. S. Saunders; Biological Sciences, University of Pittsburgh, Pittsburgh, PA

Anaphase bridges, a commonly observed segregation defect in cancer cells, is one of the major sources of genomic instability. Bridges can theoretically be produced by any of several mechanisms including telomere-telomere fusion, persistence of chromatid cohesion into anaphase or repair of broken DNA ends. DNA damage can induce anaphase bridges following exposure to agents such as hydrogen peroxide or ionizing radiation. To determine how and why cells form bridges, we first set out to determine what DNA repair pathways the cells use to heal the damage and form bridges. Our data suggest that neither of the two major pathways, used by the cell for repair of double strand breaks, homologous recombination (HR) and non-homologous end joining (NHEJ), alone, is required for bridge formation. In fact, the NHEJ pathway seems to play a role in the prevention of bridges. When NHEJ is defective, cells appear to use HR to repair the DNA resulting in a relatively high frequency of bridges. Next, we surveyed whether we can explain the bridge forming potential in cancer cells with their NHEJ activity or the level of repair proteins. While the level of NHEJ proteins Ku80 and Ku70 does not show a relationship, it appears that XRCC4 levels can be used to estimate the tendency to form bridges. Our data also indicate that bridge frequency has a positive correlation with intrinsic NHEJ activity as judged by an in vitro ligation assay.

**Life after Cleavage Failure: Centrosome Amplification and Cell Viability**

A. M. Krzywicka-Racka, G. Sluder; Cell Biology, University of Massachusetts Medical School, Worcester, MA

Persistent centrosome amplification (more than two centrosome at mitosis) is believed to cause aneuploidy, genomic instability, and promote the evolution of the transformed state. Cleavage failure clearly leads to immediate centrosome amplification and is regarded as a primary source for persistent centrosome amplification. We test whether cleavage failure per se can provoke persistent centrosome amplification in normal, immortalized human cells. Asynchronous hTERT-RPE1 cells are treated for 4-11 hours with cytochalisin D to induce cleavage failure resulting in ~30% incidence of binucleate cells. This regime is repeated another 4 times at 5 day intervals; at each round we passage a portion of the culture 7 times. We monitor the incidence of centrosome amplification before each round of cleavage failure, four days thereafter, and at the end of 7 passages. Despite repeated rounds of massive cleavage failure, we do not find the generation of a population of cells with persistent centrosome amplification. Extended time lapse observations of binucleate cells revealed that ~80% enter mitosis and usually divide in bipolar fashion due to spindle pole bundling. However, progressively fewer progeny enter subsequent mitoses; they become quiescent and do not die. None of observed binucleate cells divide more than 4 times whilst same preparation mononucleate cells continue dividing at >95% frequency. We conclude that cleavage failure leads to a reduction in viability and is insufficient to induce persistent centrosome amplification. Cleavage failure, however, may be a problem for cells that have other regulatory defects.

1595

**Does Aneuploidy Drive Tumorigenesis?**

B. A. A. Weaver, A. D. Silk, F. R. Putkey, D. W. Cleveland; Cell Biology, Ludwig Institute for Cancer Research, La Jolla, CA

For 100 years aneuploidy has been recognized as a frequent characteristic of cancer cells and has been hypothesized to cause tumorigenesis. To test this, we have created mice that produce elevated rates of aneuploidy from reduction in CENtromere associated Protein-E (CENP-E). CENP-E is an essential, kinesin-like motor protein that is accumulated and degraded in a cyclin-like pattern, localizes to kinetochores, and promotes stable kinetochore-microtubule interactions. Mitotic cells lacking CENP-E fail to attach and align a portion of their chromosomes, resulting in an elevated rate of missegregation (25% of divisions in vitro, 95% of hepatocyte divisions in vivo). CENP-E heterozygous mice are viable and fertile, but fibroblasts (MEFs) derived from CENP-E heterozygous mice are shown to exhibit 33% aneuploidy after 6 divisions in culture and 56% aneuploidy after 12 divisions. Lymphocytes from peripheral blood in CENP-E heterozygous mice were also determined to exhibit a high degree of aneuploidy (34% in 3 month old animals, rising to 66% by 10 months). Four in vivo experimental tests have been used to test the aneuploidy hypothesis. First, CENP-E heterozygous MEFs immortalized with SV40T antigen were determined to form foci in soft agar and have been injected into nude mice to test for the ability to form tumors. Second, the propensity of CENP-E heterozygous mice for development of tumors has been determined. Abnormal growths have been found in 29% of ovarian and 11% of spleen and lung tissues from aged (18-20 months old) mice heterozygous for CENP-E. Third, mice have been treated with chemical carcinogen (DMBA) to test the effect of elevated aneuploidy on tumor initiation. Fourth, cohorts of CENP-E heterozygotes that also lack the p19 tumor suppressor gene have been produced. Together, these approaches provide a direct test of the potential causal link between aneuploidy, tumorigenesis, and tumor progression.

**Metabolism of Tasidotin (ILX-651) by Cancer Cells: Mechanisms of Activation and Resistance**

R. Bai,[1] M. C. Edler,[1] T. D. Copeland,[2] S. Schmid,[3] L. E. Arthaud,[3] E. Hamel[1]; [1]Pharmacology and Toxicology Branch, National Cancer Institute at Frederick, Frederick, MD, [2]Laboratory of Protein Dynamics and Signaling, National Cancer Institute at Frederick, Frederick, MD, [3]Genzyme Oncology, Genzyme Corporation, San Antonio, TX

Intracellular metabolism of tasidotin, an analog of the marine depsipeptide dolastatin 15, is the *t*-butyl amide of *N*,*N*-dimethyl-Val-Val-*N*-methyl-Val-Pro-Pro (the "metabolite"). Tritiated tasidotin, with only the fifth residue (the second proline) radiolabeled, was initially examined in Burkitt lymphoma CA46 cells to measure uptake and potential metabolism. Three prominent intracellular radiolabeled HPLC peaks were observed at all time points (5 min to 96 h). The earliest eluting peak, identified as proline, fluctuated between 25-40% of radiolabel recovered. The second peak, identified as the metabolite, steadily rose with time, from 18 to 60% of recovered radiolabel. The last peak, identified as tasidotin, steadily fell with time, from 49 to 1% of recovered radiolabel. Since the metabolite is a more potent inhibitor of tubulin than tasidotin or dolastatin 15, and earlier studies had indicated that removal of the terminal proline from the metabolite produced an inactive compound, these findings suggested that the Burkitt cells not only activated tasidotin but also could partially detoxify the compound. NCI drug screening data suggested that T47D breast cancer cells, and three other cell lines, should be resistant to tasidotin. At 5 h, 90% of the radiolabel recovered from the breast line was as proline, and at 24 h proline was the only radiolabeled peak. In the other three cell lines the proline content at 5 and 24 h ranged, respectively, from 50-70% and 50-95%. We plan to examine the NCI breast cell lines that should be sensitive to tasidotin for differences from the T47D line and the Burkitt line.

1597

**Nanoparticles Cause More DNA Damage in Human Cells Than Microparticles**

I. Papageorgiou,[1] E. Ingham,[2] R. P. Schins,[3] C. P. Case[1]; [1]Dpt. of Orthopaedic Surgery, University of Bristol, Bristol, United Kingdom, [2]Dpt. of Medical Immunology,School of Biochemistry and Microbiology, University of Leeds, University of Leeds, United Kingdom, [3]Particle Research, Institut fur Umweltmedizinische Forschung, Heinrich-Heine University, Dusseldorf,, Germany

There is currently much interest in the application of nanotechnology to medicine. In parallel with this, however, there is a concern about an adverse effect of exposure to nanoparticles, particularly if they are present in ambient pollution. In this study we have compared the biological effects of exposure of primary human fibroblasts to nanoparticles (29.5+/-6.3 nm) and microparticles (2.9±1.1μm) of cobalt chrome alloy. The release of cytokines was assayed by ELISA and cell viability by MTT and LDH assays. The amount of DNA and chromosome damage was quantitatively analysed by the Alkaline Single Cell Gel Electrophoresis (COMET) assay with image analysis and the micronucleus Assay with FISH-labelling with pancentromeric probes. Free radical production was measured by EPR spin trap. CoCr particles caused DNA damage in a dose-dependent way. However, small particles caused more DNA damage and at lower volumetric concentrations (0.005 $\mu m^3$/cell) than larger

particles (50 $\mu m^3$/cell). The difference in the threshold point was related to the surface area of the particles. With regard to the possible mechanism of the damage, smaller particles induced more superoxide and hydroxyl free radicals than larger particles. The DNA damage was correlated with a delayed decrease in cell viability, after three days of exposure. Both sizes of CoCr particles induced micronuclei in a dose dependent manner. No significant difference was noted but the nanoparticles caused significantly more centomeric-positive micronuclei than the microparticles. No significant amounts of cytokines (IL-6, TNF-a, TGF-beta-2, IL-10) were released from the fibroblasts after exposure to either particle. However the growth factor FGF-23 was increased in a similar pattern to the DNA damage. This study has demonstrated significant differences in the genotoxic,cytotoxic and mutagenic responses of human cells to nanoparticles and microparticles.

1598

**Evaluation of Toxicity of Ceramic Particles Within Human Cells *in vitro***

A. D. Tsaousi,[1] S. S. Taylor,[2] E. Jones,[1] C. P. Case[1]; [1]Dept. of Orthopaedic Surgery, University of Bristol, Bristol, United Kingdom, [2]School of Biological Science, University of Manchester, Manchester, United Kingdom

Problems arising from wear particles of the routinely used Metal-On-Polyethylene articulation in Total Hip Replacement (THR) surgery led to the development of novel materials. Ceramic-On-Ceramic articulation produces much less wear than any other combination. The greater need for implants in younger, more active patients necessitates research on the long-term effects of THR. This project has investigated the biological effects of alumina ceramic particles, a novel implant material relevant to orthopaedic surgery. Primary human fibroblasts were treated (in culture) with a variety of doses of alumina ceramic nanoparticles (ranging from 6.25 to 1000 ug/mL) for up to 5 days. The Trypan Blue Exclusion showed no significant differences in cell viability between control and treated cells, in all doses studied, up to 5 days of treatment. Subsequent microscopy analysis (after 24h of treatment with 25ug/mL) confirmed the existence of nanoparticles within cells. Beta-tubulin staining (immunofluorescence) did not reveal any major morphological differences in the cytoplasm of treated cells (with doses up to 250 ug/mL) when compared to controls. The Micronucleus Cytochalasin-B Genotoxicity Assay showed an increase in micronuclei formation after treatment with alumina nanoparticles (up to 0.2% versus 0.05% in controls). Interestingly, despite the wide range of doses tested (0-250ug/mL), there was no clear dose response. When combined with DNA pan-centromeric Fluorescent In-Situ Hybridisation, the above assay demonstrates that the level of aneugenic damage (measured as percentage of centromere positive micronuclei) is relatively high after ceramic treatment (40% versus only 12.5% in controls). Using the Anaphase-Telophase assay, anaphase bridges and lagging chromosomes were clearly seen in almost 9% of the treated cells (50ug/mL for 24h) while control values were less than 4%.In summary, the above suggests that alumina ceramic nanoparticles may cause aneuploidy in human cells.

1599

**Incenp Dynamics and Function in Vertebrate Mitosis**

L. J. Ahonen,[1,2] U. Klein,[3] M. Bolton,[4] E. A. Nigg,[3] T. Stukenberg,[4] M. J. Kallio[1]; [1]Cancer Biology and Cell Screening, VTT Medical Biotechnology, Turku, Finland, [2]TuBS Turku Graduate School of Biomedical Sciences, University of Turku, Turku, Finland, [3]Department of Cell Biology, Max-Planck-Institute of Biochemistry, Martinsried, Germany, [4]Department of Biochemistry and Molecular Genetics, University of Virginia Medical School, Charlottesville, VA

Inner centromere protein (Incenp) is a “passenger protein” essential for the ordered execution of mitosis. Incenp exhibits a transient localization pattern during cell division: first it accumulates to chromosome arms and inner centromeres at prophase, then translocates to the microtubules of the central spindle at anaphase, and finally concentrates to the midbody at telophase. Incenp is an integral component of the Aurora B complex that regulates microtubule-chromosome associations, spindle checkpoint signalling, and cytokinesis. Here we have measured the turnover of Incenp at the inner centromeres and spindle microtubules by using Fluorescence Recovery after Photobleaching (FRAP). The recovery of GFP-Incenp was recorded at different phases of normal cell division as well as in the presence of various drugs that either induce spindle damage or inhibit Aurora B kinase activity. The preliminary experiments show that Incenp is very mobile during early phases of mitosis but stabilizes at the onset of anaphase when the protein moves from inner centromeres to central spindle microtubules. In another approach, the normal function of Incenp was neutralized by anti-Incenp antibodies microinjected into mitotic Xenopus tissue culture cells. Cells injected at early mitosis were unable to align their chromosomes and exited mitosis prematurely without anaphase and cytokinesis. Similarly, cells with spindle damage and hyperactive spindle checkpoint rapidly decondensed their chromosomes, exited M phase without cell cleavage, and formed polyploidy progeny cells after introduction of anti-Incenp antibodies. These results indicate that Incenp is required for normal chromosome alignment, cell cycle arrest in response to spindle and chromosome errors, and execution of cytokinesis. Our results underline the importance of Incenp and Aurora B complex in promotion of bi-polar chromosome orientation and maintenance of spindle checkpoint activity, and identify Incenp as a potential target for future cancer therapies.

1600

**Characterization of Alternatively-Spliced Isoforms of INCENP**

W. J. Moore, E. Enervald, J. R. Swedlow; School of Life Sciences, University of Dundee, Dundee, United Kingdom

Aurora-B, a mitotic kinase involved in chromosome condensation, chromosome segregation and cytokinesis, is overexpressed in a number of tumor types. To investigate how the activity of Aurora-B changes in tumors, we sought to identify mutant alleles of the kinase and its regulators INCENP and Survivin in mRNA samples from a range of tumors. Sequence analysis revealed several splice variants of INCENP, a critical binding partner and regulator of Aurora-B. These consisted of alternatively spliced short (12bp) exons at two sites in the coding sequence of INCENP, encoding an insertion of the residues CSFV between exons 9 and 10 and VRAQ at the end of exon 12. Alternative splicing at these two sites appears to be independent. Quantitative PCR (qPCR) analysis showed that relative amounts of the CSFV insert fluctuated between tumor and normal samples and between different normal tissues. The VRAQ insert comprises ~23% of total INCENP across all normal tissues tested, but was elevated in some tumors. An anti-CSFV peptide antibody specifically recognized a biochemically distinct complex in HeLa lysates fractionated on a Superose 6 column. Splice variant specific siRNAi abolished expression of INCENP splice variants but resulted in only mild phenotypes characteristic of reduced INCENP activity, suggesting redundancy of function. We are currently defining the association of different INCENP splice variants with centromeres using FRAP and biochemically defining their components.

**The Fission Yeast Aurora Kinase, Ark1, Promotes Bipolar Chromosome Segregation in Mitosis and Meiosis**

S. Hauf,[1] T. S. Kitajima,[2] Y. Watanabe[2]; [1]Friedrich-Miescher-Laboratory of the Max-Planck-Society, Tuebingen, Germany, [2]Institute of Molecular and Cellular Biosciences, University of Tokyo, Tokyo, Japan

Work in a number of organisms has indicated that members of the Aurora kinase family are required for the correct bipolar segregation of sister chromatids in anaphase. In particular, Aurora kinases halt the cell cycle if sister chromatids are erroneously connected to the same pole, and are also required for correcting this error. However, the cell cycle delay, which occurs if kinetochores remain unconnected to microtubules, is largely independent of Aurora in budding yeast and human somatic cells. Contrasting with these findings, the fission yeast Aurora kinase Ark1 has been found to play a role in delaying the cell cycle when kinetochores are unattached (Petersen and Hagan, 2003). We have re-examined the phenotype of Ark1 inhibition in fission yeast mitosis and meiosis, using a temperature-sensitive allele and a small-molecule inhibitor, as well as meiosis-specific shut-down by promoter exchange. We find a clear defect in bipolar chromosome segregation in mitosis, consistent with Aurora's role in other organisms. In meiosis I, Ark1 promotes the segregation of homologous chromosomes to opposite poles. However, when recombination and side-by-side-arrangement of kinetochores are abolished, so that mitosis-like chromosomes exist in a meiosis I cell, Ark1 promotes the bi-polar segregation of sister chromatids, indicating that Ark1 is able to function independently of the underlying kinetochore morphology. Furthermore, in both mitosis and meiosis, Ark1 is required to delay the cell cycle if microtubule-kinetochore interactions occur, but not in the proper bi-polar fashion. Together, this data demonstrates that the function of Aurora kinases is highly conserved in evolution. To further reveal the mechanism of action, we have extended our analysis of Ark1 by searching for genetic interactors, which has revealed candidates of downstream effectors.

1602

**Inhibition of Aurora B Produces a Dramatic Stabilization of Kinetochore-Microtubules**

D. Cimini,[1] A. Khodjakov,[2] E. D. Salmon[1]; [1]Biology, University of North Carolina, Chapel Hill, NC, [2]Wadsworth Center, New York State Department of Health, Albany, NY

We have previously found that partical inhibition of Aurora B by 3μM ZM447439 produces a 6-fold increase in anaphase lagging chromosomes in PtK1 cells (Cimini et al., 2004, 43rd ASCB Annual Meeting). Anaphase lagging chromosomes are produced by merotelic kinetochore orientation (Cimini et al., 2001, J. Cell Biol.), in which a single kinetochore binds microtubules coming from both spindle poles rather than just one. To test the hypothesis that Aurora B inhibition results in a reduced efficiency of merotelic correction in prometaphase, we measured the changes in kMT (kinetochore-microtubule) stability in cells treated with 3μM or 20μM ZM447439. We used a PtK1 cell line expressing photoactivatable-GFP-tubulin (PA-GFP-tubulin) and measured MT poleward flux and MT turnover of photoactivated fluorescent marks across 1-3 kinetochore fibers. Because ZM447439-treated cells either spend a very short time in metaphase (3μM) or do not completely align their chromosomes (20μM), most of the cells analyzed possessed unaligned chromosomes and therefore were compared to mid- late-prometaphase untreated cells. Poleward flux of kMTs was reduced in ZM447439-treated cells as compared to untreated cells, being equal to 0.40±0.18 μm/min for 3μM and 0.42±0.16 μm/min for 20μM compared to 0.93±039 μm/min for control prometaphases. In controls, ~70% of kinetochore fiber fluorescence had a half-life of 20 sec, corresponding to non-kMT dynamics, while ~30% had a half-life of about 3 min, corresponding to kMT turnover. Both 3μM and 20μM ZM447439 did not change the fraction or turnover rate of non-kMTs, but they both substantially stablilized kMT fluorescence. These results show that inhibition of Aurora B produces a dramatic increase in kMT stability. This stability would prevent correction of merotelic attachments to the wrong pole in prometaphase, and hence induce chromosome segregation errors in anaphase detectable as lagging chromosomes. Supported by NIH GM32046

**Analysis of Mad2 and Cdc20 Dynamics at Kinetochores by FLIP**

R. P. O'Quinn,[1,2] W. C. Salmon,[3] E. D. Salmon[1]; [1]Department of Biology, University of North Carolina - Chapel Hill, Chapel Hill, NC, [2]NIH-UNC Graduate Partnerships Program in Cell Motility and Cytoskeleton, Bethesda, MD, [3]Michael Hooker Microscopy Facility, University of North Carolina - Chapel Hill, Chapel Hill, NC

Faithful chromosome segregation is achieved in dividing cells with the assistance of the spindle assembly checkpoint (SAC). A complex of Mad1, Mad2, and Cdc20 forms during mitosis that prevents activation of the anaphase-promoting complex ($APC^{Cdc20}$) and mitotic progression until all chromosomes are bipolarly attached at kinetochores. Mad2 is targeted to kinetochores by Mad1, and is activated to sequester and bind Cdc20. A recently proposed "template model" of the SAC suggests that two distinct conformers of Mad2 exist in cells: a "closed" form that is bound to Mad1 or bound to Cdc20 in the checkpoint cascade, and an "open" form freely diffusing in the cytoplasm unbound to either ligand. The model predicts that 50% of Mad2 at kinetochores should be C-Mad2 stably bound to Mad1 while 50% exists as O-Mad2 that rapidly binds and releases from C-Mad2/Mad1. To test for the presence of these two distinct conformers of Mad2 at kinetochores, we used measurements of fluorescence loss in photobleaching the cytoplasm (FLIP) or fluorescence recovery after photobleaching the kinetochore (FRAP) in PtK2 cells stably expressing YFP-Mad2. For reference, we used PtK2 cells stably expressing YFP-Cdc20. Cells were treated with nocodazole to prevent microtubule interactions with kinetochores. FLIP data indicated the existence of a stable component of Mad2, averaging 28% +/- 11.3% over our 10 min measurement period. In contrast, Cdc20 exhibited no stable component. FRAP results showed on average 36% of Mad2 stable at the kinetochore over 10 min. The rapid dissociation phase for Mad2 at kinetochores had a half-life of 20s or less. We conclude that there are two distinct conformers of Mad2 at kinetochores. It is likely that the stable component is C-Mad2 and the rapidly turning over component is O-Mad2. Supported by grants from NIHGMS and HFSP.

1604

**A Polar Reeling-in Mechanism Produces the Majority of Poleward Microtubule Flux for Kinetochore Fibers in PtK1 Cells**

L. A. Cameron,[1] G. Yang,[2] D. Cimini,[1] J. C. Canman,[1] O. Kisurina-Evgenieva,[3] A. Khodjakov,[3,4] E. D. Salmon[1]; [1]Dept of Biology, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [2]Laboratory for Compuatational Cell Biology, Dept. of Cell Biology, The Scripps Research Institute, La Jolla, CA, [3]New York State Department of Health, Wadsworth Center, Albany, NY, [4]Department of Biomedical Sciences, State University of New York, Albany, NY

Poleward microtubule flux is produced by forces generated within the mitotic spindle that help segregate chromosomes and produce tension on kinetochores. Translocation of tubulin polymer poleward coupled to minus end depolymerization near the spindle poles constitutes poleward flux. Three mechanisms may drive poleward flux. In a bipolar spindle, the sliding of microtubules (MTs) toward their poles could be produced by (1) motor proteins like kinesin 5 that cross-link and slide overlapping, oppositely-oriented MTs or by (2) kinesins bound to chromosome arms. (3) Minus-end depolymerization at the poles could be coupled to reeling-in of MTs in bipolar and monopolar spindles. We have used quantitative fluorescent speckle microscopy and fluorescence photomarking methods to determine the contribution of sliding and reeling-in to poleward flux of kinetochore MTs (kMTs) in mitotic PtK1 cells. When kinesin 5 is inhibited, poleward flux of kMTs in either monopolar (no anti-parallel MTs) or bipolar spindles occurs at ~75% of the normal rate in a bipolar spindle. This indicates that, polar reeling-in is the dominant mechanism of kMT flux in mammalian tissue cell mitosis.

1605

**Analysis of Kinetochore-lesions That Promote Chromosome Missegregation but Are Not Monitored by Spindle Checkpoint Proteins**

V. M. Draviam,[1] F. Stegmeier,[2] I. Shapiro,[1] B. Aldridge,[1] S. Elledge,[3] P. Sorger[1]; [1]Biology, MIT, Cambridge, MA, [2]Biology, Harvard Medical School, Boston, MA, [3]Harvard Medical School, Boston, MA

Unattached kinetochores recruit the spindle checkpoint proteins (Mad1-2, Bub1, BubR1&Mps1). Spindle checkpoint proteins pause anaphase onset until the kinetochore-microtubule attachment is complete and thus prevent missegregation. We report two lines of evidence that show chromosome missegregation despite the normal recruitment of spindle checkpoint proteins to kinetochores. We report novel lesions in kinetochore orientation generated by depleting the MAPs EB1 or APC. These lesions cause missegregation but these are not sensed by spindle checkpoint. By tracking the history of individual centromeres in live-cells, we show that unperturbed cells orient their centromeres in an orderly fashion. In contrast, EB1 or APC depleted cells display centromeres that are under insufficient tension and disordered orientation; misoriented centromere undergo missegregation. Overexpression of EB1 mutants that fail to bind to APC promote similar errors in segregation. Missegregations due to lesions in orientation are particularly interesting, since they fail to invoke a checkpoint arrest in checkpoint-proficient cells. This is in contrast lesions generated in the absence of CLIP170, chTOG1, LIS1 or Dynein, which recruit checkpoint proteins and arrest cells. In summary, perturbing the function of EB1 or APC promotes missegregation, without abrogating the recruitment of checkpoint proteins to kinetochores. A similar missegregation phenotype is observed in the absence of a kinase required to arrest cells in the presence of Taxol (RTF1). RTF1 identified in the Elledge lab from an RNAi-based screen for Taxol-induced arrest. In the absence of RTF1, cells undergo missegregation despite normal recruitment of Mad and Bub proteins - a status similar to EB1 or APC depletions. In summary, because missegregation in these two cases occur despite normal recruitment of spindle checkpoint proteins, we propose that spindle checkpoint independent mechanisms might play a role in accurate segregation of chromosomes.

1606

**Aurora B Kinase and MCAK Are Preferentially Localized to Points of Merotelic Microtubule Attachments**

A. K. McCullough, W. Lan, T. Stukenberg; Biochemistry, UVA, Charlottesville, VA

Proper chromosome segregation during mitosis is essential for viability, and is ensured by bipolar microtubule attachment on sister kinetochores. Often during mitosis, kinetochores form merotelic attachments in which a single kinetochore is attached to microtubules from both spindle poles. The microtubule depolymerizing Kin-I kinesin MCAK regulates Aurora B kinase at kinetochores, and may play a role in releasing improper microtubule attachments during prometaphase. The outer kinetochore plate protein Ndc80 (and its associated complex) is necessary for proper chromosome segregation and checkpoint activation, and is hypothesized to be the site of microtubule end-on attachment to kinetochores. We have used three channel confocal imaging to examine merotelic attachments in *Xenopus* S3 cells. In merotelically attached kinetochores, we find the expected two sister kinetochore populations of Ndc80 and novel foci in the inner centromere region. Microtubules from both poles emanate from these Ndc80 foci suggesting that this is the point of merotelic attachment. We have systematically identified proteins whose levels are increased at these points of merotelic attachment. MCAK and Aurora B are preferentially localized to these stretched kinetochores, and immunofluorescence with phosphoantibodies suggests that Aurora B is regulating this population of MCAK. These data support the hypothesis that Aurora B-regulated MCAK is responsible for the release of microtubules from merotelically attached kinetochores. We also conclude that the outer kinetochore plate is a malleable region that can be distorted by microtubule forces.

1607

**HURP, a Spindle-Associated Protein, Promotes Chromosome Congression and Tension Across Sister Kinetochores by Modulating Microtubule Dynamics**

J. Y. Wong, G. Fang; Department of Biological Sciences, Stanford University, Stanford, CA

Accurate chromosome segregation during mitosis requires the assembly of the mitotic spindle that captures all kinetochores by spindle microtubules, aligns chromosomes along the metaphase plate, and establishes tension across the sister kinetochores. To identify key regulators in these processes, we performed a targeted functional genomic screen for proteins required for efficient chromosome congression. From this screen, we identified the hepatoma up-regulated protein (HURP), originally reported as a gene product over-expressed in liver cancer cells. We found that HURP is a spindle-associated protein that preferentially localized to chromosome-proximal regions of the mitotic spindle. siRNA-mediated depletion of HURP results in a fifteen-fold increase in the number of metaphase cells with misaligned chromosomes that arise from the lack of kinetochore capture by spindle microtubules. HURP-depleted cells at metaphase also exhibit less tension across sister kinetochores on chromosomes that have congressed to the metaphase plate. Biochemically, HURP binds directly to microtubules, facilitates microtubule polymerization, stabilizes the mitotic spindle, and promotes timely bipolar spindle formation. We conclude that HURP, by modulating spindle microtubule dynamics, is required for efficient capture of kinetochores by spindle microtubules and for the establishment of proper tension across sister kinetochores. Furthermore, over-expression of either full-length HURP or its microtubule-binding domain hyper-stabilizes spindle microtubules, alters spindle morphology, and reduces tension across sister kinetochores at metaphase. Thus, the precise physiological level of HURP protein is critical for maintaining a functional mitotic spindle that generates proper pulling forces across sister kinetochores. We speculate that over-expression of HURP in tumor cells changes the dynamics of the mitotic spindle and reduces the fidelity of chromosome segregation

during mitosis.

1608

**Regulation of Kinetochore Fiber Elongation by Dynein**

U. S. Tulu, N. P. Ferenz, P. Wadsworth; Biology, University of Massachusetts, Amherst, MA

To examine mitotic spindle formation in mammalian cells, we developed a method to monitor microtubule assembly separately at centrosomes and chromosomes. LLCPK1 cells expressing GFP-tubulin are treated with nocodazole, partially released with drug-free media, and observed with spinning disc confocal microscopy. Under these conditions, microtubules form first at centrosomes and subsequently at discrete locations on chromosomes that stain for the kinetochore protein Bub1. Kinetochore-associated microtubules rapidly coalesce into microtubule foci. Injection of anti-dynein antibodies blocks coalescence and results in a dramatic elongation of kinetochore-associated microtubules. Centrosomal microtubules are not detectably altered following these injections. We tested the possibility that elongation of kinetochore-associated microtubules results from the mislocalization of KinI kinesins following inhibition of dynein, as recently documented in spindles assembled in frog extracts (Gaetz and Kapoor, 2004, JCB). Preliminary immunolocalization experiments demonstrate that Kif2a remains localized to kinetochore-associated microtubules in cells injected with anti-dynein antibodies. Microinjection of polyclonal antibodies directed at Kif2a, or MCAK, (kind gifts of Drs. D. Compton and C. Walczak, respectively) induced elongation of centrosomal microtubules, and spindle formation, but did not phenocopy the anti-dynein antibody effect. These results demonstrate that centrosomal microtubule elongation is regulated by KinI kinesins, whereas kinetochore-associated microtubule elongation is regulated by dynein. Photoactivation experiments are being used to determine the location of kinetochore-fiber elongation in this system. These data show that dynein/dynactin complexes at the kinetochore regulate elongation of kinetochore-associated microtubules in mammalian cells.

1609

**Kinetochore Fibrils: Slender Connections between Chromatin and Spindle Microtubules Revealed by EM Tomography of Rapidly Frozen, Freeze-Substitution Fixed Cells**

R. McIntosh, M. K. Morphew, E. T. O'Toole, D. N. Mastronarde; Dept. of M.C.D. Biology, Univ. Colorado, Boulder, CO

Electron microscope tomography has been used to examine the structure of the links between spindle microtubules (MTs) and the chromosomes of three species. Mammalian cells, strain $PtK_1$, and both fission and budding yeasts were cryo-immobilized by rapid freezing at high pressure, fixed by freeze-substitution, embedded in plastic, sectioned at ~300 nm, stained, then imaged in an electron microscope at either 300 or 750 KeV. Images of mitotic cells were collected at 1 - 1.5$^o$ tilt intervals around two orthogonal axes over $\pm$ 60$^o$. Three-dimensional (3D) reconstructions were generated by back-projection, and the resulting images were viewed and modeled with the IMOD software package (see http://bio3d.colorado.edu). Mitotic chromosomes and their sites of attachment to spindle MTs were identified in 3D, and the Slicer feature of IMOD was used to extract the volume surrounding each kinetochore microtubule end. The images showed fibrils 2 - 4 nm in diameter that extended from the centromeric heterochromatin out into the region of the MT ends. The fibrils made apparent contacts with the ends of the MT protofilaments or with either the inside or the outside of MT walls. The fibrils are slender and sinuous, so they are difficult to see, except in very thin slices of well-fixed spindles, such as the 2 - 10 nm slices that can be extracted from tomograms. We interpret these fibrils as fibrous protein complexes that comprise some of the kinetochore proteins in these organisms. We speculate that the connections to different places on the MTs correspond to different molecular links between the chromosome and the spindle.

1610

**Molecular Requirements for Microtubule Formation at Kinetochores and Centrosomes Using siRNA**

U. S. Tulu, C. J. Fagerstrom, P. Wadsworth; Biology, University of Massachusetts, Amherst, MA

Microtubules are a major component of a bipolar spindle. To examine microtubule assembly, we developed an assay in which microtubule formation around chromosomes and centrosomes can be visualized separately. LLCPK1 cells expressing GFP-tubulin are treated with nocodazole to depolymerize all microtubules, washed to remove drug and spinning disk confocal microscopy was used to visualize microtubule assembly at centrosomes and at chromosomes. We used siRNA to identify molecular requirements of microtubule formation. These experiments, which were performed in HeLa cells, have shown that TPX2, one of the targets of Ran pathway, and survivin, a member of chromosomal passenger complex, are involved in assembly and stability of microtubules around chromosomes. To further investigate the functions of these proteins in living cells with flat morphology, we are using siRNA in LLCPK1 cells, following partial release from nocodazole. We first synthesized siRNA's (Dharmacon) against LLCPK-Survivin (pig-Survivin), whose complete cDNA is available from NCBI. pig-Survivin was co-transfected with fluorescently labeled siRNA s to identify the transfected cells. Following partial nocodazole release, microtubule formation around chromosomes was reduced, while no change in centrosomal microtubules was observed, confirming the phenotype observed in HeLa cells. In order to deplete gene products whose complete sequence is not available, we designed PCR primers using known EST sequences. Our first candidate, pig-TPX2 was sequenced completely following this procedure. Sequence analysis of pig-TPX2 showed that it shares 89% sequence identity to hsTPX2 at DNA level and 87% sequence identity at protein level. These experiments demonstrated that we can use siRNA to downregulate protein levels in LLCPK1 cells and that this approach will allow us to identify molecular requirements of microtubule formation at kinetochores and centrosomes separately in real time.

1611

**TOGp Depletion Increases Tension at Sister Kinetochores and Suppresses Kinetochore Directional Instability**

B. E. Becker, J. Morabito, L. Cassimeris; Department of Biological Sciences, Lehigh University, Bethlehem, PA

TOGp is the human member of the XMAP215 family of MAPs that is required for proper mitotic spindle assembly. Previous results showed that TOGp plays an important role in spindle pole organization, however, its affects on other aspects of spindle assembly and function have not been addressed. We used siRNA knockdown of TOGp in cultured cells to investigate TOGp function in spindle microtubule dynamics and kinetochore motility. FRAP of GFP-tubulin expressing cells demonstrated that the turnover of non-kinetochore microtubules is not altered in TOGp-depleted cells. The rate of microtubule plus end elongation, measured in cells expressing GFP-EB1, were equal in siRNA and sense RNA treated cells.

Together these results indicate that TOGp is not required for non-kinetochore microtubule dynamics. However, examination of sister chromatid separation in TOGp-depleted cells stained with CREST or the kinetochore marker CENP-E showed that the distance between sister kinetochores increased, indicating that kinetochores are under greater tension compared to control cells. The loss of tension at sister kinetochores suggests that there are defects in microtubule flux or in the coordination of sister kinetochore movements, or both. Preliminary observations of kinetochore motility in TOG-depleted cells expressing GFP-CENP-A demonstrated a significant decrease in kinetochore motility after TOGp depletion. Our results suggest that TOGp is required to coordinate sister kinetochore motility and/or generate kinetochore movement away from the pole (AP); either defect may explain why TOGp-depleted chromosomes often fail to bi-orient. Experiments are underway to examine kinetochore microtubule flux in TOG-depleted cells to determine whether the defects in kinetochore motility result from changes in flux.

1612

**Reduced Microtubule Dynamics Contribute to Loss of Tension at the Kinetochore**

M. K. Gardner,[1] C. G. Pearson,[2] L. V. Paliulis,[3] D. J. Odde,[1] K. Bloom[3]; [1]Biomedical Engineering, University of Minnesota, Minneapolis, MN, [2]MCDB, University of Colorado, Boulder, CO, [3]Biology, University of North Carolina, Chapel Hill, NC

Sister kinetochores in budding yeast metaphase spindles are bioriented and separated into a metaphase configuration via kinetochore-attached microtubules (kMTs). Although kMTs are dynamic during yeast metaphase, individual plus-end behavior cannot be resolved, and the role of dynamic kMTs in maintaining tension generated via the stretch of chromatin between sister kinetochores is unclear. In addition, although tension has been implicated in the establishment of bipolar attachment at the kinetochore, the effect of moderate tension loss on the fidelity of chromosome segregation has not been established. Here, we have examined kMT plus-end behavior and kinetochore clustering in a β-tubulin mutant with reduced microtubule dynamics. Through the use of 1) high temporal and spatial resolution GFP-Tub1 fluorescence recovery after photobleaching (FRAP) experiments, 2) quantitative analysis of kinetochore-associated Cse4-GFP fluorescence, and 3) computational simulations of these experiments, we find that slowed kMT plus-end dynamics result in a ~20% reduction in separation between sister kinetochore clusters, which is likely due to restricted towards-the-pole excursions of the kMT plus-ends. We find that this moderate loss in tension at the kinetochore results in significant chromosome loss, indicating that robust kMT dynamics are instrumental in establishing tension, and that a minimal level of tension is required to ensure accurate chromosome segregation.

1613

**Comparative Proteomic and Functional Analysis of *C elegans* and Human Kinetochores**

I. M. Cheeseman,[1] S. L. Kline-Smith,[1] I. McLeod,[2] J. R. Yates,[2] T. Fukagawa,[3] A. Desai[1]; [1]Ludwig Institute for Cancer Research, La Jolla, CA, [2]The Scripps Research Institute, La Jolla, CA, [3]National Institute of Genetics and SOKENDAI, Mishima, Japan

The kinetochore is a large proteinaceous structure that serves as the primary chromosome attachment site for spindle microtubules. Identification of the full complement of metazoan kinetochore components remains an important challenge. Although more than 60 budding yeast kinetochore components have been identified, the absence of catalytic domains in the majority of these proteins and high sequence divergence has limited bioinformatics-based identification of metazoan homologues. We have conducted systematic proteomic analysis to define the composition of diffuse *C. elegans* kinetochores and localized human kinetochores. This work has identified 8 novel *C. elegans* kinetochore proteins and 10 novel human kinetochore proteins. Comparison of the purifications revealed both similar kinetochore sub-complexes in *C. elegans* and humans, as well as sub-complexes that are specific to the human kinetochore. The former class includes the KNL-1/3 protein network with NDC80/Hec and MIS-12 sub-complexes. The latter class includes CENP-H/CENP-I and 6 novel associated proteins. By analyzing the consequences of depleting newly identified proteins in both systems, we have defined the contributions that they make to kinetochore assembly and function. This approach has revealed striking similarities between *C. elegans* and human cells in the localization dependencies of the sub-complexes present in both systems. In contrast, the proteins not present in *C. elegans* represents a distinct branch of human kinetochore assembly. Phenotypic analysis in human cells has revealed an important role for both sets of proteins in assembly of kinetochore fibers and chromosome alignment and segregation. In total, this comparative dissection of kinetochores in two highly divergent metazoans is helping decipher the composition, assembly, and function of this key cell division organelle.

1614

**Dynamic Localization of Aurora-C and Aurora-B during Male and Female Mouse Meiosis**

C. C. Tang, C. Lin, T. K. Tang; Inst. Biomedical Sciences, Academia Sinica, Taipei, Taiwan Republic of China

The Aurora kinases play essential roles in many aspects of cell division including the control of centrosome function, kinetochore-microtubule interactions, and cytokinesis. In mammals, three distinct Aurora kinase members (Aurora-A, -B, and -C) have been identified. We have generated both a polyclonal and a monoclonal antibody that specifically against Aurora-C. The localization of Aurora-C was analyzed by immunofluorescence staining on chromosome spreads of mouse spermatocytes or in squashed seminiferous tubules. Aurora-C was first detected as clusters of chromocenters in diplotene spermatocytes and was concentrated at centromeres in metaphase I and II. Interestingly, Aurora-C was also found along the chromosome axes, including both the regions of centromeres and the chromosome arms in diakinesis. During the anaphase I/telophase I and anaphase II/telophase II transitions, Aurora-C was relocalized to the spindle midzone and midbody. A similar distribution pattern was also observed for Aurora-B during male meiotic divisions. Interestingly, we detected no Aurora-C in mitotic spermatogonia and in the examined normal mouse somatic tissues or cell lines suggesting that Aurora-C is a meiotic chromosomal passenger protein. Furthermore, immunoprecipitation analysis revealed that INCENP associated with Aurora-C in the male testis, suggesting that INCENP may recruit Aurora-C (or some other factor(s) may recruit INCENP and Aurora-C) to meiotic chromosomes. We also analyzed the subcellular localization of Aurora-B and -C during oocyte meiotic maturation. The localization pattern of Aurora-C in female oocytes is similar to that observed in male spermatocytes. Surprisingly, we detected no Aurora-B in female oocytes either by immunoblotting or immunofluorescence analysis. Together, our findings suggest that Aurora-C appears to be mainly expressed in meiotic germ cells and may play essential roles during meiosis.

1615

**Inhibition of Microtubule Flux and Other Effects of Monastrol on Crane-fly Spermatocytes**

J. R. LaFountain,[1] C. S. Cohan[2]; [1]Biological Sciences, University at Buffalo, Buffalo, NY, [2]Pathology and Anatomy, University at Buffalo, Buffalo, NY

One model for the poleward flux of microtubules in mitotic spindles requires plus end-directed motors that slide anti-parallel microtubules of the two half spindles away from the equator and toward the two spindle poles. To test this model in crane-fly spermatocytes, which exhibit robust flux in their kinetochore fibers, we treated isolated testes with monastrol (Sigma-Aldrich), an inhibitor of vertebrate bipolar kinesin Eg5, and then ruptured testes under oil to assess flux by fluorescent speckle microscopy. 100µM monastrol, a saturating dose in vertebrate systems, had no detectable effect on spermatocytes, even after incubations of 3 hrs. 1mM monastrol arrested meiosis, and upon microinjection of rhodamine-tubulin into spermatocytes arrested in metaphase, there was no detectable rh-tubulin incorporation into microtubules, to be expected if flux is turned off by monastrol. The arresting effect of monastrol on spermatocytes is reversible in fresh insect buffer. An interpretation in terms of monastrol-specific inhibition of Eg5 is complicated, however, by other effects of monastrol none of which are readily explained simply by its action on an Eg5 homologue. For example, monastrol caused arrest of cells undergoing cytokinesis. In addition, cells in late diakinesis failed to undergo nuclear envelope breakdown, although DMSO-treated controls invariably underwent NEB within 1 hr of initial observation. Thus, a motor-based mechanism of flux may indeed be operative in spermatocytes. However, in view of the observed other apparently non-Eg5-specific effects of monastrol on these meiotic cells, additional mechanisms, e.g., intrinsic treadmilling of microtubules, cannot be ruled out, because such alternatives also could be monastrol sensitive, albeit indirectly. This study has demonstrated that monastrol is not as widely applicable for testing the role of motors in microtubule flux as it appears to be in vertebrate systems.

1616

**Effects of Jasplakinolide on Chromosome Movement in Crane Fly Spermatocytes**

L. Xie, A. Forer; Biology, York University, Toronto, ON, Canada

Previous experiments utilized the actin inhibitors cytochalasin D and latrunculin to implicate actin in anaphase chromosome movements (e.g. Forer and Pickett-Heaps 1998): these inhibitors cause depolymerization of actin and cause anaphase chromosomes to slow or to stop moving. In our experiments we use a stabilizer of actin filaments, jasplakinolide, at 0.55mM or 1.1mM, to probe the role of actin in anaphase chromosome movements in crane-fly spermatocytes. We treated living crane-fly spermatocytes at various stages of meiosis I and studied the effects on chromosome movements. We describe the effects on individual chromosomes rather than on cells because not all chromosomes in the cell responded the same. When we added jasplakinolide in anaphase, chromosomes generally slowed or stopped moving (34/46), though stopping was only temporary. Some chromosomes moved normally in the presence of jasplakinolide (11/46) and one accelerated. Jasplakinolide added in prometaphase or metaphase caused a majority of the chromosomes (19/32) to stop or to move slowly during subsequent anaphase, and some chromosomes that stopped did not resume movement; the remaining chromosomes (13/32) moved normally. In initial experiments (in three cells) we added jasplakinolide at or before the time of *nuclear membrane breakdown*: in one cell the jasplakinolide blocked chromosome attachment to the spindle; in the other two cells about half the chromosomes moved normally and half stopped or slowed during anaphase. All these experiments indicate that spindle function is disrupted when jasplakinolide stabilizes actin filaments. To try to understand why, we will use confocal microscopy to study the disposition of actin filaments in these cells.

1617

**A Role for the Anaphase Promoting Complex Inhibitor Emi2/XErp1, a Homolog of Emi1, in Cytostatic Factor Arrest of Xenopus Eggs**

J. Tung, D. Hansen, K. Ban, A. Loktev, M. Summers, P. Jackson; Stanford, Stanford, CA

Unfertilized vertebrate eggs are arrested in metaphase of meiosis II (MII) with high cyclin B/Cdc2 activity to prevent parthenogenesis. Until fertilization, exit from metaphase is blocked by an activity called cytostatic factor (CSF), which stabilizes cyclin B by inhibiting the Anaphase Promoting Complex (APC) ubiquitin ligase. The APC inhibitor Emi1 was recently found to be required for maintenance of CSF arrest. We show here that exogenous Emi1 is unstable in CSF-arrested *Xenopus* eggs and is destroyed by the $SCF^{\beta TrCP}$ ubiquitin ligase, suggesting that endogenous Emi1, an apparent 44 kDa protein, requires a stabilizing factor. However, anti-Emi1 antibodies cross-react with native Emi2/Erp1/FBXO43, a homolog of Emi1 and conserved APC inhibitor. Emi2 is stable in CSF-arrested eggs, is sufficient to prevent CSF release, and is rapidly degraded in a Polo like kinase 1-dependent manner in response to calcium-mediated egg activation. These results identify Emi2 as a CSF maintenance protein.

1618

**The Cytostatic Factor Emi2 is the Critical Target of Calcium/Calmodulin-dependent Kinase II and Polo-like Kinase 1 in Exit from Metaphase-II of Meiosis**

D. V. Hansen,[1] J. J. Tung,[1] P. K. Jackson[2]; [1]Program in Cancer Biology, Stanford Univ. School of Medicine, Stanford, CA, [2]Pathology and Microbiology & Immunlogy, Stanford Univ. School of Medicine, Stanford, CA

In vertebrate meiosis, unfertilized eggs are arrested in metaphase-II by cytostatic factor (CSF), which is required to maintain mitotic cyclin-dependent kinase activity. Fertilization triggers a transient increase in cytoplasmic free $Ca^{2+}$, causing CSF inactivation and ubiquitin-dependent destruction of mitotic cyclin by the Anaphase-Promoting Complex (APC). Previous studies have shown that calcium/calmodulin-dependent kinase II (CaMKII) and the Polo-like kinase Plx1 are essential factors for $Ca^{2+}$-induced meiotic exit, but the critical targets of these kinases are unknown. We recently characterized the APC inhibitor Emi2/Erp1 as a pivotal component of CSF. Upon fertilization, a degron in Emi2 is phosphorylated by Plx1 and then recognized by the $SCF^{\beta TrCP}$ ubiquitin ligase, allowing ubiquitination-dependent destruction of Emi2, APC activation, and meiotic exit. An important question is how the increase in $Ca^{2+}$ targets Plx1 towards Emi2, especially since Plx1 is active before fertilization. We find that inhibition of CaMKII prevents $Ca^{2+}$-induced Emi2 destruction, and that a dominant, activated CaMKII drives Emi2 destruction in the absence of $Ca^{2+}$. Moreover, phosphorylation of Emi2 by CaMKII induces a strong interaction between Emi2 and the PoloBox domain of Plx1, allowing subsequent phosphorylation of the Emi2 degron by Plx1 and recruitment of βTrCP. A specific motif in Emi2 contains consensus sites for phosphorylation by CaMKII and, when phosphorylated, Plx1 recruitment. Mutation of this motif in Emi2 causes failure to recruit Plx1 and failure to be destroyed in response to $Ca^{2+}$. Thus, the CSF component Emi2 is a critical and direct target for both CaMKII and Plx1, providing the first

detailed molecular mechanism explaining how CaMKII and Plx1 coordinately direct the activation of the APC and meiotic exit upon fertilization. Evidence for an independent mode of Emi2 inactivation will be presented.

## Kinetochores (1619-1644)

1619

### Kinetochore Ultrastructure of *Drosophila* S2 Cells Previously Observed in Life

H. Maiato,[1,2] P. Hergert,[2] Y. Dong,[2] C. Rieder,[2] B. McEwen[2]; [1]Institute for Molecular and Cell Biology, Porto, Portugal, [2]Laboratory of Cell Regulation, Division of Molecular Medicine, Wadsworth Center, New York State Department of Health, Albany, NY

Cell cultures of *Drosophila melanogaster* are widely used as a model system for the molecular dissection of mitosis in animals. However, little is known about the ultrastructure of the mitotic apparatus in these cells, in particular, the kinetochore and its microtubules (MTs). To obtain a detailed ultrastructural analysis of the kinetochore and kinetochore-fiber in S2 cells we developed a correlative light and electron microscopy (EM) approach. We followed S2R+ cells, an S2 clone which adheres to glass surfaces in the absence of any coating, by DIC time-lapse light microscopy as they entered mitosis. When most chromosomes were aligned at the spindle equator the cells were fixed, circled with a diamond scribe and processed for serial section EM. Direct MT counts from 31 kinetochores derived from 3 serially sectioned metaphase cells gave an average distribution of 11 ± 2 MTs per kinetochore. These numbers contrast with the numbers of 4-6 MTs per kinetochore that are reported for *Drosophila* spermatocytes. In addition, we sought to characterize the ultrastructure of the *Drosophila* mitotic kinetochore deprived of microtubules by treating S2R+ cells with colchicine. When compared with the vertebrate kinetochore, we found striking differences in kinetochore morphology. Overall, the results of this study provide important information needed for interpreting subsequent live cell studies on *Drosophila* cell cultures, particularly those involving the introduction of fluorescence combined with RNAi.

1620

### Role of Spindle Checkpoint Protein ZW10 in Chromosome Segregation

I. M. Shapiro, V. M. Draviam, P. K. Sorger; Biology, MIT, Cambridge, MA

The spindle assembly checkpoint ensures accurate segregation of chromosomes by monitoring the formation of bipolar attachments by paired sister chromatids to kinetochore fibers. When unattached or maloriented chromatids are present, the checkpoint delays anaphase onset, increasing the time available for completion of kinetochore-microtubule binding. The checkpoint involves a group of well conserved proteins, including Mad1-3, Bub1, Bub3, and Mps1 as well as several proteins such as ZW10 (Zeste-white 10), ROD (Rough deal) and Zwilch, that are specific to metazoans and whose precise functions remain unknown. Given the high degree of conservation of Mad and Bub proteins from yeast to man, it is of considerable interest to determine the role of checkpoint proteins that are specific to higher eukaryotes. To investigate the role of ZW10 in chromosome segregation and checkpoint control we have performed RNAi-mediated depletion of ZW10 in HeLa cells and then followed them by live-cell imaging. We find that depletion of ZW10 causes checkpoint failure and errors in chromosome segregation. These errors manifest themselves during metaphase as a failure of congression and during anaphase as lagging chromatids. We find that many kinetochore fibers in ZW10-depeleted cells are unstable, and unlike normal kinetochore fibers, depolymerize in the cold. Several important kinetochore microtubule-binding proteins are absent from ZW10-depleted kinetochores, possibly explaining this instability. Ongoing studies are aimed at determining why these lesions do not arrest cell division.

1621

### CENP-A Deposition Occurs De Novo and Independently of DNA Replication Following Fertilization in C elegans

F. E. Hyndman,[1] P. S. Maddox,[1] J. Monen,[1] S. Ward,[2] K. Oegema,[1] A. Desai[1]; [1]LICR, UCSD, La Jolla, CA, [2]Molecular and Cellular Biology, University of Arizona, Tuscon, AZ

Nucleosomes in which the histone variant CENP-A replaces H3 serve as the structural foundation for kinetochore assembly and are proposed to be an epigenetic mark that propagates centromere identity. Quantitative retention of CENP-A nucleosomes during mammalian spermatogenesis, despite removal of H3 nucleosomes, suggested that this chromatin domain is transmitted through fertilization. However, a role for sperm-derived CENP-A in propagating centromere identity has not been demonstrated. We have analyzed CENP-A deposition following fertilization in *C. elegans*, an organism with holocentric chromosomes that form diffuse kinetochores. ~30 min after fertilization, sperm and oocyte chromosomes have replicated and formed CENP-A chromatin domains on opposing poleward faces. Quantitative immunoblotting revealed that *C. elegans* sperm have essentially no CENP-A (<300 copies per sperm), in contrast to ~300,000 copies per embryonic nucleus. *In vivo*, no CENP-A is detected on wild-type sperm chromosomes introduced into CENP-A depleted oocytes. Thus, CENP-A on sperm chromosomes is recruited *de novo* after fertilization. We also analyzed oocyte nuclei, which undergo meiosis after sperm entry. Surprisingly, CENP-A is removed from chromosomes after meiosis I and does not reappear until after meiosis II is complete, indicating that CENP-A deposition on oocyte chromosomes also occurs *de novo.* CENP-A deposition is replication-independent in mammalian cells. To test if the same is true in *C. elegans*, we depleted CDT1 and CDC6, two proteins essential to initiate replication. DAPI fluorescence was decreased by half and chromosomes did not have paired sister chromatids, but CENP-A incorporation, and subsequent targeting of outer kinetochore proteins, was still detected. These results indicate that CENP-A deposition following fertilization in *C. elegans* occurs *de novo* albeit independently of DNA replication. Thus CENP-A nucleosomes do not propagate an epigenetic mark through fertilization in this system.

1622

### Probing Kinetochore Assembly in *Xenopus* egg Extracts

K. J. Milks, A. F. Straight; Biochemistry, Stanford University, Stanford, CA

Kinetochores are responsible for attaching chromosomes to the mitotic spindle, monitoring proper chromosome alignment, and coupling chromosomes to spindle forces during mitosis. Kinetochore proteins can be divided into two classes: those that constitutively mark the centromere throughout the cell cycle, and those that assemble only during mitosis to form an active mitotic kinetochore. Two constitutive kinetochore proteins that are required for both interphase and mitotic kinetochore function are the histone H3 variant centromere protein A (CENP-A) and the

centromere binding protein centromere protein C (CENP-C). We are using the *Xenopus laevis* egg extract system to ask how CENP-C is recruited to centromeric chromatin during interphase and how it contributes to kinetochore assembly in mitosis. We have isolated the *X. laevis* homolog of CENP-C, which colocalizes with CENP-A at centromeres of cultured cells and in nuclei assembled in egg extracts. Immunolocalization of CENP-A in artificially-decondensed *Xenopus* sperm indicates that *Xenopus* CENP-A is maintained in chromatin throughout meiosis but that CENP-C is removed. Upon incubation of sperm in mitotic or interphase egg extract, CENP-C is loaded at the centromere. Furthermore, highly clarified egg extracts support CENP-C assembly onto sperm chromatin. We are using this *in vitro* assembly assay to explore the mechanisms of CENP-C assembly onto centromeres and to determine its role in the higher order assembly of mitotic kinetochores.

**A Myb Domain Protein Directs Assembly of CENP-A Containing Centromeric Chromatin in the *C elegans* Embryo**

P. S. Maddox, F. Hyndman, K. Oegema, A. Desai; LICR, UCSD, La Jolla, CA

Nucleosomes containing the histone H3 variant CENP-A form the structural foundation for kinetochore assembly and are proposed to act as an epigenetic mark for centromere identity. We are investigating the mechanism of CENP-A deposition in the one-cell stage *C. elegans* embryo. Depletion of CENP-A in this system results in a "kinetochore null" phenotype characterized by a severe chromosome segregation defect, inability to assemble a mechanically stable spindle, and failure to target all other kinetochore proteins to chromosomes. By re-screening embryonic lethal genes identified in genome-wide RNA interference (RNAi) screens, we have identified KNL-2, a divergent Myb domain-containing protein, as uniquely required for CeCENP-A chromatin assembly. Depletion of KNL-2 prevents CeCENP-A localization to chromosomes without affecting the amount of CeCENP-A protein. KNL-2 depleted embryos exhibit a kinetochore null phenotype and a chromosome condensation defect similar to CeCENP-A depleted embryos. KNL-2 co-localizes with CeCENP-A throughout the cell cycle and depletion of CeCENP-A disrupts KNL-2 targeting. Depletion of KNL-2 in post-embryonic divisions resulted in severe developmental defects and lethality, indicating that KNL-2 function is not restricted to the one-cell stage embryo. KNL-2 and CeCENP-A co-fractionate in nuclei prepared from embryos. Together, our results show that KNL-2 is specifically required for assembly of CeCENP-A chromatin and consequently for kinetochore assembly and chromosome segregation. We hypothesize that KNL-2 binds DNA directly via its divergent Myb domain, and acts in concert with CeCENP-A to mark centromeric regions on chromosomes and form the specialized centromeric chromatin structure required for kinetochore assembly and function.

**Investigating the Role of a CHD-Family Chromatin Remodeling Complex in the Establishment of Centromeric Chromatin Structure**

I. M. Brennan, A. F. Straight; Department of Biochemistry, Stanford University, Stanford, CA

Centromeric chromatin in all eukaryotes is marked by the incorporation of nucleosomes containing CENP-A in lieu of histone H3. Evidence from multiple organisms indicates that CENP-A-containing chromatin has both a unique higher-order structure and a pattern of covalent histone amino-terminal tail modifications distinct from surrounding heterochromatin. Though the mechanism of CENP-A loading and centromeric chromatin establishment is unknown, it is likely that chromatin remodeling complexes play a role in specification of centromeric chromatin structure. By affinity chromatography in Xenopus egg extract we have identified a CHD-family histone deacetylase and ATP-dependent chromatin remodeling complex that preferentially binds to the amino-terminal tail of CENP-A. We have investigated the role of this complex in CENP-A loading and maintenance in Drosophila and human cell lines as well as a Xenopus egg extract system. Depletion of each member of the complex by RNA interference or immunodepletion from Xenopus extract do not influence the level of CENP-A at the centromere. This result suggests that the CHD complex is not directly involved in CENP-A loading. We are currently investigating whether the CHD complex is recruited to the centromere by specific binding to CENP-A and plays a role in establishing the higher-order structure of centromeric chromatin and pericentric heterochromatin.

**Characterization of a Novel Kinetochore Protein Scm3p in *Saccharomyces cerevisiae***

M. Hou,[1] K. T. Simons,[2] C. W. Espelin,[1] S. C. Harrison,[2] P. K. Sorger[1]; [1]Biology, Massachusetts Institute of Technology, Cambridge, MA, [2]Biological Chemistry and Molecular Pharmacology and Pediatrics, Howard Hughes Medical Institute, Harvard Medical School, Boston, MA

Chromosome segregation at mitosis is crucial for maintenance of genetic integrity in eukaryotic cells. To ensure high-fidelity chromosome segregation, the accurate assembly of kinetochores and their stable attachment to microtubules are necessary. Recent studies in *Saccharomyces cerevisiae* have shown that kinetochores are complex proteinaceous structures containing at least 50 protein components. The assembly of this large structure begins with the binding of CBF3 directly to the essential CDEIII element of CEN DNA. CBF3 contains four protein subunits, Ndc10p, Cep3p, Ctf13p and Skp1p, but it has been difficult to determine the precise role of CBF3 in kinetochore formation. Despite the recent explosion in the number of known kinetochore subunits, few Ndc10p, Cep3p or Ctf13p binding proteins are known. Here we describe the characterization of a new Ndc10p binding protein Scm3p (suppressor of chromosome missegregation). Scm3p is essential for cell viability that has previously been identified as a high copy suppressor of *cse4-1*. We find that Scm3p interacts with Ndc10p *in vivo* and *in vitro* and that, in living cells, it exhibits a bilobed localization typical of core kinetochore components. By ChIP, Scm3p is specifically bound to CEN DNA and we have been able to reconstitute this interaction *in vitro* using band shift assays. Scm3p-CEN binding *in vivo* requires Ndc10p but not Ndc80p or Spc25p, suggesting that Scm3p is downstream of the CBF3 complex but upstream of Ndc80p complex. Intriguingly, Scm3p also binds to microtubules at micromolar affinities *in vitro*, via a short $NH_2$-terminal domain that is dispensible for Ndc10p binding. Thus, Scm3p may function as a microtubule-binding protein that associates directly with CBF3, a hypothesis that is currently under investigation.

1626

**Counting the Number of Ndc80 and Dam1-DASH1 Protein Complexes at Budding Yeast Kinetochores by Quantitative Fluorescence Microscopy**

A. Joglekar, K. Bloom, E. D. Salmon; Biology, U. of N. Carolina, Chapel Hill, NC

In eukaryotes, the Ndc80 and Dam1-DASH complexes of kinetochore proteins are critical for anchoring spindle microtubules to the centromeres. As in higher eukaryotes including human cells, sister chromosomes in budding yeast get aligned at the spindle equator at metaphase, and segregate to the poles in anaphase by movement generated by kinetochores attached to the plus ends of spindle microtubules. Unlike higher eukaryotic

kinetochores which have multiple attached microtubules, each kinetochore in budding yeast is persistently attached to only one microtubule. This makes budding yeast ideal for extending the structural study of the microtubule-centromere connection to the molecular level. In budding yeast, the Ndc80 complex is proposed to link centromeres to microtubule plus ends by binding to a microtubule-associated ring of Dam1-DASH subunits. To measure the number protein molecules/kinetochore, we used digital imaging and analysis methods to quantify fluorescence signal at clusters of 16 kinetochores in anaphase-telophase cells expressing GFP-fusion protein from the native promoter. As a reference, we used Cse4p-GFP. Cse4p is a modified histone at the centromere, and the number of Cse4p molecules per kinetochore is thought to be either 2 or 4. The ratio of GFP-fusion protein fluorescence to that of Cse4p-GFP at kinetochores was ~ 3.5 for Nuf2p-GFP, ~ 3.5 for Ndc80p-GFP, thus confirming the stoichiometry measured by biochemical methods. The ratio was found to be ~ 6 for Ask1p-GFP, one of 10 proteins in the Dam1-DASH complex. These results indicate that anchorage of kinetochores to microtubule plus ends for chromosome segregation involves only 7-14 Ndc80 complexes and 12-24 Dam1-DASH complexes per microtubule attachment site. The same method may be extended for counting the number of other kinetochore complexes such as Ctf19, Mtw1, and Ndc10. Supported by NIH GM24364.

**Regulation of Individual Kinetochore Microtubule Dynamics by Kinetochore Proteins in Budding Yeast**

J. F. Dorn,[1] K. Jaqaman,[1] G. S. Jelson,[2] J. D. Tytell,[2] C. Gonzalez,[2] P. K. Sorger,[2] G. Danuser[1]; [1]Cell Biology, The Scripps Research Institute, La Jolla, CA, [2]Biology, MIT, Cambridge, MA

Even in systems as simple as the budding yeast *S. cerevisiae*, the kinetochore consists of over 60 different proteins. The function of these proteins in assembly and maintenance of the kinetochore, and in cell cycle signaling is fairly well understood. However, their function in the mechano-chemical regulation of kinetochore microtubule dynamics is largely unknown, partly because mutations rarely result in strong dynamic phenotypes. We have established methods to probe the effect of kinetochore protein mutations on the dynamics of individual kinetochore microtubules, and to distinguish between phenotypes with unprecedented sensitivity. We record three-dimensional time-lapse movies of *S. cerevisiae* spindles that are fluorescently tagged at the spindle poles and at a centromere-proximal chromosomal region, and we recover microtubule length trajectories with super-resolution image analysis. Describing these trajectories with a combination of standard descriptors of microtubule dynamics and ARMA models allows us to statistically detect minute differences in kinetochore microtubule dynamics between wild type and mutant strains. For example, the temperature sensitive mutant *dam1-1* has been suggested to be unable to make strong attachments between kinetochores and microtubules. Indeed we find that in G1, in 20% of *dam1-1* cells microtubules detach from kinetochores. Our analysis is capable of distinguishing two more phenotypes among the cells with attachment, however: one half of these cells exhibits significantly perturbed regulation of microtubule growth and shrinkage, while in the other half the kinetochore seems to have completely lost the ability to regulate switches from microtubule growth to shrinkage. Such detailed readouts from a systematic screen of kinetochore proteins will allow us to elucidate the mechano-chemical role of kinetochore proteins.

1628

**The Kinetochore Ring Complex Moves Processively on Depolymerizing Microtubule Ends**

S. Westermann,[1] A. Avila-Sakar,[2] H. Wang,[2] D. G. Drubin,[1] E. Nogales,[3,1] G. Barnes[1]; [1]Molecular and Cell Biology, UC Berkeley, Berkeley, CA, [2]Lawrence Berkeley National Laboratory, Berkeley, CA, [3]Howard Hughes Medical Institute and Lawrence Berkeley National Laboratory, Berkeley, CA

The molecular mechanism by which the depolymerization of kinetochore microtubules drives the movement of chromosomes to poles during anaphase of mitosis has long remained elusive. In budding yeast the essential 10-protein Dam1 complex is the major microtubule-binding component of the kinetochore and the purified complex oligomerizes into a 50 nm ring around the microtubule. Here, we have developed a microscopy assay to directly observe the interaction of the complex with dynamic microtubules in vitro. Using live two -color fluorescence microscopy we show that Alexa labeled Dam1 ring complex moves processively at the ends of depolymerizing microtubules, where it slides for several micrometers without detaching from the lattice. The sliding mechanism is independent of the mode of microtubule disassembly as it is observed with both dilution and XMCAK induced depolymerization. While individual Dam1 rings slide effectively, a dense assembly of rings slows down or stalls microtubule depolymerization. On stable microtubules, Dam1 rings show undirected one-dimensional diffusion. To understand the structural basis for this type of microtubule based motility, we have examined electron micrographs of microtubule ends decorated with Dam1 ring complex. Image analysis of these “end-on” views reveals a 16-fold rotational symmetry of the complex with no apparent correlation to the microtubule lattice. This arrangement could allow the peeling protofilaments of depolymerizing microtubules to move the ring with a power-stroke mechanism. In conclusion we provide direct evidence that the Dam1 ring complex acts as a coupling device that can translate the force generated by microtubule depolymerization into movement along the lattice to drive chromosome segregation. The dynamic plus-end of the microtubule and the ring complex form a molecular machine that converts the chemical energy of GTP hydrolysis into mechanical work to generate directed movement independent of motor proteins.

1629

**Bir1p Links CBF3 to Passenger Proteins and Anaphase Progression**

S. Thomas, S. Hansen, A. Gillis, K. Kaplan; MCB, University of California, Davis, CA

The accurate segregation of chromosomes requires that anaphase is coordinated with the onset cytokinesis. In metazoans, kinetochore proteins called passenger proteins have been proposed to coordinate these events as they act at kinetochores and are required for inducing cytokinesis. In *Saccharomyces cerevisiae*, sequence homology suggests that Ipl1p, Sli15p and Bir1p are homologues of the metazoan passenger proteins, Aurora B, INCENP and Survivin, respectively. In addition, these proteins transit from kinetochores to interpolar microtubules in anaphase. Recent findings from our lab suggest that the inner kinetochore complex CBF3 works together with these passenger proteins to regulate the progression of anaphase and septin function necessary for proper cytokinesis. The CBF3 subunit Ndc10p interacts with Bir1p and mutations in CBF3 or BIR1 affect septins and cytokinesis. In contrast, mutations in IPL1 or SLI15 do not exhibit septin defects suggesting that these proteins regulate other aspects of anaphase. These results lead us to hypothesize that multiple passenger protein complexes form and regulate specific aspects of mitosis. To test this hypothesis, we have examined the interactions between CBF3 and passenger proteins using yeast two hybrid and *in vitro* biochemistry. Our

findings are consistent with Bir1p mediating the formation of distinct passenger complexes. Consistent with there being multiple Bir1p-passenger complexes, mutations in BIR1 compromise distinct aspects of mitosis causing aberrant chromosome segregation as well as cytokinetic defects. To further elucidate the mitotic functions of Bir1p complexes, we have created BIR1 mutants that specifically perturb its interaction with each passenger protein. This analysis will address the contribution of Bir1p complexes to both chromosome segregation and anaphase progression.

1630

**Identification of the Human Centromere Complex Proximal to the CENP-A Nucleosome**

D. R. Foltz,[1,2] B. E. Black,[1,2] A. O. Bailey,[3] J. R. Yates,[3] D. W. Cleveland[1,2]; [1]Ludwig Institute for Cancer Research, La Jolla, CA, [2]Department of Cellular and Molecular Medicine, UCSD, La Jolla, CA, [3]Department of Cell Biology, The Scripps Research Institute, La Jolla, CA

The faithful segregation of sister chromatids requires that each chromosome contain a single active centromere, the site of kinetochore assembly. The histone H3 variant CENP-A, in conjunction with the other core histones (H2A/H2B/H4), forms a centromere-specific nucleosome that plays an integral role in centromere function and may act as part of an epigenetic mark of the centromere and its associated kinetochore. To identify how the CENP-A nucleosome nucleates assembly of a functional kinetochore, an affinity purification approach has been used to purify CENP-A nucleosomes. Parallel purifications of histone H3.1 nucleosomes were also conducted in order to cull out factors also found in bulk chromatin. Several novel human centromere components were identified in each complex using mass spectrometry. Three of the factors associated with CENP-A nucleosomes, named CENP-K, CENP-L and CENP-M, were shown to be resident components of centromeres. Suppression of CENP-M by siRNA results in a mitotic phenotype that is consistent with an inability of chromosomes to make proper microtubule attachments. Subsequent affinity purifications of epitope tagged CENP-K, L, and M were conducted from stable cell lines each individually expressing one of the newly identified components. In each case purification of the tagged construct (CENP-K, L, or M) co-purified the other two proteins, demonstrating that CENP-K, L, and M exist within a common protein complex. Selective association of this complex with CENP-A nucleosomes derived from functional centromeres identifies these new centromere/kinetochore components as the most DNA proximal elements of the centromeric nucleosome.

1631

**Functional Replacement of CENP-A at the Centromere by a Chimeric Histone H3 Containing the CENP-A Targeting Domain (CATD)**

B. E. Black, L. E. T. Jansen, P. S. Maddox, J. V. Shah, D. R. Foltz, A. Desai, D. W. Cleveland; Ludwig Institute for Cancer Research, UCSD, La Jolla, CA

In humans, as well as in the overwhelming majority of all eukaryotic species, the chromosomal location of the centromere is not defined by a particular DNA sequence. Rather, all active centromeres are marked by the presence of a histone H3 variant, called CENP-A. While studying the features of CENP-A that are essential for its role in epigenetically marking and maintaining the location of the centromere we identified a portion of the histone fold domain consisting of the loop 1 and α2 helix of CENP-A that is sufficient to convert canonical H3 into a centromeric histone both in terms of its structural properties and sub-chromosomal targeting (Black *et al*., 2004, ***Nature*** 430:578-582). Here we have examined the degree to which this chimeric protein, $H3^{CATD}$, can replace CENP-A function. Using a plasmid-based sequential RNAi approach in HeLa cells, we have introduced a cocktail of selectable constructs against multiple CENP-A target sequences in order to deplete the endogenous protein. Stable expression of $H3^{CATD}$ rescues the long-term depletion of CENP-A that is lethal to control cells in colony outgrowth assays. Multiple clonal lines were isolated exhibiting both continued expression of $H3^{CATD}$ and an RNAi-directed reduction of endogenous CENP-A protein levels. These *rescued* cells have a normal cell cycle, arrest at metaphase upon treatment with spindle poison, recruit normal levels of centromere/kinetochore proteins, and undergo a normal mitotic division as observed by live cell microscopy. Subsequent inhibition of $H3^{CATD}$ expression was lethal, indicating that $H3^{CATD}$ provides an essential function when CENP-A is depleted. Thus, the major if not sole role of CENP-A is to provide a unique nucleosome structure that distinguishes the centromere from the rest of the chromosome.

1632

**Identification of Factors Involved in Centromeric Chromatin Formation**

C. M. Betts,[1] S. Erhardt,[2] B. Mellone,[2] G. Karpen,[2] A. F. Straight[1]; [1]Biochemistry, Stanford Medical School, Stanford, CA, [2]Molecular and Cellular Biology, UC Berkeley, Berkeley, CA

Identification of factors involved in centromeric chromatin formation. Accurate chromosome segregation in mitosis requires attachment of chromosomes to the microtubule spindle through the kinetochore. During mitosis, kinetochores are assembled on the specialized chromatin of the centromere. Centromeric chromatin is characterized by a core region containing nucleosomes in which Cenp-A, the centromeric histone H3 variant, replaces histone H3. The centromere is embedded in large regions of heterochromatin characterized by repressive histone modifications and the localization of the heterochromatin marker, heterochromatin protein 1 (HP1). The pathways that control the incorporation of Cenp-A into chromatin and the assembly of the centromere are unknown. In an effort to identify factors responsible for Cenp-A incorporation into chromatin and pericentric heterochromatin formation, we performed a whole-genome RNAi screen in *Drosophila melanogaster* cultured cells. *Drosophila* tissue culture cells were treated with double stranded RNAi corresponding to each gene in the *Drosophila* genome, fixed and stained for DNA, CID (the *Drosophila* Cenp-A homologue), and HP1 and then imaged using high throughput automated microscopy. We have developed computational methods to automate image segmentation and analysis; this has allowed us to take quantitative measurements at the single cell level and rapidly identify potential CID and HP1 interacting factors. We have identified three classes of genes: those that are specifically required for the localization of Cenp-A to the centromere, those that are necessary for proper localization of HP1 and those that modify both processes. This screen should allow us to comprehensively analyze the process of centromere and heterochromatin formation in eukaryotes.

1633

**Phosphorylation of Hec1/hNdc80 is Important in Ndc80 Complex Function**

S. A. Miller,[1] M. L. McCleland,[2] P. T. Stukenberg[1]; [1]Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA, [2]Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA

In mitosis, a large, proteinaceous structure called the kinetochore, assembles on centromeric heterochromatin and is responsible for the faithful

transmission of a single complement of chromosomes to each daughter cell. The kinetochores of sister chromatids must be attached to opposite spindle poles before they can be properly segregated. Improperly attached kinetochores generate an “anaphase wait” signal that halts the cell cycle until all sister chromatids are aligned on the metaphase plate with proper bipolar attachments. The Ndc80 complex has been shown to play a role in kinetochore structure, microtubule-kinetochore attachment, and spindle checkpoint signaling. Although it is involved in all of the functions of the kinetochore, the mechanism and regulation of the Ndc80 complex are poorly understood. We systematically screened kinetochore proteins for the ability to be substrates for post-translational modification and found that both Hec1/hNdc80 and xNdc80 can be phosphorylated by Aurora B in vitro. It is believed that the mitotic kinase Aurora B is essential for faithful chromosome segregation by releasing improperly attached microtubules from kinetochores. We are currently mapping the phosphorylation site(s) as well as investigating the effect of this modification on Ndc80 complex function.

1634

**Examination of the Kinetochores Microtubule Nucleation and Binding Activities**

M. J. Emanuele,[1] M. J. Kallio,[2] G. J. Gorbsky,[3] T. Stukenberg[1]; [1]Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA, [2]Turku Centre for Biotechnology, Turku, Finland, [3]Molecular, Cell and Developmental Biology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK

The vertebrate kinetochore assembles on centromeres from over 50 proteins into a structure which mediates microtubule attachment and chromosome movement during mitosis. Prior to the identification of its numerous components, the kinetochores biochemical activities with respect to microtubules were defined in classic studies from Mitchison and Kirschner (1985). These in vitro activities included the ability of kinetochores to both bind and nucleate microtubules. An important unanswered question is which kinetochore proteins mediate these activities. Using function blocking antibodies and pharmacological inhibitors we have begun to address the in vitro functions of numerous kinetochore proteins. Inhibition of the outer plate protein Ndc80 has a clear effect on the kinetochores ability to bind microtubules. This data, combined with the observed phenotypes from tissue culture cell injections, further confirms a critical role for Ndc80 in microtubule binding. In addition, antibodies raised against Zwilch, a member of the Rod Complex, have a similar effect on the kinetochores ability to bind microtubules. These results implicate the Rod complex as having a role in microtubule binding at the kinetochore. The continued utilization of this in vitro system will provide us with a better understanding of the biochemical activities of many known kinetochore proteins.

1635

**Lagging without Bub3: New Role for the Checkpoint Protein Bub3 at the Kinetochore-Microtubule Interface**

E. Logarinho, T. Resende, H. Bousbaa; Grupo de Biologia Celular e Molecular, CESPU, Instituto Superior de Ciencias da Saude-Norte, Gandra PRD, Portugal

The genomic stability of all organisms depends on the correct segregation of chromosomes during cell division. The accuracy of this process is monitored by the spindle checkpoint, a signal transduction system comprised of conserved Mad, Bub and other proteins, which act to induce a prometaphase arrest until proper bipolar attachment is achieved. Among the checkpoint proteins, Bub3 has remained the one most poorly studied. Therefore, we further investigated the functions of the human checkpoint protein Bub3 at the kinetochore-microtubule interface. We show that RNAi depletion of Bub3 causes a prometaphase delay, indicative of a checkpoint response. Interestingly, and in contrast to other Bub knockdown phenotypes, chromosomes in Bub3-depleted cells are able to congress and even organize a metaphase plate that, however, exhibits a few permanently misaligned chromosomes close to the plate. We show that kinetochore-microtubule attachments are unstable in the absence of Bub3. Also a significant fraction of Bub3-depleted cells enter anaphase with lagging chromosomes. Furthermore, we show that Bub3 is required for kinetochore localization of Mad2 and Cdc20, the checkpoint effectors that halt anaphase, and we relate it to the high number of anaphases with lagging chromosomes observed for Bub3-depleted cells. However, persistent low levels of Mad2 can also contribute to the prometaphase delay found for the Bub3 knockdown, as cells exit mitosis prematurely upon Mad2 depletion. We propose Bub3 as a core component of a kinetochore catalytic platform which directly links the establishment of proper kinetochore-microtubule attachments to the activation of the anaphase inhibitory checkpoint complex.

1636

**Structural and Functional Analysis of Human Zw10 Interacting Protein, hZwint**

L. J. Vos, G. K. T. Chan; Oncology, University of Alberta, Edmonton, AB, Canada

The human Zw10 interacting protein, hZwint, is a novel kinetochore protein originally discovered by a yeast 2-hybrid screen for interactors of Zw10 (Starr *et al*. 2000). hZw10 and hROD form a complex which recruits dynein/dynactin to the kinetochore and it is an essential component of the mitotic checkpoint (Chan *et al.* 2000). hZwint localizes to the kinetochore in prophase, prior to hZw10 localization, and as such that hZwint might be a scaffold protein to which hZw10 binds. We are examining the domain(s) that are necessary for hZwint kinetochore localization and hZw10 binding. We are using two approaches for mapping the domains of hZwint. We have created a library of 23 hZwint mutants with 5 amino acids randomly insertion. We have analyzed these mutants to determine the domain(s) that are important for hZwint kinetochore localization. Based on these results, we have further produced 17 mutants by site-directed mutagenesis. By transiently transfecting HeLa cells with these mutants in a GFP-hZwint vector, it was determined that the N-terminal region is crucial for kinetochore localization. The Zw10 interacting domain is being mapped by employing the mutants in yeast 2-hybrid, co-immunoprecipitation and fluorescence resonance energy transfer (FRET) analysis. With the structural mapping of hZwint, I am hoping to analyze its function by designing dominant negative mutants that bind kinetochores but cannot interact with Zw10.

1637

**Three-dimensional Protein Domains at Centromeres**

O. J. Marshall,[1,2] A. T. Marshall,[3] K. H. A. Choo[1,2]; [1]Chromosome Research, Murdoch Childrens Research Institute, Melbourne, Australia, [2]Department of Paediatrics, The University of Melbourne, Melbourne, Australia, [3]Department of Zoology, La Trobe University, Melbourne, Australia

Throughout all eukaryotes, the centromere is the fundamental structure that controls the correct segregation of chromosomes during cell division. Although many of the major centromere proteins are known and have been characterised via immuno-fluorescence, few have been studied in detail using immuno-electron microscopy, none have been mapped across the three-dimensional kinetochore structure, and no model has been produced that relates the extant chromatin immunoprecipitation data with the physical evidence of immuno-electron microscopy. CENP-A is a modified histone protein that replaces histone H3 in centromeric chromatin at the kinetochore. Its presence is essential for the correct loading of many other centromere proteins and thus for the formation of a functional kinetochore. Here we describe for the first time the detailed domain structure of CENP-A, defined in relation to the kinetochore and the primary constriction. Using immuno-electron microscopy a three-dimensional model of the constriction, the kinetochore and the region of chromatin bound by the protein can be constructed via serial sections. We demonstrate that CENP-A occupies a domain that stretches across the kinetochore in a narrow band, occupying only a fraction of the height and depth of the constriction. Combining this in vivo structure with the linear domain maps generated by chromatin immuno-precipitation, we suggest a new model for chromatin folding at the centromere.

1638

**Functional Analysis of hMis12-Associated Kinetochore Proteins in Human Cells**

S. L. Kline-Smith, I. M. Cheeseman, A. Desai; Ludwig Institute for Cancer Research, University of California, San Diego, La Jolla, CA

Accurate chromosome segregation relies on precisely regulated interactions between kinetochores of mitotic chromosomes and microtubules of the spindle. In previous work, we identified a network of 10 interacting kinetochore proteins conserved between C. elegans and human cells. This network includes the HEC1/Ndc80 complex, Mis12 and KNL-1. Here, we present functional analysis of three novel human kinetochore proteins, DC31, PMF1 and Q9H410, which were identified utilizing tandem affinity purification of hMis12. Like hMis12, DC31, PMF1 and Q9H410 localized to kinetochores coincident with the inner kinetochore protein CENP-A throughout mitosis. RNAi-induced depletion of DC31, PMF1 or Q9H410 suggests that these proteins are not required for kinetochore targeting of CENP-A. In addition, DC31, PMF1, Q9H410 and hMis12 exhibited inter-dependence for their kinetochore localization, suggesting that they may function as a subcomplex within the kinetochore. Knockdown of DC31, PMF1 or Q9H410 resulted in cells with severe defects in chromosome alignment, although spindle formation appeared to be normal. Many depleted cells remained in mitosis for more than 10 hours as judged by analysis of fluorescently labeled chromosomes in living cells. Despite this extended delay, chromosomes were never able to fully congress to the metaphase plate, and many cells contained abnormally positioned chromosomes located outside the region between spindle poles. Live analysis of fluorescently labeled kinetochores suggests that chromosomes in depleted cells could attach to microtubules, as kinetochore oscillations were observed. Unlike kinetochore fibers in control cells, many k-fibers in depleted cells depolymerized upon cold treatment. This instability of k-fibers is likely due to a reduction in kinetochore-localized HEC1/Ndc80, which was observed in depleted cells. These results provide evidence that DC31, PMF1 and Q9H410 function with hMis12 at the inner kinetochore and are critical for proper chromosome alignment and progression through the cell cycle in human cells.

1639

**The Role of the P97-Ufd1-Npl4 Complex in Chromosome Congression During Mitosis**

Q. Vong, Y. Zheng; Carnegie Institute, Baltimore, MD

The AAA-ATPase Cdc48/p97 and its adapters Ufd1-Npl4 (U-N) form a complex (p97-U-N) that has a well-established role in regulating interphase membrane functions. Some of the membrane functions of the p97-U-N complex have been linked to the ubiquitin and proteasome system. Recently, we showed that the p97-U-N complex also has a role in mitosis by regulating spindle disassembly in a separate pathway from the mitotic exit network. We have now further studied the function of this complex in mitosis and found that it has an earlier role in mitosis. RNAi-mediated down-regulation of Ufd1 significantly prolonged the time HeLa cells spend in prometaphase and metaphase. Time-lapse imaging revealed that many mitotic cells treated by Ufd1 siRNA have difficulty in achieving chromosome congression. Interestingly, after a delay, many cells proceeded into anaphase without chromosome congression. This led to failure in cytokinesis. Consistent with our previous finding, Ufd1 down-regulation did not block spindle assembly. However, we observed an increase in multipolar spindles in Ufd1 siRNA-treated cells as compared to control siRNA-treated cells. We are in the process of identifying the down-stream target(s) of p97-U-N that regulates chromosome congression.

**Cenp-F and Vertebrate Mitosis**

A. Salmela,[1,2] A. Varis,[3,1] M. J. Kallio[1,3]; [1]Cancer Biology and Cell Screening, VTT Medical Biotechnology, Turku, Finland, [2]Turku Graduate School of Biomedical Sciences, University of Turku, Turku, Finland, [3]Centre for Biotechnology, University of Turku, Turku, Finland

The spindle assembly checkpoint (SAC) safeguards genomic stability by preventing sister chromatid separation in presence of a misaligned or unattached chromosome. Kinetochores of chromosomes are composed of stable structural proteins and transiently associating molecules many of which are SAC molecules that promote or inhibit mitotic progression in a microtubule attachment and kinetochore tension dependent manner. We are investigating Cenp-F, a large 350 kD coiled-coil protein that transiently associates with mitotic kinetochores. The protein has been proposed to have multiple functions in cell proliferation but its mechanism of action is poorly understood. To study Cenp-F function we utilized two different techniques. First, by introducing Cenp-F siRNA into human tissue culture we demonstrate a role for the protein in chromosome alignment and SAC signalling. Most cells in a Cenp-F siRNA treated population have one or more chromosomes unaligned that causes a pseudometaphase arrest. Many of these cells however, undergo anaphase and exit M phase despite the presence of misaligned chromosomes. BubR1 is not efficiently retained at the unaligned kinetochores in Cenp-F depleted cells. In another approach, we microinjected antibodies against Cenp-F into human tissue culture cells at different phases of mitosis. The average time the anti-Cenp-F antibody injected cells spend at metaphase is significantly longer compared to controls. Moreover, in some antibody injected cells one or more chromosomes fail to congress to the cell equator. Our results support previously proposed hypothesis that the few unaligned chromosomes of Cenp-F silenced cells are not sufficient to create SAC signals to inhibit onset of anaphase. This could be due to inability to retain BubR1 at these kinetochores. However, when the SAC is hyperactivated by induction of spindle damage and the kinetochores of all chromosomes contribute to creation of the “wait anaphase” signal, the cells accumulate at mitosis.

**Hec1 Regulates Kinetochore-Microtubule Dynamics Through its N-terminal Globular Domain**

J. G. DeLuca, E. D. Salmon; Biology, UNC-Chapel Hill, Chapel Hill, NC

Chromosome movements during mitosis are dependent on forces that are generated in the kinetochore outer plate by attached microtubules. The Ndc80 complex, comprised of Ndc80 (Hec1), Nuf2, Spc24, and Spc25, is essential for kinetochore microtubule formation and metaphase chromosome alignment. To further understand the role of Hec1 in chromosome motility, we injected monoclonal antibodies to Hec1 into mitotic PtK1 cells. Epitope mapping revealed antibody binding at the N-terminal globular domain of Hec1, away from the protein regions involved in dimerization with Nuf2 and tetramerization with Spc24 and Spc25, and putatively away from kinetochore-targeting regions. In PtK1 cells, injected Hec1 antibodies localized to kinetochores, consistent with Hec1's known localization to the kinetochore outer plate. Injected cells exhibited poor chromosome alignment and underwent anaphase with unaligned chromosomes. Interestingly, all kinetochores of injected cells were able to form robust kinetochore microtubules, but there was a significant increase in attachment errors, including syntelic attachment and merotelic attachment. Live cell imaging revealed that sister kinetochores in injected cells were hyper-stretched, and no kinetochore oscillations were observed, suggesting that Hec1 plays a role in regulating microtubule dynamics at kinetochores. Using a photo-activatable GFP-Tubulin-expressing PtK1 cell line, we observed a decrease in microtubule turnover at kinetochores in injected cells. In addition, kinetochore microtubules in EB1-GFP expressing cells were unable to persistently polymerize after injection of Hec1 antibodies. Our results suggest that antibodies to the N-terminus of Hec1 block kinetochore microtubules from growing or shortening, and thereby prevent chromosome movement and error correction. These findings reveal a key role for the N-terminal globular region of Hec1 in controlling the dynamic behavior of kinetochore microtubules. Supported by NIH GM24364 to EDS and NIH GM66588 to JGD.

**Arrangement of Fibers and Microtubules in the Mammalian Kinetochore**

Y. Dong, K. Vendenbeldt, X. Meng, B. F. McEwen; Wadsworth Center, New York State Dept Health, Albany, NY

The dynamic interaction between microtubules and kinetochores during mitosis is essential for chromosome attachment to the mitotic spindle, chromosome movement, and activation of mitotic checkpoint. Recent studies have begun to define the molecular composition of the kinetochore with more than 60 molecular components identified in *S. cerevisiae*. Several homologues of these proteins have been found in vertebrates. Kinetochore proteins form at least 14 different complexes that assemble hierarchically into an inner core, a linker domain, and an outer domain. This arrangement reflects the classical structural model for the vertebrate kinetochore, which consists of an inner plate, an outer plate, and corona material. The heterotetrameric Ndc80 complex is located within the kinetochore outer plate, where it functions to organize the microtubule-kinetochore interface. Recombinant human Ndc80 complex forms an elongated shape that is 40-45 nm long and is predicted to align perpendicularly to the outer plate. In this study, we use electron tomography of $PtK_1$ cells prepared by high-pressure freezing and freeze substitution to obtain a high resolution structural map of the kinetochore outer plate. Our results show that the outer plate of the unbound Ptk1 kinetochore is composed of a network of cross-linked fibers which are roughly parallel to the outer plate surface. The average length of these fibers is close to the length of Ndc80 coiled-coil structure. This suggests that Ndc80 is oriented parallel rather than perpendicular to the outer plate surface. Upon microtubule binding, the fibrous arrangement becomes less organized and tends to form a cage-like structure around the microtubule plus ends. In addition, there are irregular attachments directly to the microtubule plus ends that likely influence microtubule dynamics. Supported by NSF grant MCB0110821 and NIH grants R01GN6627001, and P41RR01219.

**Sgt1p interacts with Hsp82p and Sti1p to Form a Chaperone Complex**

M. G. Catlett, K. B. Kaplan; Molecular and Cellular Biology, University of California, Davis, Davis, CA

Sgt1p is an essential protein found in all eukaryotes. In budding yeast, Sgt1p is required for formation of the CBF3 core kinetochore complex as well as additional roles including progression beyond G1. While the biochemical function of Sgt1p remains unknown, Sgt1p contains two domains that suggest it could be an Hsp90 co-chaperone: an N-terminal tetracopeptide repeat (TPR) and a C-terminal domain with homology to the known co-chaperone p23/Sba1p. Hsp90p co-chaperones bind to Hsp90p and affect the substrate specificity of the chaperone. Recent results from numerous organisms have shown that Sgt1p and Hsp90p interact in vivo, suggesting that Sgt1p may be a bona fide co-chaperone. However, in contrast to characterized co-chaperones, only a small percentage of Sgt1p associates with Hsp90p. To better understand how Sgt1p influences Hsp90p function, we have used recombinant proteins to reconstitute the interactions between Sgt1p, Hsp82p (one of two yeast HSP90 genes) and other co-chaperones. We find that Sgt1p binds directly to Hsp82p and that this interaction is sensitive to the nucleotide bound state of Hsp82p. Further, we find that Sgt1p can bind Hsp82p in the presence of other co-chaperones, including Sti1p (Hop in human cells). Genetic and biochemical approaches are consistent with the possibility that Sgt1p, Sti1p and Hsp82p form a functional complex. As co-chaperones often interrupt the ATPase cycle of Hsp90p, we have examined the effect of Sgt1p on the ATPase rate of purified Hsp82p and see no evidence that Sgt1p can inhibit the chaperone's ATP turn-over rate. To address how this novel chaperone complex interacts with bona fide clients, we propose to reconstitute the steps necessary to assembly the CBF3 complex from purified components.

1644

**Caspase-Independent Mitotic Apoptosis (CIMA): A Novel Type of Caspase-Independent Cell Death That Occurs during Mitosis in BUB1-Deficient Cells**

Y. NIikura, K. Kitagawa; Molecular Pharmacology, St. Jude Children's Research Hospital, Memphis, TN

The spindle checkpoint protects cells from aneuploidy by monitoring the status of the kinetochore-microtubule attachment. When cells have defects in this mitotic checkpoint pathway and in kinetochore-microtubule attachment, substantial aneuploidy is thought to result. We report here a novel type of caspase-independent apoptosis that occurs during mitosis_CIMA (caspase-independent mitotic apoptosis). Simultaneous depletion of BUB1, but not MAD2, and treatment with nocodazole (a microtubule-depolymerizing drug), paclitaxel (Taxol, a microtubule-stabilizing drug), or 17-AAG (17-allylaminogeldanamycin, an HSP90 inhibitor) induced DNA fragmentation in cells during early mitosis. The common defects caused by the microtubule inhibitors and 17-AAG are defects in kinetochore-microtubule attachment. Therefore, we conclude that CIMA occurs when the

kinetochore-microtubule attachment is altered and BUB1 function is disrupted. This novel mitotic cell death appeared to be independent of caspase activation. We found that AIF (apoptosis-inducing factor) and EndoG (endonuclease G), which are effectors of caspase-independent apoptosis, are released from mitochondria during the activation of CIMA, and that DNA fragmentation is dependent on EndoG. Our results suggest that BUB1 is a critical factor in regulating CIMA, and we propose that CIMA protects cells from aneuploidy by inducing the death of cells prone to substantial chromosome missegregation.

## Pre-College and College Science Education (1645-1676)

1645

### Understanding of Mitosis and Meiosis and Genetic Information Among Higher Secondary Students of Northeast India and the Implications in Genetics Education

A. Chattopadhyay; Centre for Science Education, North Eastern Hill University, Shillong, India

Almost hundred years after coining of the terms “genetics” and “gene” the science of genetics has become increasingly molecular particularly after the work of Watson and Crick (1953). By the end of the twentieth century, reports of animal cloning and recent completion of the Human Genome Project, as well as techniques developed for DNA fingerprinting, gene therapy and others, raised important ethical and social issues, about applications of such technologies. To understand these issues, appropriate genetics education is needed in schools. A good foundation in genetics also requires knowledge and understanding of topics such as structure and function of cells, cell division, and reproduction. Studies at the international level report poor understanding by students of genetics and genetic technologies, with widespread misconceptions at various levels. Similar studies were nearly absent in India. In this study, I examine Indian higher secondary students’ (289 students; 16-18 yrs; 3 colleges) understanding of mitosis, meiosis, genetic information related to cells using written questionnaire. It was observed that most of the students had a fragmented knowledge, incomplete and inconsistent in nature without a coherent view of the cells, chromosomes and genetic information within the cells [Chattopadhyay (2005), Cell Biology Education, 4, spring, 97 - 104]. These misconceptions were rooted in their lack of understanding of mitosis and meiosis. Only 15% - 40% students ticked the correct choice and gave a scientifically valid reason. Although preliminary in nature, the results provide cause for concern over the status of genetics education in India. The possible reasons for such misunderstanding and the probable steps to overcome such problems will be discussed in the paper.

### Community Building to Promote Careers in Biomedical Science

C. H. Evans, M. I. Klopf, A. L. French; Department of Human Science, Georgetown University, Washington, DC

We have developed a rural underserved community partner education model to stimulate interest of high school students in biomedical science by working with students, their school, and community mentors. The goals are to 1) increase engagement of individuals from rural areas in the intellectual and work life of biomedical scientists and health care professionals and 2) test the usefulness of a technologically-driven education model to higher education institutions in drawing rural communities into the intellectually and culturally rich life of institutes of higher learning. 70 high school junior and senior students and adults (52 youth and 18 adults) from the Oglala Lakota Sioux American Indian Pine Ridge Reservation in SD (20 participants), the African-American and Cajun Assumption Parish, LA community (36 participants) and Mexican-American migrant farm worker communities in Florida and Texas (14 participants) traveled to Georgetown University during 2003-5 for 3-week summer science institutes. The on-campus residential experiences featured educational skill evaluation and science classroom and hands on laboratory instruction by Georgetown University faculty, students, and invited experts, as well as career exploration activities. Continuing biomedical science education throughout the year is provided through a biological virtual laboratory that offers students innovative exercises to build qualitative and quantitative science critical thinking and analysis, and communications skills. Validating the effectiveness of this biomedical science education model for increasing individuals in the biomedical and health care related pipeline is being pursued by measuring the success of student participants in entering college and evaluating the biological virtual laboratory as a useful tool for distance interaction, learning and quantitative assessment. Supported by a NIH NCRR Science Education Partnership Award.

**The Microscope Imaging Station: Choosing Biomedically Relevant Samples for Public View**

K. R. Yu,[1] J. Ma,[2] C. Carlson[1]; [1]Life Sciences, Exploratorium, San Francisco, CA, [2]Visitor Research and Evaluation, Exploratorium, San Francisco, CA

The Exploratorium, an interactive museum of science, art, and human perception, has developed an interactive Microscope Imaging Station (MIS) for use by museum visitors. The MIS provides museum visitors with the unique opportunity to control research-grade microscopes to explore live, biomedically relevant samples. The imagery from these samples presents a source of educationally rich material. However, microscopic imagery can also serve be a significant source of visitor confusion and frustration, if not thoughtfully presented. One of the most critical choices in the development of the MIS was the presentation of live, biomedically relevant samples that were appropriate for public view. Through a series of evaluation studies with visitors and logistical evaluations in the museum laboratory, we have developed guidelines that are used to choose appropriate samples and associated educational messages. Here we discuss the conceptual hurdles involved in choosing samples, propose some criteria for the determination of appropriate educational specimens, and explore the need for a visual hook as well as personal or topical relevance when presenting biology to the museum-going public.

**Classroom Exercise: Treating Bull Sperm with Caffeinated Drinks Induces Hyperactivation**

P. C. Jones,[1] S. Suarez[2]; [1]Science, Homer High School, Homer, NY, [2]Biomedical Sciences, Cornell University, Ithaca, NY

A laboratory exercise was developed to enable students to examine the effects of caffeinated drinks on sperm motility. Caffeine induces hyperactivation in mammalian sperm by raising intracellular $Ca^{2+}$. Hyperactivation is required for fertilization, particularly sperm penetration of the oocyte zona pellucida. On a microscope slide, hyperactivated sperm swim rapidly in circles because of an asymmetrical increase in flagellar beat amplitude. High school teachers can start the lab as an introduction to mammalian reproduction. Teachers can purchase bull semen frozen in egg yolk extender and packaged in 0.5 ml plastic artificial insemination straws. Students working in pairs can thaw semen by submerging a straw in a 37C water bath for 30 sec. The straw is then emptied into 2 ml of Carnation Instant Non-Fat Milk prepared with distilled water as per instructions on the package and brought to pH 8.3 using 1 molar NaOH. The students can observe the sperm under a microscope using a 40x objective to see their linear, progressive swimming movements. Students can then add instant coffee (dissolved in milk diluent and adjusted to pH 8.3 with 1 M NaOH) to sperm at a 2:5 dilution and observe them immediately. Approximately half of the sperm will be killed by the introduction of coffee; however, some surviving sperm will exhibit hyperactivation. As a control, students can treat sperm with decaffeinated coffee. Again, half will be killed; however, the surviving sperm will not exhibit hyperactivation. The experiment can be expanded to include tea and cola drinks. This exercise can be used to stimulate student discussion about fertilization, possible effects of caffeine on their bodies, and using proper experimental controls (caffeinated *vs* decaffeinated drinks). Development of the exercise was supported by a Research Experiences for Teachers supplement to NSF grant MCB-0421855.

1649

**Influencing Science Graduate Students' Professional Identities through K-12 Partnerships**

A. K. Busch, K. D. Tanner; Biology, San Francisco State University, San Francisco, CA

With the growth of scientist-teacher collaborations, scientists are increasingly placed in K-12 classrooms with little or no formal training in science education, pedagogy, or partnership. These collaborations are often viewed as service or outreach for participating graduate student scientists and typically occur outside formal graduate school experiences. Consequently, insights into science teaching and learning may not become integrated into scientists' identities as researchers and future undergraduate instructors. In 2004, the Science Education Partnership and Assessment Laboratory (SEPAL) at San Francisco State University (SFSU) extended previous research on the impact of partnerships on scientists (Tanner, 2000; Phillips, 2002) and began examining the impact of formally integrating K-12 partnership experiences into the training of graduate students. Specifically, the SEPAL GK-12 partnership program engages SFSU Master's science students in time-intensive, one-on-one partnerships with secondary science teachers, simultaneous with a seminar course in science education and pedagogy. The research reported here examines how these scientific trainees were influenced by this formalized science education aspect of their graduate experience. Through reflective essays and pre- and post-assessment responses, graduate students reported that this experience: 1) improved their ability to communicate their thesis research, 2) significantly influenced their teaching philosophy, 3) established for them a role for scientists in K-12 education, and 4) enabled them to articulate a new professional identity as a "scientist educator." These results extend previous findings and suggest that inclusion of formal training in science education into the graduate school experience enabled these graduate students to more fully integrate their K-12 partnership experiences into their identities as developing scientists. As such, formalizing partnership experiences as part of graduate training is a promising approach to generating young scientists that consider K-20+ science education reform integral to their professional lives. [NSF #DGE0337949]

1650

**Student Models of Cell Division Measure Ongoing Conceptual Gains and Challenges**

E. M. Stone; Berkeley High School, Berkeley, CA

Scientists build models to represent and explain their ideas, test alternate hypotheses, and brainstorm solutions to problems. Research in science education tells us that that not only is building models an essential part of the practice of science, but it can also be crucial for students in learning complex concepts. A computer-based high school curriculum called "Cell Reproduction & Human Diseases" was designed in the Web-based Inquiry Science Environment (WISE, http://wise.berkeley.edu) to promote cell division learning by guiding students to create models of related human diseases. Models were analyzed at three points in the unit- early, middle and late- with rubrics that determined students' conceptual understanding of the structure and function of cellular components required for cell division, and their ability to reason about causes of diseases. The rubrics were particularly useful for measuring student drawings, which are typically difficult to analyze objectively for evidence of learning. Data obtained from scoring with these rubrics showed that students progressively integrated their knowledge of cell division from the beginning to the end of the unit. Moreover, students developed a greater understanding of the nature of science by learning to evaluate their own models and to appreciate the purpose of models in general. This study demonstrated that adaptations to the curriculum after its first year resulted in increased

learning gains in the second year of its implementation. Additionally, analysis of student data demonstrated areas for which students continue to have difficulty in conceptual understanding, which suggests changes in the curriculum for a third year of implementation. Overall, this work identifies ways in which instructors may undertake ongoing formative assessment of their curricula and introduce iterative modifications that result in improved student learning.

### A Novel Summer Program Designed to Educate and Train Students for a Career in Bioinformatics

J. Momand,[1] W. Johnston,[2] S. Sharp,[3] N. Warter-Perez,[4] B. Krilowicz[3]; [1]Chemistry and Biochemistry, California State University Los Angeles, Los Angeles, CA, [2]Biology, Pasadena City College, Pasadena, CA, [3]Biological Sciences, California State University Los Angeles, Los Angeles, CA, [4]Electrical Engineering, California State University Los Angeles, Los Angeles, CA

**Objective:** To design and implement a summer program for undergraduates and graduate students that teaches bioinformatics concepts, offers skills in professional development, and provides research opportunities in bioinformatics. **Methods:** The program, first implemented in Summer 2003, was divided into a three week didactic session followed by a seven week research internship. The didactic session addressed topics in bioinformatics, ethics, statistics, and computer programming. Professional development sessions helped students develop skills in oral presentation, milestone setting, and resume writing. Students were placed into bioinformatics research laboratories at five academic research institutions and four companies. At the end of the ten-week period students presented their research to instructors, research mentors and peers. **Results:** Combined assessments of "overall teaching ability" of seven instructors by participants (n=24) enrolled in programs of 2003 and 2004 indicated that 87-91% of participants ranked instructors "good" to "excellent" with 9-13% ranking them in the "fair" or "no opinion" category. Students' performances on culminating research presentations were ranked by principal investigators, research mentors, and peers using quantitative rubrics designed to assess specific aspects of final oral presentations. On a scale of 1 to 4, with 1 = not acceptable and 4 = excellent, mean overall student (n = 24 interns over 2 years) performance were rated 3.4 by principal investigators (n= 3-4), 3.1-3.3 by research mentors (n = 1-4), and 3.5-3.6 by peers (n= 12 for each year). **Conclusions:** Assessment data suggest that the program is offering high quality education and training. Out of 24 participants, 16 are continuing their education in a field related to bioinformatics, 4 are searching for employment, and 1 is employed outside the bioinformatics sector. The status of three participants is not known.

1652

### Total Immersion Biology: A Course That Engages First-Year Undergraduate Students in Cell Biology Research

C. A. Lindgren,[1] C. H. Sullivan,[1] D. E. Lopatto[2]; [1]Biology, Grinnell College, Grinnell, IA, [2]Psychology, Grinnell College, Grinnell, IA

To enhance the environment for collaborative student/faculty research, many departments offer a research methods course to students in their second or third year of undergraduate study. We offer such a course that emphasizes the process of science. The difference is that this course is the **first** course students take. Multiple sections of *Introduction to Biological Inquiry* are offered each semester. Each faculty member teaches a section focused on a unique biological question that is related to her or his research interests. However, all sections teach similar skills such as reading the scientific literature, defining a good question, designing experiments, learning the tools to carry out that experiment, analyzing and presenting data, and writing scientific papers. Instead of the more traditional three lecture classes and one three-hour lab per week, each section is taught in the "workshop" format where lecture, laboratory, and discussion are integrated. Students meet two or three times a week in larger blocks of time that usually total the same six hours per week. The course concludes with a poster session where students from all sections of the course present their major projects to one another. The students who continue in our curriculum to the next course in *Molecules, Cells, and Organisms* bring a variety of perspectives based on the section of *Introduction to Biological Inquiry* they took. On end of course evaluations, students indicated that they (1) had better insight into how biological knowledge was advanced, (2) were more confident in their ability to understand new scientific topics, (3) were more confident in their ability to critique scientific work and (4) improved their writing skills. Pre-test/post-test comparisons demonstrate significant improvement in the areas of factual information, data interpretation, and experimental design.

1653

### Freshman and Sophomore Research Workshops for Early Research Awareness

V. Navas,[1] M. Chaparro,[1] R. Montalvo,[1] N. Diffoot,[1] D. Ramirez,[2] R. Buxeda[1]; [1]Biology, University of Puerto Rico Mayaguez Campus, Mayaguez, PR, [2]Chemistry, University of Puerto Rico Mayaguez Campus, Mayaguez, PR

The Biology Department at the University of Puerto Rico, Mayagüez Campus, sponsored by the Howard Hughes 2000 to 2004 Undergraduate Science Education Program and the MARC and Sloan Programs, has been offering for the past four years research workshops for freshman and sophomore students. This initiative, which has had excellent outcomes, offers freshman and sophomore students from the Biology, Biotechnology and Chemistry Departments a three day cutting edge research workshop in one of the following fields: electron microscopy, molecular biology, computational biology and biochemistry. Mentoring by upper successful undergraduate MARC or Sloan students as well as discussion of undergraduate and graduate research programs and opportunities is included throughout the workshops. Participants have assessed all workshops as excellent. They consider the experience as meaningful for their academic and professional development. These workshops have motivated students into pursuing other undergraduate research opportunities, as well as make them aware of graduate studies leading to careers in biomedical science research.

### Requiring Undergraduate Research for a BS Degree in Biology: Does It Do Any Good?

H. G. Kuruvilla, A. E. Schaffner, B. E. Phipps; Science and Mathematics, Cedarville University, Cedarville, OH

Undergraduate research is a wonderful tool for helping students learn the scientific method. Research provides opportunities for students to invest of their time and skills, and become part of the scientific process. Students learn valuable critical thinking skills, as well as the value of perseverance. Many graduate and professional schools look for research experience as part of their requirements for entrance into their programs. However, left to their own devices, many students will not choose to do research as part of their undergraduate career. Several years ago, the biology faculty at Cedarville University decided to make research mandatory for the BS degree in biology, leaving it as an elective for the BA

degree. Since then, we have had several classes of majors graduate. Here we provide data which shows that students appreciate being "forced" into research, and find the experience to be an important stepping stone into further education. In addition, students who have been co-authors on publications share some of their experiences related to the publishing process.

1655

**Directional Bias of Yeast Actin in Non-directional Cloning Procedure Provides a Problem-Based Approach for the Molecular Biology Laboratory**

A. Tuan, E. Jonasson, M. W. Black; Biological Sciences, California Polytechnic State University, San Luis Obispo, CA

The utility of molecular tools in a variety of disciplines has led to the design of undergraduate laboratory courses that teach the fundamentals of lab techniques and their utility in a variety of disciplines. The Molecular Biology Laboratory course taught at Cal Poly ties a variety of separate lab procedures to a common goal: the cloning and analysis of the cDNA corresponding to the yeast actin gene (ScACT1). Although many of these techniques are standard for this type of course, the use of ScACT1 has provided us with an interesting twist that promotes a problem-based approach to provide students with a self-guided, capstone lab experience. Problem: upon transforming cells with plasmids generated from a non-directional cloning procedure, all of the white colonies examined (those expected to be recombinant) were found to carry only one of the two possible orientations of the amplified ScACT1 ($<1x10^{-9}$ probability). Response: the class is led to identify 4 possible hypotheses: (1) a bias in ligation by the “non-directional” cloning system; (2) DNA sequence in ScACT1 interferes with plasmid replication in one orientation; (3) a toxic product is produced by *E.coli* from insert in one orientation; (4) students serve as the selective agent due to the analysis of only those colonies that are white, while the other orientation is propagated in blue colonies. Student groups then design relatively simple experiments to support or reject their particular hypothesis, perform these experiments, and then report the results and conclusions to the class. Contrary to student expectations, the significant directional bias demonstrated in this cloning step was due to a combination of plasmid replication interference (prokaryotic promoter elements in ScACT) and student selection (one orientation resulted in light blue colonies).

1656

**An Interactive General Biology Laboratory Manual for Latin America Students**

J. Velez-Gavilan, V. Navas, N. Diffoot, D. Delgado; Biology Dept., University of Puerto Rico-Mayaguez Campus, Mayaguez, Puerto Rico

Personnel from the Biology Department, University of Puerto Rico, Mayagüez Campus, sponsored by Howard Hughes, has written an interactive laboratory manual in Spanish to be used by freshman students in the first part of the General Biology course. The manual consists of a CD with twelve laboratory exercises that include ethics in science, the scientific method, scientific article analyses, macromolecules, the cell and those processes that occur within the cell such as membrane transport, cellular respiration, photosynthesis and molecular activities. Exercises were modified and designed to develop in students important scientific skills which include critical thinking, investigation, team work, computer and communication skills. They also aim to expose students to modern scientific issues and technology as well as emphasize ethical values. Integration of chemistry and math to biology is also emphasized. The effectiveness of the exercises included in the manual has been assessed for the past four years through the Howard Hughes curriculum enhancement program. The interactive component of the manual allows for a text with easy and direct access to photographs, to the web, to further explanations and to complementary lectures. Because of its interactive nature, procedures are illustrated by means of digital color pictures and/ or through demonstration videos which allow for easier understanding. Also, possible experimental outcomes are presented for students to accurately compare and identify their own results. The main objective for developing this laboratory manual is to offer Latin-American students a manual in their language, in an affordable CD format, that facilitates learning and understanding by offering immediate access to available information. This laboratory manual is expected to be available in spring 2006.

1657

**Genomics Perspective Provided by Undergraduate Synthetic Biology Research Using Mathematics and Molecular Biology**

A. M. Campbell,[1] L. J. Heyer,[2] K. DeCelle,[1] T. Odle,[1] N. Cain,[2] A. T. Drysdale,[1] M. P. Gemberling,[1] O. G. Hernandez,[1] A. J. Ryan[1]; [1]Biology, Davidson College, Davidson, NC, [2]Mathematics, Davidson College, Davidson, NC

Genomics and Systems Biology present new challenges to biology education. Many of the methods are expensive and data collection too massive to be reproduced by undergraduates. These challenges present a formidable barrier to bringing genomics and systems biology into the undergraduate laboratory curriculum. A new area of investigation, called Synthetic Biology, blends the perspective and interdisciplinary nature of systems biology with molecular methods available to many undergraduates. We have joined the MIT-hosted 2005 intercollegiate Genetically Engineered Machine competition (iGEM; http://parts2.mit.edu/iGEM), along with 12 other campuses in the US, Canada, and Europe. Synthetic Biology offers every biology department the opportunity to use existing resources to conduct cutting-edge research within a typical biology curriculum. Mathematics and biology can be integrated beyond simple statistical data analysis. Using iGEM resources, undergraduates designed, built, analyzed, and characterized standardized biological parts and machines that performed complex functions such as decoding and displaying results in a human readable display. Funded by HHMI, NIH, and Davidson College. Thanks to MIT's iGEM competition.

**Center for Undergraduate Research Opportunities: Promoting Engagement of Undergraduate Students and Faculty in Research at the University of Georgia**

P. Kleiber,[1] M. Fechheimer[2]; [1]Center for Undergraduate Research Opportunities, University of Georgia, Athens, GA, [2]Department of Cellular Biology, University of Georgia, Athens, GA

The Center for Undergraduate Research Opportunities (CURO) was established to promote and coordinate the engagement of students with faculty in the research enterprise at the University of Georgia. CURO coordinates an array of programs, events, and classes that serve students and faculty from all disciplines and academic departments. Programs initiated with external funding from FIPSE, HHMI, or NSF have achieved institutionalization and stability within CURO (http://www.uga.edu/honors/curo/ ). CURO engages students at various stages of the research process with: 1) a web-based directory of research projects and mentors; 2) discipline-specific gateway seminars; 3) undergraduate research forums to promote interdisciplinary interaction of lower and upper division undergraduate students; 4) funded research apprenticeships for minority

students for the first four semesters; 5) honors research courses (one-on-one) for academic credit, including the thesis capstone; 6) funded summer research experiences which are immersive and intensive; 7) opportunities to share research findings at an annual statewide undergraduate research symposium; 8) publication opportunities in *the Journal for Undergraduate Research Opportunities* (JURO) and *The Undergraduate Science Bulletin* (TUSB); 9) support to attend a national research meeting such as National Conference for Undergraduate Research (NCUR) or a professional society such as American Society for Cell Biology (ASCB); and 10) encouragement for publication in peer reviewed journals. Evaluation methods using a combination of quantitative and qualitative assessment tools along with program specific and institutional data demonstrate that engagement of undergraduates in research has been dramatically enhanced since the creation of the CURO not only in biological and physical sciences, but also in other scholarly disciplines at the university. We hope that these efforts will be of interest to others engaged in similar work at other institutions.

**Bio 4342, Research Explorations in Genomics: An Undergraduate Investigation of the Dot Chromosomes of Drosophila**

S. C. R. Elgin,[1] E. Slawson,[1] W. Leung,[1] M. Itano,[1] E. Kellmann,[1] C. Craig,[1] C. Shaffer,[1] J. Buhler,[2] E. Mardis[3]; [1]Biology, Washington University, St. Louis, MO, [2]Computer Science & Engineering, Washington University, St. Louis, MO, [3]Genetics & GSC, Washington University, St. Louis, MO

We have developed a genomics-based undergraduate lab course through a collaboration of the Biology Dept., Computer Science & Engineering Dept., and the Genome Sequencing Center at Washington University in St. Louis. This lab course (Bio 4342, Research Explorations in Genomics; 8 hr lab/wk) brings students together in a collaborative investigation of an outstanding problem, potentially different each year. During spring '04 and'05, students sequenced and analyzed fosmid clones derived from the dot chromosome of a strain of *Drosophila virilis*. In the first half of the semester (at the GSC) students contributed to a large data set of DNA sequencing reads and used computer-based assembly, reiterative analysis and additional sequencing to generate high quality finished sequence. The second half of the semester was focused on extensive annotation and inter-species comparison with other drosophilids. While most of the same genes are found on the dot chromosomes of D. *melanogaster* and *D. virilis*, extensive rearrangement is evident. Significant differences in the pattern of interspersed repeats are observed, with the *D. melanogaster* dot showing enrichment for DNA transposons. Coupled with other evidence, the differences in the amount and type of repetitious element present suggest a basis for the earlier observation that the dot chromosome is heterochromatic in *D. melanogaster*, but euchromatic in *D. virilis*. Long-term pedagogical goals include the development of a multi-college web-based collaborative project where larger data sets can be produced and analyzed. [We thank the student participants in Bio 4342. This work is supported by a grant from HHMI to Washington University for SCRE.]

**Design of an Advanced Cell Biology Course Wherein Undergraduates Propose, Conduct, and Publish Original Research**

S. K. DebBurman; Biology, Lake Forest College, Lake Forest, IL

Undergraduate educators face significant challenges in preparing diverse graduates for a scientifically sophisticated and interdisciplinary 21st century community. Science curricula that integrate training in research with undergraduate teaching have enjoyed much funding support. The goal of providing comprehensive original research experiences within a course is a particular challenge, but was achieved in an NSF-supported advanced cell biology course described here. Students conducted individualized projects integrated to the original discovery of 86 yeast genes, which enhanced the human gene alpha-synuclein's toxicity (Willingham et al. Science 302, 1769-72, 2003). Not knowing the cellular mechanism of how these genes enhanced toxicity provided impetus for student-driven discovery. To begin with, each student picked a "my favorite gene" (MFG). Students then organized and led in-depth discussions (or lectures) to familiar each other with MFG background. Next, they uncovered current gaps in knowledge by presenting journal clubs on articles that bridged MFG with alpha-synuclein. In their quest for new knowledge, students wrote grant proposals to conduct original research based on the technologies and approaches available to them at the home institution, and they spent the first six labs mastering them. They spent rest of the semester conducting, troubleshooting, repeating experiments, and interpreting data. Instead of a traditional final exam, each wrote a primary article that was 1) published in an in-house student research journal (EUKARYON; this journal discussed as a separate poster at this meeting); and 2) submitted for publication review to national undergraduate research journals; and/or 3) presented at local or national scientific conferences. Such courses, while necessarily small and self-selective, provide successful authentic research experiences that prepare undergraduates for professional scientific careers. (Supported by NSF-MRI, NSF-CCLI & NIH R15)

1662

**EUKARYON: Design, Publication, & Governance of a Student Peer-reviewed Undergraduate Journal of Life Science Scholarship at Lake Forest College**

S. K. DebBurman, K. Brandis, T. Vaidya; Biology, Lake Forest College, Lake Forest, IL

Inquiry-based undergraduate science education is becoming an increasingly crucial component in colleges and university curricula in the United States. The opportunity for students to publish undergraduate scholarship not only increases scientific literacy and significantly, but may motivate them towards future engagement in scientific discovery. Eukaryon is a new undergraduate research journal at Lake Forest College that publishes outstanding life science scholarship conducted by its undergraduate students. The journal's goal is to celebrate the scholarship students achieved within the College's research-rich undergraduate classrooms and student-centered research labs. The inaugural issue was published in January 2005 and featured seventeen articles in diverse categories including news and views, review articles, primary articles, research proposals, book reviews, and research proposals. Seventeen students, ranging from freshmen to graduating seniors, authored these articles. The journal is governed by a 14-member undergraduate editorial board, which not only peer review articles, but also authors the journal's editorial policies, and manages the journal's web site, with the goal to sustain Eukaryon as a truly student peer-reviewed publication that maintains high scientific journalism standards. Eukaryon website: http://www.lakeforest.edu/eukaryon (Supported by NSF-CCLI)

**Undergraduate Computational Science**

G. W. Shiflet,[1] A. B. Shiflet[2]; [1]Biology, Wofford College, Spartanburg, SC, [2]Computer Science, Wofford College, Spartanburg, SC

Many significant scientific research questions are interdisciplinary in nature, involving biological and/or physical sciences, mathematics, and computer science in an area called "computational science"; and much scientific investigation now involves computing as well as theory and experiment. Despite the critical need for computational scientists, few programs and textbooks appropriate for undergraduates exist. However, computers have become fast and cheap enough; networks sophisticated enough; scientific visualization mature enough; and the Internet pervasive and friendly enough so that meaningful undergraduate computational science programs are now possible. NSF CCLI Grant 0087979 helped to fund development of an undergraduate computational science program at Wofford College, creation of extensive online educational materials (http://www.wofford.edu/ecs), and promotion of such education nationally. Biology majors have been particularly interested in Wofford's Emphasis in Computational Science (ECS), which began in 2000. ECS requirements include a B.S.; C++, Data Structures, Calculus I, Data and Visualization (C++ prerequisite), and Modeling and Simulation (calculus but no programming prerequisite); a summer internship involving computation in science. Over sixty application rich, Web-accessible course modules are used in the two computational science courses. A textbook based on these materials will appear in Spring, 2006. In the program students develop system dynamics models, such as enzyme kinetics and spread of SARS; build cellular automaton simulations, such as the immune system attack of HIV; implement algorithms, such as genomic sequence comparison; and program scientific visualizations, such as a 3D interactive animation of DNA. ECS students have had internships at such institutions as NIH, national laboratories, Greenwood Genetic Center, and various REUs. After graduation, they have obtained scientific positions in organizations, graduate, and medical schools. As Woffordâ€™s experiences demonstrate, schools can develop effective undergraduate computational science programs that provide meaningful and needed educational opportunities for students.

**Frontiers in Human Embryonic Stem Cells: Advanced Lab and Conceptual Training**

C. S. Navara,[1] C. J. Redinger,[1] H. Qidwai,[1] J. D. Mich-Basso,[1] C. R. Simerly,[1] D. A. McFarland,[1] E. S. Jacoby,[1] A. Ben-Yehudah,[1] D. L. Carlisle,[1] P. J. Sammak,[1] R. A. Pedersen,[2] G. P. Schatten[1]; [1]Pittsburgh Development Center, University of Pittsburgh, Pittsburgh, PA, [2]Department of Surgery, University of Cambridge, Cambridge, United Kingdom

To realize the biomedical potentials of human embryonic stem cells (hESCs) more cell biologists and other investigators need to master the special methods for sophisticated hESC investigations. As the field of stem cell biology is young and developing, the NIH recognized a need for instruction and sharing of successful techniques and established educational grants for hosting courses that address this need. Since 2003, the Pittsburgh Development Center of Magee Women’s Research Institute has offered the Frontiers in Human Embryonic Stem Cells (FrHESC) course using federally-approved stem cell lines. FrHESC is an intensive, comprehensive, two-week lecture and laboratory training course providing hands-on experience and interactive lab sessions instructed by some of the most prominent researchers and luminaries in the field of hESC derivation, maintenance, nuclear transfer, directed differentiation and ethics. Successful culture and maintenance of hESCs can be an arduous task, however, the FrHESC course enables participants to learn valuable techniques reducing the learning curve for these procedures. More specifically, laboratory instruction includes: 1. isolation, passaging and freezing of mouse embryonic fibroblasts (MEFs) and hESCs; 2. preparation of MEF feeder plates and feeder-free plates using Matrigel®; 3. identifying undifferentiated and differentiated hESC colony morphology; and subsequent manual and enzymatic passaging of hESCs; 4. immunocytochemistry (Oct-4, SSEA1, 3, 4 and TRA1-60, 1-81) for characterization of pluripotent hESCs using; confocal imaging and epifluorescent microscopy and 5. directed differentiation experiments that coax hESC down neuronal lineages. Additionally, lectures in the past have introduced topics covering the entire gamut of stem cell research including somatic cell nuclear transfer (SCNT); therapeutic cloning; hematopoietic-, placental-, male germline-, neural-, and muscle stem cells; patient specific SCNT hESCs for disease discoveries; and ethical and legal issues of oocyte donation and embryonic stem cell derivation. Supported by the NIH

1665

**Developing Faculty-Student Collaborations: An Improvisational Performance**

R. M. Holmes; Center for Computational Science, Boston University, Boston, MA

The idea that people learn through "performing" as learners offers a fresh perspective with which to understand and practice the teaching of biology at the college level. The performance approach to learning, applied most frequently to early childhood and elementary school aged children, posits that learning is co-created and improvisational. The language of theater, improvisation in particular, is helpful to understanding the collaborative and co-creative process between faculty and students. To professional performers, improvisation refers to a set of tools and methods used to create scenes and stories without a script. In addition to spontaneity, improvisation involves listening, accepting and working with contribution of fellow performers. The improvisational challenge in science education is to include current understandings of the field without negating novices during the performance of a scientific conversation. We introduce performance and improvisation, the metaphor and practice, in the context of a research experience in which undergraduate research assistants helped to develop instructional materials on computer-based modeling of the cell cycle. The research group met once a week for an hour and a half. Improvisation games were used throughout the research experience to build the group and highlight the experience of co-building conversation. The improvisational process of accepting each other’s contributions and building a scientific conversation continued as we developed our understanding of mathematical models. Students were introduced to two mathematical models of the cell cycle (Goldbeter, 1991; Tyson, 1991) and asked to develop with the faculty an understanding of the models and materials for teaching novices. Students developed skills analyzing experimental results and organizing data in graphs and tables. A preliminary chapter on cell cycle dynamics was produced through the group’s collective, improvisational performance as researchers. Materials used and produced by the research ensemble and student perspectives will be presented.

1666

**Mathematical Modeling of the Cell Cycle: A Research Project in Undergraduate Cellular, Developmental Biology**

R. M. Holmes; Center for Computational Science, Boston University, Boston, MA

The National Research Council Committee on Undergraduate Biology Education reported in Bio2010 that the introduction of computational methods such as modeling within undergraduate biology curricula might support the development of skills needed by future biologists. ”To understand system function in biology in a predictive and quantitative fashion, it is necessary to describe and model how the system function results from the properties of its constituent elements” (National Research Council, 2002). Some biology courses are beginning to incorporate

aspects of mathematical models into their curricula (Steen, 2005). We experimented with implementing a module on numerical modeling of the cell cycle within the Cell, Developmental Biology Course at Beloit College. The overall goal of the module was to introduce students to the methods of constructing numerical models and the dynamic aspects of the cell cycle. The module was one of four projects in the research-based course taken by twenty-two students, freshmen to seniors. Text based materials consisted of excerpts from the *Cell Cycle* by Murray and Hunt, "Cell Cycle" and "Introduction to Modeling" chapters from text by Dr. Holmes (in progress) and from a list of existing mathematical models of the cell cycle. Students were asked to modify an existing minimal model of the cell cycle (Goldbeter, 1991) by including additional factors (size, binding kinetics, regulation, etc). During the project, students reviewed literature, developed their own models using *Stella*, and reported their projects as scientific articles. We present the module format and content as well as student perceptions of properties of the cell cycle and modeling as ascertained through a questionnaire using a Likert-like Scale.

1667

**Enhancing Student Learning with Tablet Technology**

M. J. Grossel, D. Eastman; Biology, Connecticut College, New London, CT

Tablet computers are being used in two courses and our peer-mentoring program at Connecticut College with the following learning objectives: (1) to integrate bench research and informatics; (2) to improve student writing; (3) to enhance classroom learning; and (4) to encourage students to seek out individual assistance. The wireless tablet technology will engage students in Genetics and Molecular Biology courses and will support our peer-mentoring program in the following manner: (1) Existing classrooms and laboratories will become integrated technology and learning environments. (2) Students will combine bench research, information literacy and database searching. (3) In the classroom, instructors will be able to write directly on projected digital images and animations. (4) Space-saving tablets will replace traditional lab notebooks, paper and pens, by allowing students to take notes directly onto digital documents. 5) Tablets will provide a unique and exciting platform for students to work together as they revise scientific papers and lab reports and when they attend peer-mentoring sessions. The expected outcomes of this new curricular design include: improved information fluency, enhanced abilities and interest in writing and critiquing papers, and better understanding of the complex concepts and mechanisms that are fundamental to genetics and molecular biology. An HP tablet will be on display at the poster.

1668

**Teaching Structural Analysis across the Biology Curriculum with Digital Microscopy**

D. R. Howard; Biology Department, University of Wisconsin-La Crosse, La Crosse, WI

The goal of this project was to provide students opportunities to learn how to obtain and interpret structural data. To accomplish this goal, digital microscopy was incorporated into a series of guided-inquiry experiments in multiple Biology courses. The project is designed to gradually develop the students' structural data skills. Over 1,300 students a year get their first exposure to digital microscopy in the Introductory Biology labs. To provide each group of 4 students a digital microscopy station at their bench, 14 student-grade trinocular compound microscopes were equipped with consumer-grade digital cameras. In addition, two digital stereomicroscopy stations are shared. In these introductory labs, students capture and label digital images in order to construct their own taxonomic keys and to analyze and present data from osmosis experiments and from genetics experiments. In the upper level Cell Biology course, 180 students use similar student-grade imaging stations to conduct histochemical investigations into the distribution of alkaline phosphatase in earthworms. In addition, Cell Biology students use two research-grade fluorescence microscopes equipped with digital cameras to analyze and present the results of immunofluorescence experiments. In the elective Microscopy course, students perform independent research projects with this equipment. In the upper level courses, students engage in more in depth image analysis and processing. Results from student and faculty surveys and external review indicate that the program is successful. Over 85% of introductory students report their imaging skills and ability to interpret structural data both improve. Over 90% of Cell Biology students indicate that digital microscopy improves both their ability to analyze data and their understanding of their results. Overall, digital microscopy allowed numerous inquiry exercises to reach their full potential for student learning. The program was supported by an NSF CCLI grant (# DUE-0127622).

**An Undergraduate Science Education and Research Program in Computational Molecular Biology and Bioinformatics**

C. A. Hutton, R. P. Donaldson; Biology, George Washington University, Washington, DC

The Howard Hughes Medical Institute (HHMI) Undergraduate Science Education Program at George Washington University aims to promote undergraduate research and scholarship in Computational Molecular Biology and Bioinformatics (CMBB). Faculty and curricular development, facilities and equipment, training workshops and research opportunities facilitate interdisciplinary learning. The program's goal is to expose students to the rapidly expanding fields of CMBB study and to engage them in professional biomedical research. The program has done this by developing new courses (e.g. Bioinformatics; Biology of Proteins for freshmen) and interdisciplinary teaching modules for preexisting courses, engaging faculty in cross-disciplinary teaching, establishing scientific communication between departments, and training undergraduates in research through a summer workshop and laboratory experience. The program has altered the dynamics of scientific research at GWU: students trained in Biology work for Medical School Biochemists, Computer Scientists work for Biologists, members of the Physics and Biological Sciences departments work jointly. People from Statistics, Genetics, Molecular Biology, Microbiology and Tropical Medicine, Pharmacology, and Chemistry are also involved in the program. Importantly, it has created a cohesive community of undergraduate researchers. Crucial components of the student research program are a three week training workshop in the summer, eight weeks of research, three presentations, and opportunities to continue projects during the academic year. Students have worked in labs across the Washington, DC area: at GWU, GWU Medical School, Children's National Medical Center, National Institutes of Health, and The Institute for Genomic Research (TIGR). Of the 57 students who have participated in the summer workshop and laboratory experience, most have continued in the sciences, actively participating in research or moving on to medical school, public health, or graduate school.

1670

**Impact of Interactive Engagement on Student Learning in a Large, Advanced, Majors Biology Class**

J. K. Knight, W. B. Wood; MCD Biology, Univ. of Colorado, Boulder, Boulder, CO

We have carried out an experiment to determine whether student learning gains in a large, traditionally taught, upper-division lecture course in developmental biology, required for MCDB majors, could be increased by changing to a more interactive classroom format. In two successive semesters, we presented the same course syllabus with the same instructors using different teaching styles. In fall 2003, we used the traditional lecture format. In spring 2004, we lectured less and added classroom activities requiring student participation and cooperative problem solving, including frequent in-class assessment of understanding. We used performance on the same pre- and post-tests and on similar homework problems to estimate and compare student learning gains between the two semesters. Our results indicated significantly higher (~30%) learning gains and better conceptual understanding among students in the interactive course. To assess reproducibility of these effects, we repeated the interactive course in spring 2005 and obtained similar results. B students registered the largest increases in learning gains between the two types of classes. Student attitudes toward the interactive style of instruction were mixed, probably partly because the students were primarily seniors whose previous large classes in the major were taught as traditional lecture courses. Our findings parallel results of similar teaching-style comparisons made in other disciplines. On the basis of this evidence, we propose a general model for teaching of large biology courses that incorporates interactive engagement and cooperative work in place of some lecturing, while retaining course content by demanding greater student responsibility for learning outside of class.

1671

**Prototype Textbook for Teaching Cancer Biology to Non-science Majors**

P. K. Hanson; Biology, Birmingham-Southern College, Birmingham, AL

Education research has documented several factors that hinder learning in introductory science courses, including excessive use of jargon, failure to relate to other disciplines, emphasis on content rather than process, lack of a unifying concept, and irrelevance to life outside the classroom [1-3]. Thematic courses help overcome many of these problems by providing a central topic (cancer, AIDS, the physics of music, etc.) that is interdisciplinary and relevant to students' development into educated, proactive citizens, one of the central goals of a liberal education [4]. Despite these advantages, the resources available for thematic courses are scattered at best, and at worst they are out of date or incorrect. To overcome this problem for non-majors courses in cancer biology, I have developed a prototype textbook that uses an interdisciplinary, evidence-based approach to acculturate students to the process of science while teaching them about the origins, diagnosis, treatment, and prevention of cancer. This interdisciplinary text explores statistics (what does cancer "risk" really mean?), physics (the nature of the electromagnetic spectrum and its role in causing, detecting, and treating cancer), as well as the ethical, legal, and social implications of the disease. Preliminary student feedback indicates the textbook helps students understand the process of science by encouraging them to critically evaluate evidence and arrive at educated conclusions. 1. 1672

**The Nature of Life: An Orientation Course That Introduces Freshmen to the Disciplines of Biology, Builds Community, and Teaches Strategies for Success in College**

R. Wright, J. S. Anderson, D. Biesboer, S. Cotner, S. Gilbert; College of Biological Sciences, University of Minnesota, Minneapolis, MN

The University of Minnesota aims to increase the retention and graduation rates of entering freshmen. To help accomplish this goal, the College of Biological Sciences has developed a one-credit orientation course called "The Nature of Life" that is required for all of its incoming freshmen, a class of ~350 students. The Nature of Life program introduces students to the breadth of biological disciplines, acquaints them with college and university resources, and helps them become integrated into a community of learners. The program begins with a four-day experience at the Itasca Biological Station and Laboratories located at the headwaters of the Mississippi River. During this time, students participate in three different interactive learning modules that focus on topics ranging from bioethics and neurobiology to aquatic ecosystems and spatial modeling. Additional programming includes plenary lectures and discussions about career planning, time management, research involvement, campus resources, and University of Minnesota traditions. A college-level exam is given, graded, and returned to students on the last evening of the program, followed by a discussion of strategies for more effective learning. To receive credit for the course, students must also prepare three reflective essays, attend events on campus, and participate in discussions of articles from a popular science magazine. First semester freshmen who participated in the Nature of Life program have higher overall GPAs and fewer failing grades than those of previous years. In addition, one year retention in the college increased from 66% to 81%. To our knowledge, this program is unique among research universities in the United States and provides a model for supporting a successful transition of students from high school into the academic challenges of the university.

1673

**Teaching the Cognitive Elements in Scientific Reasoning to Students of Cell Biology**

W. S. Bradshaw,[1] S. Reeve,[1] J. Bell,[2] R. Sudweeks[3]; [1]Microbiology and Molecular Biology, Brigham Young University, Provo, UT, [2]Physiology and Developmental Biology, Brigham Young University, Provo, UT, [3]Educational Psychology and Technology, Brigham Young University, Provo, UT

The objectives of a course in cell biology course can well include an explicit effort to promote the acquisition of scientific thinking skills. Our specific focus is the development of the ability to draw conclusions from experimental data, particularly those that support the most fundamental conceptual principles in the field. This skill is assessed by the ability of students to write sentences that demonstrate their ability to interpret figures and tables and answer the questions that investigators have posed through the use of specific experimental protocols. We believe this ability is not intuitive for most people, and is rarely required in high school or undergraduate courses. We report here experimental attempts in the classroom to identity those separate components of analytical thinking that are practiced in cell biology. The existence of these variables has been demonstrated through the use of statistical methods such as generalizability analysis and the occurrence of unique patterns in exam score distributions. Problems have been constructed that distinguish the need for background conceptual knowledge from those that don't because the data are self evident for the person possessing "figure literacy." Other problems reveal some of the conditions under which the student is able to exhibit transfer, the ability

to apply prior understanding of principles in an unfamiliar setting. The results of surveys of students' affective response to this kind of problem solving also suggest separable attributes of the thinking process. We conclude by reporting attempts to design pedagogical strategies that promote improvement in these various aspects of scientific reasoning.

1674

**Rethinking Exams and Letter Grades: How Much Can Teachers Delegate to Students?**

W. S. Bradshaw,[1] J. Bell[2]; [1]Microbiology and Molecular Biology, Brigham Young University, Provo, UT, [2]Physiology and Developmental Biology, Brigham Young University, Provo, UT

Modification in the design of a cell biology course have been made in order to promote metaconitive assessment and provide formative feedback. Traditional midterm exams were replaced by weekly formative assessment problems, solved under exam-like conditions, which were accompanied by extensive self-, peer-, and instructor-review. The routes to final letter grades were defined by demonstrated competence with tasks at various levesl of analytical complexity. These include comprehension of conceptual models and biological mechanisms, and solving problems requiring the interpretation of experimental data. A mechanism was provided by which students could evealuated their cumulative performance , and then propose and negotiate a letter grade. We report the positive impact of this design on measures of both student performance and affect.

1675

**An Inquiry-, Experience(and Exercise)-, and Observation-Based Understanding of Integration of Cell and Human Biological Systems for Integration of Cell Biology and Health Education**

Y. Atomi, S. Matsuo, T. Sakurai; Dept Life Scis, Univ Tokyo, Tokyo, Japan

Paradoxically a progress of cell and molecular biology is promotion to increasing of life-style-relating diseases in recent years. Understanding of own cell (life) system working his/her body may contribute to cell biology education as well as health education. For undergraduate students we have supplied Sport Science Course before five years ago. In this course, students learns self system through dynamicity at different striatum of self-individuals, functional tissues in mammalian, and cells in mammalian tissues and cultured cells on dishes. Introductions of self-recognition, exercise physiology for self body in early stages of the course are effective for extracting motivation of learning and understanding self biological system of the body. Successful orders of understanding are 1) Integrative brain system and disagreement of his/her intension and the output, 2) Supporting system of endurance running from hear rate (linear) and respiratory (non-linear phenomena) responses to gravity (posture) and dynamic/static exercises, 3) Observations of mammalian tissues from cellular basis using fluorescent dyes, and 4) Beating cultured heart cells and muscle differentiation process from myoblasts to myotube, and neuronal cells, which constituting a use-dependent brain integrating system of human body and mind educating facing oneself. Especially beating heart cells and a process of muscle differentiation are appropriate for understanding autonomous, self-propagating chemical system constituted by fibrous protein cytoskeleton and motor system developing tension from cell to human body. A principle of a use dependency in brain and muscle function at cellular level is educable hypothesis for self-oriented health education.

1676

***The God Gene* in the Classroom: An Analysis of VMAT2 Polymorphisms in a Non-majors Undergraduate Laboratory Class**

L. A. Silveira; Biology Department, University of Redlands, Redlands, CA

In his book *The God Gene* (Doubleday, 2004), Dean Hamer describes an A/C polymorphism in the human VMAT2 gene that correlates weakly with self-transcendence scores on a psychological test. VMAT2 encodes a monoamine transporter that packages neurotransmitters into vesicles in the brain. Hamer proposes that variations in this gene and others render one more or less open to spiritual experiences. In an interdisciplinary undergraduate course on biotechnology we used *The God Gene* as a springboard for discussing concepts in genetics and biotechnology. In the laboratory, we replicated Hamer's study on a smaller scale. The students, mostly sophomores majoring outside the sciences, isolated DNA from their cheek cells, used PCR to amplify a region of VMAT2, purified the amplified DNA, sent it to a facility for sequencing, and analyzed the sequence at the sites of three polymorphisms. We compiled the data, then the students conducted a statistical test to see if any of the polymorphisms correlated significantly with self-transcendence or other aspects of personality measured by the psychological test. In the classroom, we discussed the Central Dogma, protein function, mutation, basic Mendelian genetics, simple and complex traits, neuron function, experimental design, and peer review, as well as each of the laboratory techniques. Pre- and post-tests assessed student learning and attitudes. Students embraced the project enthusiastically and gained in understanding of the core concepts. By the end of the project students were able to choose a complex trait and, in a final paper, make a case for or against a genetic contribution to that trait.

## Actin-Associated Proteins III (1677-1697)

1677

**The Tobacco LIM Protein NtWLIM1 Stabilises the Actin Cytoskeleton against Depolymerisation by Latrunculin B**

C. Hoffmann, C. Thomas, A. A. Steinmetz; Plant Molecular Biology, CRP-Sante, Luxembourg, Luxembourg

NtWLIM1 is one of six LIM domain proteins identified in tobacco. Transcripts of the gene have been detected in all organs of the tobacco plant, but not in pollen grains and cell suspension cultures. Initial attempts to express the protein in fusion with GFP and under the control of the cauliflower mosaic virus 35S promoter failed to generate transgenic cell lines as well as tobacco plants, suggesting that an overproduction of the protein interferes with an essential cellular function. Therefore, in order to study the subcellular localisation of the protein, we have placed the fusion construct under the control of an inducible promoter in the plant transformation vector pTA7002 (Aoyama and Chua, 1997). The recombinant plasmid was then introduced into tobacco BY2 cells using Agrobacterium-mediated transformation, and recombinant cell lines were selected on appropriate medium. We observed that NtWLIM1 exhibits a dual nuclear and cytoplasmic distribution. In the cytoplasm it was predominantly associated with a filamentous network identified as the actin cytoskeleton by co-labeling experiments as well as by treatment of the cells with latrunculin B, a drug that specifically disrupts actin filament assembly. Importantly, we noticed that the ratio of actin-associated NtWLIM1 relative to the unbound protein varied with the culture conditions: for instance, a reduction of cell oxygenation significantly enhanced

the binding of NtWLIM1 to microfilaments. In addition, when these cells were treated with latrunculin B and subsequently analysed at different times after addition of the drug, the actin cytoskeleton was still clearly visible after 40 minutes while in control cells not expressing the protein the filamentous structures had completely disappeared. These data indicate that binding of the NtWLIM1 protein to the actin cytoskeleton stabilizes the latter against depolymerisation by latrunculin B.

1678

**Characterization of Role of LIM and SH3 Protein-1 (Lasp-1) in Epidermal Growth Factor (EGF) Endocytosis and Macropinocytosis**

T. E. Rajapaksa,[1] C. S. Chew,[2] C. T. Okamoto[1]; [1]Department of Pharmaceutical Sciences, University of Southern California, Los Angeles, CA, [2]Institute of Molecular Medicine and Genetics, Medical College of Georgia, Augusta, GA

Lasp-1 is a ~40 kDa multidomain protein that is overexpressed in several breast cancer cell lines and normally expressed at relatively high concentrations in a select number of secretory epithelial cells and in certain brain cells. Lasp-1 co-localizes with F-actin and the endocytosis-regulating protein, dynamin, in several cell types, particularly in regions of active remodeling of the plasma membrane, such as filopodia and lamellipodia. In this study, we sought to determine if lasp-1 plays a role in regulating receptor-mediated endocytosis by assaying EGF uptake in HeLa cells transfected with wild type lasp-1 or with wild-type lasp-1 fused to enhanced Green Fluorescence Protein tagged (Lasp-eGFP). Under both transfection conditions, there was an increase in punctate EGF-containing structures compared to those present in untrasfected and mock transfected cells. These structures were surrounded by a "coat" of Lasp-1 staining. In addition, lasp-1 transfection was correlated with the appearance of large (~3-5µm diameter) EGF-containing structures that were morphologically similar to macropinosomes. This observation led us to investigation of possible role of lasp-1 in regulating macropinocytosis. TRITC-dextran uptake was analyzed with or without EGF stimulation in untransfected and mock transfected HeLa cells as well as in cells transfected with different lasp-1 constructs. Again, cells transfected with wild-type lasp-1 showed increased formation of macropinosomes compared to untransfected and mock transfected cells. These results support a role for lasp-1 in the regulation of macropinocytosis in HeLa cells.

**Chromosomal Assignment of Lasp1 and Lasp2 Genes and Organization of the Lasp2 Gene in Chicken**

A. G. Terasaki,[1] H. Suzuki,[1] J. Ando,[2] Y. Matsuda,[2] K. Ohashi[1]; [1]Chiba University, Chiba, Japan, [2]Hokkaido University, Sapporo, Japan

Lasp-1 and lasp-2 are actin-binding proteins that contain a LIM domain, two nebulin repeats and an SH3 domain with significant identity. We determined the chromosomal locations of the LASP1 and LASP2 genes in chicken by fluorescence in situ hybridization. The LASP1 gene was localized to a pair of microchromosomes and the LASP2 gene was localized to chromosome 2p3.1, indicating that the chromosomal locations of the LASP1 and LASP2 genes are highly conserved between chicken and human. The comparison of genomic and cDNA sequences of chicken lasp-2 and nebulette, a nebulin-related protein in muscle, suggested that both the corresponding mRNAs shared exons in the same manner as their human homologues. When compared with the domain structure of nebulette, another nebulin repeat was predicted for lasp-2, and all the nebulin repeats of lasp-2 were better conserved than those in nebulette. We also found the exon boundaries in nebulin repeats of lasp-2 were similar to those of other nebulin-related proteins.

**LIM Domain Proteins from Arabidopsis thaliana**

C. Thomas, M. Dieterle, C. Hoffmann, A. Steinmetz; Plant Molecular Biology, CRP-Sante, Luxembourg, Luxembourg

The Arabidopsis genome encodes six CRP-related LIM domain proteins three of which are specifically and abundantly expressed in mature pollen (AtPLIM1, AtPLIM2 and AtPLIM3), while the other three (AtWLIM1, AtWLIM2 and AtWLIM3) are expressed in the vegetative tissues. We are investigating the function of AtWLIM1 (At1g10200) in various tissues of the Arabidopsis plant. Microarray data have shown that of the three WLIM genes this is the most abundantly expressed in Arabidopsis (Zimmermann et al., Plant Physiol. 136:2621-2632, 2004; https://www.genevestigator.ethz.ch/). We have analysed the subcellular localisation of the protein following inducible expression of the GFP-fusion protein in transgenic Arabidopsis seedlings. Laser scanning confocal microscopy observations showed that the fusion protein associates with filamentous structures in several cell types. Following incubation of the seedlings with Latrunculin B the cortical cytoskeletal structures disappeared while the more internal structures appeared to be more resistant. This sensibility of the LIM-GFP-labeled cables to Lat B identified these structures as actin filaments. Interestingly also, while in root hairs the cytoskeletal organisation was identical to that observed for fimbrin-GFP-expressing cells, in another root cell type marked differences in cytoskeletal structure were observed : most notably, the AtWLIM1-GFP expressing cells showed thick, more randomly organized actin cables, whereas in fimbrin-GFP-expressing cells the cables were much thinner and longitudinally oriented. These data suggest that plant LIM proteins represent new actin cytoskeleton organisers that can stabilize the actin cytoskeleton network.

**Coronin Functionally Interacts With Cofilin And Arp2/3 Complex To Regulate Actin Dynamics**

M. Gandhi, H. I. Balcer, B. Goode; Rosentiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA

Coronins are a conserved family of actin-associated proteins that contain an N-terminal WD-repeat region and a C-terminal coiled-coil (CC) domain. The WD-repeat region of yeast coronin (Crn1) mediates high affinity binding interactions with F-actin and a modest ability to accelerate actin filament assembly in vitro by an unknown mechanism (Goode et al., 1999). In contrast, the CC domain of Crn1 is required for homo-oligomerization, bundling of actin filaments, and direct spatial inhibition of Arp2/3 complex (thought to promote filament branching) (Humphries et al., 2002). Here, we report a novel functional interaction that provides mechanistic insights into how coronin regulates actin dynamics in cells. Through its WD-repeat-containing region, coronin synergizes with cofilin biochemically and genetically to sever actin filaments and accelerate actin turnover in vivo. The new activity we describe for coronin synergizing with cofilin explains the ability of Crn1 to promote actin assembly in vitro. Further, it is consistent with genetic interactions between crn1 and cof1-22 and act1-159. Using a charged-to-alanine mutagenesis approach, we are now mapping the actin-binding site(s) on the WD-repeat region of coronin. We have also dissected the CC domain and identified a single residue that when mutated suppresses the lethality caused by CRN1 overexpression. Thus, coronin regulates actin dynamics by two distinct yet

possibly integrated activities, functional synergy with cofilin in promoting filament turnover and spatial regulation of Arp2/3 complex activity.

**Effect of Yeast Arp2/3 Complex on Muscle/Yeast Hybrid Actins**

P. A. Rubenstein, K. Wen, M. McKane; Biochemistry, University of Iowa College of Medicine, Iowa City, IA

Arp2/3, in combination with an activating protein such as N-WASP, creates filament branches leading to enhanced rates of actin polymerization. We recently demonstrated that yeast Arp2/3 (yArp2/3) alone efficiently facilitates polymerization and branching of yeast actin, although with muscle actin, an activating factor is required. Conversely, bovine Arp2/3 requires an activating factor to affect both yeast and muscle actins. To investigate the molecular basis for the difference in activity of yArp2/3 toward yeast and muscle actins, we constructed yeast strains expressing hybrid muscle/yeast actins as their only actins. One hybrid (sub1) has all 18 of the muscle specific residues in subdomain 1 except that the muscle 4-acidic residue N-terminal fragment contains only 3 acidic residues. The second hybrid, (sub1,2) contains in addition the 3 subdomain 2 muscle specific substitutions. Both strains exhibit a mildy decreased maximum cell density in complete medium and die at 37$^{o}$. Both strains grow on glycerol as sole carbon source indicating normal mitochondrial function. By phalloidin staining, both strains appear to have lost actin filaments, and patches are depolarized. Abnormal actin assemblies are seen in both strains but appear more prevalent in the sub1,2 cells. In the presence of excess ATP, both purified hybrid actins polymerize relatively like WT actin. In the absence of excess ATP, unlike WT actin, both actins begin to polymerize and then depolymerize suggesting a greatly increased critical concentration for ADP-actin. yArp2/3 alone will not facilitate polymerization of sub1 actin but will in the presence of N-WASP VCA. With sub1,2 actin, neither yArp2/3 alone nor with the VCA fragment will facilitate actin polymerization. These results show that differences in subdomain 1 and 2 surface residues alone are insufficient to explain the difference between the action of yArp2/3 on yeast vs. muscle actins.

**Structure of the Arp2/3 Complex Branch on F-actin**

D. Sept, A. R. Rammohan; Biomedical Engineering, Washington University, St. Louis, MO

The arp2/3 complex is a central player in the dendritic nucleation model since it branches off of exisitng actin filaments and nucleates the growth of new filaments There has been little information about the molecular level interactions between the arp2/3 complex and F-actin but the key proteins in the arp2/3 complex have been identified as p20 and p34. Through detailed computational studies using a combination of molecular dynamics and molecular docking simulations, we have developed a model for the arp2/3 complex branch structure. Indeed we find the prime contacts between the complex and F-actin are via p20 and p34 with p16 making additional interactions. Our model is in excellent agreement with parallel mutagenesis studies and provides some hints about the activation pathway.

**Unravelling the Multiple Levels of SCAR/WAVE Regulation**

A. Y. Pollitt, R. H. Insall; School of Biosciences, University of Birmingham, Birmingham, United Kingdom

Cells move by protruding and retracting pseudopods, which are principally made of branched actin filaments. These networks are formed by the activity of the Arp2/3 complex. SCAR/WAVE proteins are important activators of the Arp2/3 complex. SCAR/WAVE has recently been shown to form a macromolecular complex with four other proteins: PIR121, Nap1, Abi2 and HSPC300. There is still much controversy about the mechanism of SCAR/WAVE regulation. We have therefore generated gene knockouts of individual SCAR complex members in *Dictyostelium discoideum* to investigate their roles in the function and regulation of SCAR *in vivo.* Unexpectedly they all produce distinct phenotypes: • PIR121 null cells display a complex, dominant active SCAR phenotype • Nap1 null cells are more severely affected than SCAR null cells and possess an adhesion defect not seen in other mutants. • HSPC300 null cells are comparable to SCAR null cells. • Abi null cells exhibit a cytokinesis defect not seen in other mutants. This implies that the pathways that regulate SCAR/WAVE are more complex than previously thought. Additionally some complex members, in particular Nap1, form part of additional pathways independent of SCAR/WAVE. We are investigating the pathways behind each complex member and their relationships to SCAR/WAVE regulation. We have also demonstrated that SCAR/WAVE is phosphorylated in multiple positions providing a further important level of regulation.

1685

**Loss of Scar1 in Mouse Embryonic Fibroblasts Does Not Detectably Affect the Actin Cytoskeleton**

J. A. Legg; Biosciences, Birmingham University, Birmingham, United Kingdom

Scar1, a member of the Wiskott-Aldrich syndrome protein family, has been identified as an activator of the Arp2/3 complex, leading to the formation of new actin filaments. The aim of this study was to determine the importance of Scar1 in the formation of actin structures, such as filopodia, lamellipodia and dorsal ruffles. Here, we report a comparative analysis of actin structure formation when comparing wild-type and Scar1 knock out primary mouse embryonic fibroblasts. In cell spreading assays on fibronectin and laminin substrates, both the wild-type and Scar1 null cells spread at the same rates and produced similar actin protrusions. The motility of the cells was also comparable, as determined by using wound-healing assays. Using platelet derived growth factor to stimulate the formation of circular dorsal ruffles, both the wild-type and Scar1 knock out primary cells peaked in dorsal ruffle formation after 5 minutes and the same percentage of cells responded to growth factor stimulation at each time point. The ability of fibroblasts to produce multiple dorsal ruffles per cell was also not impaired by the loss of Scar1. When these primary cells were compared to immortalized wild-type and Scar1 null mouse embryonic fibroblasts cell lines, although the immortalized cells displayed a hypersensitivity to platelet derived growth factor stimulation, neither set of cells displayed a phenotype in dorsal ruffle formation. Taken together, these data suggest that there is a redundancy amongst the Scar protein family and that Scar1 is not essential for the formation of dorsal ruffles or lamellipodia in fibroblasts.

1686

**Calcineurin Dephosphorylates the C-Terminal Region of Filamin in an Important Regulatory Site: A Possible Mechanism for Filamin Mobilization and Cell Signalling**

E. Garcia, D. J. Jay; Cardiovascular Biomedicine, National Institute of Cardiology, Tlalpan, Mexico

Calcineurin is a calcium/calmodulin-dependent threonine/serine protein phosphatase which is required for the dephosphorylation and subsequent translocation of nuclear factor of activated T cells (NFAT) proteins from the cytoplasm to the nucleus in most immune system cells. Inactivation of calcineurin by cyclosporin A, however, can also alter a spectrum of other cellular functions in cells outside the immune system. The results of the present study indicate that a purified C-terminal recombinant region of the cytoskeletal protein filamin A is a suitable substrate for calcineurin in vitro. Furthermore, 1 μ M cyclosporin A reduced the dephosphorylation of the C-terminal recombinant fragment in 293FT cells. Site directed mutagenesis analysis showed that the dephosphorylation steps occurred in serine 2152 which was previously shown to provide resistance to calpain cleavage when endogenous PKA is activated. In contrast, phosphorylation of Ser2152 was recently reported to be necessary for membrane dynamic changes. In this regard, we report that cyclosporin A protects in a doses-dependent manner native filamin in platelets from calpain degradation. The results presented here could be combined with the available information in a single model, assuming that some of the peptide fragments released by calcineurin-regulated calpain action could participate as "signaling integrator proteolytic peptides" (SIPP) mediating actions in downstream pathways, with implications to other cellular routs like insulin signaling, androgen receptor translocation or immune response, which may help to explain the controversies reported on the role of filamin phosphorylation in actin dynamics. The possibility that other cytoskeleton-associated proteins like tau could function in a similar fashion is discussed.

1687

**Evolution of Specificity in Cytoskeletal Remodeling by Diverging the Activation Domains of MIM and ABBA**

J. Jin, R. Gonzalez-Quevedo, B. Strong, J. Hui, A. E. Oro; Program in Epithelial Biology, Stanford University, Stanford, CA

Remodeling of the actin cytoskeleton drives the migration, invasion and proliferation of epithelia. A consortium of modular actin-binding, polymerization, and bundling proteins coordinate development and tumor invasion, but how specific spatial rearrangments occur in response to global and local patterning signals remains poorly understood. We have previously identified the inducible actin bundling protein Missing in Metastasis (MIM), whose levels are controlled by the morphogen Sonic hedgehog. MIM activity at the membrane is controlled by its activation domain, sequences distinct from the actin bundling domain, binding to the cytoplasmic tail of Receptor Protein Tyrosine Pshosphatase (RPTP) delta. Here we show how these modular regulatory proteins evolve by examining the function of ABBA, a closely related protein that shares with MIM 95% identity in the IMD actin bundling domain and 55% identity in the activation domain. Both proteins alter the actin cytoskeleton by cross-linking individual actin filaments to form thick bundlings thus promoting cell adhesion. The IMD domains appear interchangeable, as they readily form heterodimers. In contrast to MIM, levels of ABBA RNA are not responsive to Shh signaling, but instead appear to be more uniformly distributed in the tissues. Moreover, MIM and ABBA have distinct activation domains that respond to different membrane signals. MIM binds and relocalizes RPTPdelta to the plasma membrane while ABBA responds to a non-RPTPdelta protein. Chimeric protein analysis demonstrates that the MIM activation domain confers the specificity to interact with and relocate RPTP delta. Our data show how small alterations in the activation domain can confer new cytoskeletal re modeling paradigms during evolution.

**Identification of a cAMP-Dependent Protein Kinase Phosphorylation Site in the N-Terminal Region of Human Filamin**

D. J. Jay, R. Uribe, E. Garcia; Cardiovascular Biomedicine, National Institute of Cardiology, Tlalpan, Mexico

Filamin A (FLNa) cross-links actin filaments (F-actin) into three-dimensional gels in cells, attaches F-actin to membrane proteins, and serves as an integrator of cell mechanics and signalling by collecting diverse proteins. Previous studies indicated that a dynamic phosphorylation/dephosphorylation process may modulate the interaction of ABP with other cytoskeletal elements. In this regard, the analysis of the amino acid sequence of ABP revealed multiple consensus sequences specific for diverse kinases including three sites for cAMP-dependent protein kinase (PKA) at residues 167, 2152 and 2336. In this study an N-terminal region of the cytoskeletal protein FLNa was subcloned and expressed in the pT7-7/NT - E. Coli BL21 (DE3) system. As predicted by the aminoacid sequence, this recombinant fragment, a 26 kDa peptide containing the actin-binding domain, could be phosphorylated by the catalytic subunit of PKA. Site-directed mutagenesis analysis confirmed that $^{32}P$ incorporation occurred in threonine 167, the only potential PKA phosphorylation site predicted to be present in this region of the molecule. This residue belongs to a threonine-proline motif and was previously suggested to be involved in regulating F-actin interactions even though its phosphate content was not apparent in native FLNa. Results also showed that phosphorylation of the ABP fragment resulted in an increased interaction with a low-speed sedimentable complex obtained from Triton X-100-solubilized platelets (platelet cytoskeleton). Possible implications of the phosphorylation of this site are discussed in terms of the role of filamin in cytoskeleton reorganization.

1689

**Image-based Searches for the Molecular Targets and Pathways Damaged by Sulfur Mustard**

R. J. Werrlein, C. R. Braue, J. F. Dillman; Cell and Molecular Biology, USAMRICD, Aberdeen Proving Ground, MD

To determine how the blistering agent sulfur mustard (SM, bis-2-chloroethyl sulfide) disrupts epidermal basal-cell attachments in human skin, we have been tracking the development of postexposure lesions by using non-invasive multiphoton microscopy, high-resolution immunofluorescent imaging, and gene-array analysis. From the onset of preclinical lesions in human epidermal keratinocytes (HEK), we have found that SM induces early and progressive disruptions of F-actin organization and of mRNA expression that are coincident in space and time. The coincident changes in gene expression include 5 of 13 myosin I isoforms, 1 of 3 myosin II isoforms, Cdc 42, $\beta_4$ integrin and other proteins that localize and concentrate in areas of dynamic HEK attachment (lamellipodia, filopodia) and of rapid actin reorganization. These characteristic changes occur within 15 minutes of exposure, i.e., early in the “clinical latent phase” of toxicity, and well in advance of vesication. With the aid of these preclinical biomarkers, we have produced image-based search strategies that may link the onset of SM toxicity to actin-coupled signaling pathways.

1690

**Non-muscle Caldesmon Plays a Role in Actin Stress Fiber Disassembly**

J. Kordowska, S. Jiang, C. Wang; Muscle and Motility Group, Boston Biomedical Research Institute, Watertown, MA

Previously we have found that depending on the state of the cell, non-muscle caldesmon (l-CaD) assumes different distributions: In quiescent, well-spread cells unphosphorylated l-CaD is closely associated with organized actin cytoskeleton such as stress fibers and helps to maintain the cell

shape. In stimulated cells l-CaD is phosphorylated and moves to nascent focal adhesions where further modification may occur in order to enable cell attachment to the substratum (Kordowska and Wang, Mol. Biol. Cell, 15, S802, 2004). This potentially regulatory function of l-CaD was tested by expressing GFP-tagged, non-phosphorylatable mutants in cultured rat aortic fibroblast cells. Over-expression of either wild-type l-CaD or Ser-to-Ala mutants at the two ERK sites (Ser497 and Ser527) resulted in cells with thicker actin bundles and more prominent focal adhesions. Treatment with phorbol 12-myristate 13-acetate (PMA) induced disassembly of actin stress fibers and focal adhesions in cells expressing wild-type l-CaD more extensively than in untransfected cells. Contrary to this, mutant-expressing cells exhibited less disassembly of actin stress fibers and focal adhesions upon PMA stimulation compared to untransfected cells or cells transfected with pEGFP alone. Taken together, these observations suggest that exogenous, unphosphorylatable l-CaD is able to compete off endogenous l-CaD and occupies actin stress fibers, thereby preventing quick disassembly even in the presence of stimulants. Our data also suggest that over-expressed wild-type l-CaD becomes phosphorylated upon PMA stimulation; such phosphorylated protein plays an active role in promoting disassembly of actin cytoskeleton. Supported by NIH (P01 AR41637).

1691

**Filamin A Plays a Role in the Stress-Stiffening Response of Melanoma Cells**

K. E. Kasza,[1] S. Hu,[2] F. Nakamura,[3] T. P. Stossel,[3] N. Wang,[2] D. A. Weitz[1]; [1]DEAS, Harvard University, Cambridge, MA, [2]Physiology Program, Harvard School of Public Health, Boston, MA, [3]Hematology Division, Brigham and Women's Hospital, Boston, MA

Filamin A (FLNa) is an abundant protein in vertebrate cells that cross-links actin filaments and connects the cytoskeleton to the cell membrane. Disruption of FLNa expression impairs cellular motility and membrane stability. Reconstituted gels of short actin filaments cross-linked with FLNa mimic many of the mechanical properties of cells, while actin filaments cross-linked with other proteins do not. The dramatic stiffening of these gels in response to applied stress closely replicates cellular stiffening behavior. The molecular origins of cell mechanical behavior is poorly understood, and it is unclear whether filamin plays a similar dominant role in the cell as it does in reconstituted networks. To investigate this, we compare the role of FLNa in the stress-stiffening response of a human melanoma cell line (M2) deficient in FLNa with a transfected subline (A7) expressing FLNa. We probe cell stiffness using several techniques, including magnetic twisting cytometry (MTC) and atomic force microscopy. We determine the level of contractile stress in the cytoskeleton using traction force microscopy and also apply stress to cells using MTC. Cells are plated on polyacrylamide substrates of physiological stiffness, coated with extracellular matrix (ECM) proteins. On soft substrates, we find that A7 cells both exert traction forces and have stiffnesses several times larger than M2 cells do. Further, we find that as the stress applied to cells with MTC is increased, the mean stiffness of A7 cells increases by several times while the mean stiffness of M2 cells remains relatively constant. This effect is robust across a variety of different substrate stiffnesses coated with various ECM proteins. These results are consistent with data from the reconstituted network, and support the hypothesis that the filamin-actin network is a key cytoskeletal structure mediating the stress-stiffening response in cells.

1692

**Filopodia Formation in Neuronal Cells**

F. V. Korobova, T. M. Svitkina; Department of Biology, University of Pennsylvania, Philadelphia, PA

We recently proposed a convergent elongation model for filopodia formation, which suggests that filopodia are formed by reorganization of the branched actin network into bundles. It remains unclear whether this model is applicable to growth cones of neuronal cells, which are extremely rich in filopodia, but apparently do not display conventional dendritic network. Here we analyzed filopodia initiation in primary Xenopus neurons and two neuroblastoma lines. By electron microscopy, growth cones contained abundant filopodial bundles, but the veils between bundles had dendritic organization and contained Arp2/3 complex and cortactin. Kinetic analysis of filopodia initiation by phase contrast or fluorescent microscopy after YFP-actin expression (in neuroblastoma cells) revealed that filopodia originated either from veils between pre-existing filopodia in growth cones, or from small lamellipodia transiently formed on minor neurites. Filopodia formation began as condensation of phase-dense material (or YFP-actin) in the lamellipodia/veil interior followed by appearance of a bump at the cell edge, which then quickly protruded making a filopodium. Lamellipodia-to-filopodia transition was very fast and completed within a few seconds. Correlative electron microscopy of forming filopodia revealed dendritic organization of actin at sites of the initial condensation of material and at the bases of bumps and nascent filopodia. The patches of dendritic network giving birth to filopodia were very transient and could not be detected at filopodial roots a few seconds after their formation, probably, because of turnover. Thus, our findings indicate that filopodia formation in neuronal cells also occurs by the convergent elongation mechanism. However, the transformation of the dendritic network to filopodia is extremely efficient in these cells and requires a limited amount of network to form a large number of filopodia. Supported by NIH grant GM 070898.

1693

**Missing in Metastasis Interprets Global and Local Patterning Signals to the Actin Cytoskeleton**

A. E. Oro, R. Gonzalez-Quevedo; Program in Epithelial Biology, Stanford University, Stanford, CA

During development, dynamic remodeling of the actin cytoskeleton allows the precise placement and morphology of tissues. Morphogens such as Sonic hedgehog (Shh) and local cues such as receptor protein tyrosine phophatases (RPTPs) mediate this process, but how these signals result in precise spatial regulation of the cytoskeleton is poorly understood. We previously identified *Missing in Metastasis* (*MIM*) as a Shh-inducible, WH2 domain-containing protein that, together with Gli, can recapitulate Shh effects in regenerated human epidermis by potentiating Gli transcription (Genes and Dev 8:2724; 2004). We have extended our studies to show that MIM is an inducible actin-bundling protein whose levels are controlled by Shh. MIM-dependent cytoskeletal remodeling and stable cell extensions require an activation domain distinct from sequences required for bundling *in vitro*. This activation domain binds RPTPδ and directs both MIM and RPTPδ membrane localization. MIM-dependent cytoskeletal changes can be inhibited using a soluble RPTPδ-D2 domain. Enhanced F-actin deposition occurs in a MIM-dependent manner when RPTPs are crosslinked using an antibody to the extracellular domain, suggesting RPTP ligand binding provides additional levels of specificity. Our data suggests how *MIM* links global patterning morphogens like Shh and paracrine signaling pathways like RPTPs to induce precise cytoskeletal changes in developing epithelia.

1694

**Mammalian Coronins Regulate Actin Dynamics, Leading Edge Protrusion and Cell Motility**

J. E. Bear, L. Cai, T. Marshall; Cell & Developmental Biology, UNC-Chapel Hill, Chapel Hill, NC

Coronins are actin-binding proteins that regulate cell motility and endocytosis in model organisms. Despite the fact that Coronins are highly conserved across species and have a proven role in motility and endocytosis, the mechanism(s) by which they regulate cellular processes, such as lamellipodial protrusion, remains unclear. Our studies of mammalian Coronins have focused on two representative family members, Coronin 1B and 2A. Coronin 1B is ubiquitously expressed and is localized to protruding leading edge of fibroblasts. This protein interacts directly with the Arp2/3 complex both in vivo and in vitro. The interaction of Coronin 1B and Arp2/3 is regulated by phosphorylation of Ser2 on Coronin 1B. Rat2 fibroblasts expressing the Coronin 1B S2A mutant show enhanced ruffling in response to PMA and increased speed in single cell tracking assays, while the S2D mutant expression attenuates PMA-induced ruffling and slows cell speed. Expression of the S2A mutant partially protects cells from the inhibitory effects of PMA on cell speed. These data demonstrate that Ser2 phosphorylation is responsible for a measurable fraction of PMA's effects on motility. Gene knockdown experiments further indicate that Coronin 1B plays an important role in leading edge protrusion and whole cell motility. Knockdown of Coronin 1B expression can suppress hyper-ruffling phenotypes induced by some, but not all treatments. The second representative Coronin gene, Coronin 2A, is expressed mainly in epithelial and neuronal cell types and is localized along actin stress fibers, but is specifically excluded from the leading edge. Over-expression of Coronin 2A in fibroblasts induces the formation of actin-cofilin rods and reorganizes actin stress fibers into thick bundles that concentrate at the periphery of cells. Together, these data indicate that mammalian Coronins play important roles in actin organization and cell motility.

1695

**Pyk2 Phosphorylation in Osteoclasts is Regulated by the Dynamin GTPase and Src Activity**

A. Bruzzaniti, L. Neff, W. Horne, R. Baron; Dept. of Orthopaedics, Yale University School of Medicine, New Haven, CT

Signaling from the Pyk2-Src-Cbl protein complex is essential for the dynamic regulation of podosomes, which mediate osteoclast (OC) attachment, migration and bone resorption. Accordingly, deletion of any of these genes leads to decreased OC motility, and to osteopetrosis in $Src^{-/-}$ and $Pyk2^{-/-}$ mice. While much is known about Pyk2-Src-Cbl complex assembly, the factors that promote the disassembly of this complex are unknown. We previously showed that dynamin (Dyn) interacts in a Src-sensitive manner with Cbl and localizes to podosomes in OCs. Moreover, overexpression of dominant-negative DynK44A slows actin turnover in podosomes and decreases bone resorption *in vitro*. Since Pyk2 is activated by $Ca^{2+}$ mobilization following integrin engagement and has been implicated in cytoskeletal reorganization, we examined the potential interactions between Dyn and Pyk2. We report that Dyn colocalizes with Pyk2 in the podosome actin ring and forms a complex with Pyk2, independent of the kinase activity of Pyk2. Importantly, phosphorylation of Pyk2 at Tyr402, a residue that is autophosphorylated upon Pyk2 activation and forms the binding site for the Src SH2-domain, is dramatically decreased by the presence of Dyn but not DynK44A. Although Dyn-Pyk2 complex formation was not dependent on Src's adaptor function, Src was required for the Dyn-induced Tyr402 dephosphorylation. Thus, once activated by integrin engagement, Pyk2 is autophosphorylated at Tyr402, recruiting and activating Src at attachment sites. Our study shows that Dyn is also recruited by Pyk2, possibly in the same Src- and Cbl-containing complex. Furthermore, the recruitment of Dyn, in the presence of active Src, leads to the Dyn GTPase-dependent decrease in the phosphorylation of Pyk2 at Tyr402, potentially leading to the dissociation of Src from Pyk2 and/or to decreases in Src and Pyk2 kinase activities which affect podosome turnover and OC function.

1696

**Mammalian Septins Regulate Cell Morphology Through the Adapter Protein NCK**

B. E. Kremer, I. G. Macara; University of Virginia, Charlottesville, VA

Septins are a class of structural GTP-binding proteins found in all eukaryotes except plants. Mammalian septins, of which at least 13 are known, have been proposed to play roles in cell division, secretion, and cytoskeletal regulation. During interphase in cultured cells, Septins 2, -6, and -7 are found in heteromeric filaments that partially align along the actin cytoskeleton. Septin depletion results in the loss of these filaments, as well as disruption of the actin cytoskeleton, defects in cell division, altered focal adhesions, increased rate of cell spreading, and changes in cell morphology. In order to determine the molecular mechanisms underpinning the effects of septin depletion on the actin cytoskeleton and cellular morphology, we stained control- or septin-depleted cells for a variety of proteins involved in cell polarity and actin regulation. We discovered that NCK, a family of two 47-kDa SH2 and SH3 domain-containing adapter proteins, translocates from the cytoplasm to the nucleus following septin depletion. This phenomenon appears to cause the morphological changes following septin depletion. Overexpression of wild type or nuclear export signal (NES)-tagged NCK1 causes knockdown cells to regain their normal elongated morphology. Conversely, nuclear localization signal (NLS)-tagged NCK1 fails to revert the knockdown morphology, and control siRNA cells co-transfected with NLS-NCK1 adopt the rounded morphology characteristic of septin depletion. These results suggest a novel mechanism by which septins regulate the actin cytoskeleton. We are currently investigating the mechanism by which septins regulate NCK localization, as well as the links between NCK localization and the actin cytoskeleton.

1697

**Role of Vinculin in Cytoskeletal Dynamics and Regulation**

L. Jaafar, C. Mierke, D. Paranhos-Zitterbart, P. Kollmannsberger, J. Pauli, W. H. Goldmann, B. Fabry; Center for Medical Physics and Technology, Biophysics Group, Friedrich Alexander Universität, Erlangen-Nürnberg, Erlangen, Germany

The focal adhesion protein vinculin has been implicated in transmembrane mechanical coupling and focal adhesion contact formation [Ezzell et al., *Exp. Cell Res.* **231**:14, 1997]. We and others have demonstrated that F9 mouse embryonic carcinoma cells lacking vinculin (Vin (-/-)) show reduced stress fiber formation and cell stiffness. To test whether vinculin also controls cytoskeletal dynamics, we measured the creep response in F9 Wt, F9 Vin(-/-), and F9 Vin(+/+) rescue cells. Fibronectin-coated superparamagnetic microbeads (diameter 4.5 μm) were bound to the cell surface for 30 min and then pulled in a magnetic field gradient with step forces $F$ ranging from 0.5 to 10 nN. The resulting bead displacement $d$ showed strict power-law behavior over 3 time decades (from $t$ = 0.01 to 10 sec): $d(t) = d_0 t^{\beta}$. Larger $d_0$ implies softer behavior, and a larger power-law exponent β indicates a more viscous (as opposed to elastic), more dynamic behavior [Bursac et al., *Nature Mat* **4**:557, 2005]. At $F$ = 1 nN, F9 Wt cells (n=30) showed $d_0$ = 0.18 μm and β = 0.25 ±0.07; F9 Vin(-/-) cells (n=42) showed $d_0$ = 0.44 μm and β = 0.19 ±0.05; F9 Vin(+/+) rescue

cells (n=29) showed $d_0$ = 0.13 μm and β = 0.27 ±0.05. These results indicate that (i) F9 Vin(-/-) cells are softer, confirming earlier reports that vinculin is important for transmembrane mechanical coupling and (ii) F9 Vin (-/-) cells are less viscous and more elastic, indicating a less dynamic, more stable structure of the cytoskeleton and associated focal adhesions. The findings suggest that vinculin has an important regulatory role in controlling cytoskeletal dynamics. (Financial support for this work came from Deutsche Forschungsgemeinschaft, grant No. Is 25/8-1).

## Actin Dynamics & Assembly II (1698-1716)

1698

### Polymerization of Actin-Nucleotide Complexes

E. L. Weitzke,[1] R. E. Mahaffy,[2] T. D. Pollard,[2] L. M. Loew[1]; [1]Center for Cell Analysis and Modeling, University of Connecticut Health Center, Farmington, CT, [2]Department of Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT

The long-term objective of this work is to understand the molecular mechanisms controlling assembly and disassembly of actin filaments at the leading edge of motile cells in terms of the rates of specific biochemical reactions. In this work, the characterization of ATP-, ADP- and ADP-$P_i$-actin monomer and filament behavior is investigated under dynamic and steady state conditions. We aim to quantitatively elucidate nucleation and elongation rate parameters for a wide range of actin concentrations under varying conditions, through a combination of experiment and mathematical modeling. Experimentally, actin polymerization is measured by collecting pyrene fluorescence as a function of time in a fluorimeter. The affect of pyrene labeling on ADP-actin dynamics is investigated under conditions of ADP-actin concentrations close to and far from the critical concentration. Quantitative values for nucleation, elongation and critical concentration for black ADP-actin, actin without pyrene, are obtained through *in vitro* assays and mathematical modeling using the Virtual Cell biological modeling framework. The fraction of pyrene labeled actin affects nucleation curves at concentrations near the critical concentration for ADP-actin, but does not seem to affect elongation rates. Characterization of the three forms of actin is assessed with mathematical modeling and the simulation results are compared with data from *in vitro* polymerization studies involving varying actin concentrations of the three actin forms. ADP-actin polymerizes significantly more slowly than ATP- or ADP-$P_i$-actin, while the latter 2 actin species behave quite similarly. The model permits the derivation of parameters for both the nucleation and elongation phases of these dynamic processes.

### Direct Observation of the Assembly of ATP- and ADP-Actin by Mammalian and Yeast Formins and Profilin

D. R. Kovar,[1,2] E. S. Harris,[3] D. Vavylonis,[4] B. O'Shaughnessy,[4] H. N. Higgs,[3] T. D. Pollard[1]; [1]MCDB, Yale University, New Haven, CT, [2]Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, [3]Biochemistry, Dartmouth Medical School, Hanover, NH, [4]Chemical Engineering, Columbia University, New York, NY

Formins are large multi-domain proteins required for the assembly of actin filaments found in many cellular structures such as contractile rings, stress fibers and filopodia. Formins nucleate actin filaments and remain processively associated with the fast-growing barbed ends. We have addressed substantial disagreements in the literature by using total internal reflection fluorescence (TIRF) microscopy to observe directly the assembly of individual filaments from ATP- and ADP-actin in the presence of purified constructs containing formin homology domains 1 and 2 (FH1FH2) of two mammalian formins (mDia1 and mDia2) and two yeast formins (Bni1p and Cdc12p). These formins remain processively attached to elongating barbed ends in both the absence and presence of profilin. The four differ in the rapid equilibrium between states that either block or do not block actin subunit addition to the end of the filament. Optimal profilin concentrations increase the rate of barbed-end elongation up to ~5-fold relative to actin alone. ATP-hydrolysis is not required for elongation or processivity. We conclude that although the rates of particular assembly steps vary, these diverse formins are mechanistically similar. In agreement, we have constructed a complete mathematical model that can explain our experimental results and previous crystallographic and biochemical analysis.

### Model for Formin Mediated Elongation of Actin Filaments with Fastened Ends: Filament Torsion, Oscillations and Solution of the Rotation Paradox

T. Shemesh,[1] T. Otomo,[2] M. K. Rosen,[2] A. D. Bershadsky,[3] M. M. Kozlov[1]; [1]Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel, [2]Department of Biochemistry, UT Southwesterm Medical Center at Dallas, Dallas, TX, [3]Department of Molecular Cell Biology, The Weizmann Institute of Science, Rehovot, Israel

The FH2 domains of formin family proteins act as processive cappers of actin filaments. Previously suggested stair-stepping mechanisms of processive capping imply that a formin cap rotates persistently in one direction with respect to the filament (Pollard, 2004). This challenges the formin-mediated mechanism of intracellular cable formation and contradicts the *in vitro* results. We suggest a novel scenario of processive capping driven by developing and relaxing torsion elastic stresses. Based on the recent crystal structure of an FH2-actin complex, we propose a second mode of processive capping, the screw mode. Within the screw mode the formin dimer rotates with respect to the actin filament in the direction opposite to that generated by the stair-stepping mode so that a combination of the two modes prevents the persistent torsion strain accumulation. Based on elastic analysis of torsion stresses within an actin filament, we determine an optimal regime of processive capping, whose essence is a periodic switch between the stair- stepping and screw modes. One cycle of this regime consists, in average, of about 12 stair-stepping steps followed by one screw step. We estimate the torsion angle, which can result in actin filament supercoiling and show that within the suggested regime supercoiling of actin filaments is prevented and the filament elastic energy does not exceed feasible values. We analyze coupling between the filament torsion and extension and predict that, upon processive capping by an immobilized formin cap, addition of one actin monomer within the stair-stepping mode should result in filament elongation of about 3.4nm. This excessive elongation is predicted to be balanced by periodic contraction of the filament by about 5nm as a result of screw steps.

1701

### Molecular Regulation of Full-length Formin Proteins

B. L. Goode,[1] S. Maiti,[1] J. B. Moseley,[1] D. Sousa,[1] N. Grigorieff,[2] J. B. Wallingford[3]; [1]Biology, Brandeis University, Waltham, MA,

[2]Biochemistry, Brandeis University, Waltham, MA, [3]Molecular Cell and Developmental Biology, University of Texas, Austin, TX
Formin proteins directly assemble actin filaments through their conserved C-terminal FH2 domains. Within the Diaphanous-related formin (DRF) subfamily, nucleation is thought to be tightly autoregulated by interactions between C-terminal DAD and N-terminal DID domains. Further, it is hypothesized that auto-inhibition is relieved by interactions with Rho-family GTPases. However, full-length formins have not been purified to date to test this mechanism. Here, we developed methods to isolate three full-length DRFs: mouse mDia1 and budding yeast Bni1 and Bnr1, permitting the first direct examination of activity and regulatory mechanisms for full-length formins. In agreement with previous work using fragments (Li and Higgs, 2003), full-length mDia1 is completely autoinhibited. Full-length Bnr1 also is autoinhibited. In contrast, full-length Bni1 exhibits no autoinhibition, despite containing conserved DAD and DID domains. Thus, direct autoinhibition is not a universal DRF regulatory mechanism. Truncation of the DAD fully relieves mDia1 autoinhibition, but RhoA only partially activates full-length mDia1 (10-15% activation), suggesting that alternate mechanisms may control formin activation. To explore this further, we examined the human formin Daam1, which regulates planar cell polarity through the non-canonical Wnt signaling pathway. Daam1 is fully autoinhibited, but Rho, which binds directly to Daam1, fails to relieve autoinhibition. This is consistent with placement of Rho downstream of Daam1 by genetic analyses. Strikingly, Daam1 is fully activated by nanomolar concentrations of its C-terminal ligand Dishevelled, which genetically is placed upstream of Daam1. These data suggest that, in contrast to the prevailing dogma, C-terminal ligands are critical activators of formins. Further, we show that activation involves “opening” and tetramerization of the formin structure, as revealed by analytical gel filtration and electron microscopy and single particle analysis.

1702

**Comparative Analysis of Formin Activities and Regulation**

S. Maiti, J. B. Moseley, B. L. Goode; Rosenstiel Center, Brandeis University, Waltham, MA

Formin proteins directly nucleate actin assembly and processively cap filament barbed ends to allow insertional growth. In all formins examined, the C-terminal FH2 domain mediates these activities on actin. However, due in part to differences in expression source and purification scheme, it has been unclear how the activities of formins from different cell types and organisms compare. Hence, we developed methods in yeast to express and isolate formin proteins from a wide range of species and compare quantitatively their effects on actin assembly. Our comparison includes yeast Bni1 and Bnr1, mouse mDia1 and mDia2, and human Daam1. Thus, the approach we describe should be universally applicable to the purification and analysis of formins from any eukaryote. We show that active FH1-FH2 containing fragments of Bni1, Bnr1, mDia1, mDia2, and Daam1 are each tetrameric, whereas the FH2 domain alone is dimeric. The possible *in vivo* functions of formin tetramerization are presented in models. The FH1-FH2 fragments nucleate actin with variable efficiencies, as high as one actin filament per formin tetramer. We further have used this purification method to isolate soluble full-length mDia1, Bni1, and Bnr1, which have not been possible to purify from bacterial sources. By isolating active formin fragments and full-length formins in parallel, we provide quantitative analyses that address their activities and mechanisms of regulation. We show that three different Diaphanous-related formins (Drfs) are autoinhibited through interactions between their N- and C-termini, yeast Bnr1 and mammalian mDia1 and Daam1. Further, we provide evidence that formins have distinct molecular mechanisms triggering their release from an autoinhibited state.

1703

**Structural Basis for the Autoinhibition and Activation of Diaphanous-Related Formins**

A. Nezami,[1,2] F. Poy,[1] M. J. Eck[1,3]; [1]Dana-Farber Cancer Institute, Boston, MA, [2]Harvard Medical School, Boston, MA, [3]Department of Biological Chemistry and Molecular Pharmacology, Harvard Medical School, Boston, MA

Diaphanous-related formins (DRFs) regulate the nucleation and polymerization of unbranched actin filaments. DRFs are regulated by the intramolecular binding of the C-terminus Diaphanous-autoinhibitory domain (DAD) to the N-terminus DAD-interacting domain (DID). This inhibition is relieved by Rho-GTP binding to the N-terminal GTPase binding domain (GBD). We have determined high resolution crystal structures of the DID region of mDia1, both alone and in complex with the inhibitory DAD domain. Additionally we have determined the structure of a large N-terminal fragment of mDia1 containing the DID, dimerization, and coiled coil domains. The DAD domain adopts a mostly helical conformation and binds via extensive hydrophobic and polar interactions to a highly conserved groove on the DID domain. Comparison of these structures with the previously reported structure of the activated mDia1 N-terminus in complex with a Rho GTPase reveals that release of the inhibitory DAD interaction is effected mainly by Rho-induced conformational changes in the mDia1 N-terminus, and to a lesser degree by direct steric clash between Rho on the DAD sequence. Calorimetric analyses of the interaction of N-terminal fragments of mDia1 with C-terminal fragments including either or both of the FH2 and DAD domains indicate that the DAD/DID interaction revealed in the crystal structure is the complete autoinhibitory contact.

1704

**Studies of Diaphanous-related Formin Autoregulation Yields Novel Activated Variants of the mDia2 Sufficient to Induce Filopodia Assembly**

H. A. Holman, B. J. Wallar, A. S. Alberts; Cell Structure & Signal Integration, Van Andel Research Insitute, Grand Rapids, MI

Rho GTPases activate the mammalian Diaphanous-related (mDia) formins by disrupting an intramolecular autoinhibition mechanism maintained by the association of conserved Dia-inhibitory (DID) and the C-terminal Dia-autoregulatory (DAD) domains that flank the formin homology-2 (FH2) domain. The loss of autoinhibition allows the FH2 domain to nucleate and elongate non-branched actin filaments. In this study, we have defined additional regions with DAD that are required for DID binding. Versions of mDia2 that lack the N-terminal autoinhibitory domains, including all or part of the GTPase-binding domain and/or DID induce the formation of thin actin filaments resembling stress fibers. In contrast, expression of DAD-truncated mDia2 or DAD-mutated versions of mDia2 that block binding to DID - leaving the GTPase-binding domain intact - leads to the generation of filopodia in the absence of other stimulation. Time-lapse microscopy shows these activated variants of mDia2 at the tips of elongating actin structures. These findings are consistent with the observation that mDia2 is a critical component of actin filament assembly at the cell cortex.

1705

**RhoB and the Mammalian Diaphanous-related Formin mDia2 Govern Actin Dynamics on Endosomes Necessary for Trafficking and Vesicle Fusion**

B. J. Wallar, J. Peng, K. A. Collins, K. M. Eisenmann, A. S. Alberts; Cell Structure & Signal Integration, Van Andel Research Institute, Grand Rapids, MI

Mammalian Diaphanous-related (mDia) formins nucleate and elongate actin filaments following binding and activation by Rho GTPases. While all three mDia proteins (mDia1/2/3) have been shown to localize to endosomes, the role of GTPase-activated formins in actin assembly on endocytic vesicles has not been fully characterized. Some models have been proposed based on the observation that constitutively activated Rho GTPase and mDia proteins trigger the assembly of stress fiber-like actin filaments that act as conduits for vesicle transport. Here, in a study of a functional relationship between RhoB and mDia2, we show that: 1) RhoB and mDia2 interact on endosomes; 2) GTPase activity - the ability to hydrolyze GTP to GDP - is required for the ability of RhoB to govern endosome dynamics; and 3) actin treadmilling controlled by RhoB and mDia2 is necessary for vesicle trafficking as well as for the process of vesicle fusion. These studies further show that Rho GTPases significantly influence the activity of mDia family formins to drive cellular membrane dynamics through the process of actin treadmilling.

1706

**Actin Nucleation by Cappuccino-family Formins is Regulated by Spir-family Proteins**

M. E. Quinlan,[1] S. Hilgert,[2] E. Kerkhoff,[2] R. D. Mullins[1]; [1]Cell and Molecular Pharmacology, UCSF, San Francisco, CA, [2]Institut fur Medizinische Strahlenkunde und Zellforschung, Universitat Wurzburg, Wurzburg, Germany

The actin cytoskeleton is essential for many cellular functions including shape determination, intracellular trafficking, and locomotion; formin-family proteins contruct many of the actin networks involved in these functions. Phylogenetic analysis identifies seven classes of actin-nucleating formins in metazoa. Most of these classes contain a conserved regulatory domain (Diaphanous Autoregulatory Domain, DAD), which inhibits nucleation activity in the absence of an upstream activator. Formins related to the *Drosophila* Cappuccino protein, however, lack the DAD domain and their regulation is poorly understood. We find that a novel domain originally discovered in Spir-family proteins (the kinase non-catalytic C-lobe domain, or KIND), binds the FH2 domain of Cappuccino-family formins with submicromolar affinity. The interaction directs localization of Cappuccino in tissue culture cells and potently inhibits its actin nucleation activity *in vitro*. The interaction is conserved from *Drosophila* to mammals and is highly specific, as we find that Spir proteins do not interact with other classes of formins (e.g. the Diaphanous-family proteins). Spir proteins are themselves actin nucleation factors that operate by a mechanism distinct from those of the formins or the Arp2/3 complex. Spir assembles actin nuclei using four monomer-binding WH2 domains and an additional motif, conserved among Spir proteins. We find that each WH2 domain plays a distinct role in the nucleation reaction and that the identity and position of each WH2 domain is important for maximal activity. Previous work has shown that Spir and Cappuccino are both required for axis specification in *Drosophila* oocytes and embryos and that mutation of either protein produces the same phenotype. Spir and Cappuccino homologs in mammals also have identical tissue distributions in both embryos and adults. Together our data indicate that Spir and Cappuccino interact directly and collaborate to construct essential cytoskeletal structures required for development.

1707

**Model of Formin-Associated Actin Filament Elongation and the Role of Profilin**

D. Vavylonis,[1,2] D. R. Kovar,[2] B. O'Shaughnessy,[1] T. D. Pollard[2,3,4]; [1]Chemical Engineering, Columbia University, New York, NY, [2]Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT, [3]Cell Biology, Yale University, New Haven, CT, [4]Molecular Biophysics and Biochemistry, Yale University, New Haven, CT

Formins control the kinetics of actin filament assembly by remaining processively attached at the growing actin filament barbed ends. The formin FH2 domain associates with the barbed end while FH1 interacts with profilin and is thought to mediate profilin-actin polymerization. We combined total internal reflection microscopy (Kovar et al., separate submission) with theoretical modeling to study the dependence of the rate of actin filament elongation on profilin and actin concentrations for four different FH1-FH2 constructs (mouse mDia1, mouse mDia2, budding yeast Bni1p, and fission yeast Cdc12p). Taking into account earlier crystallographic and biochemical data we constructed a kinetic model which explains the main experimental trends. The model is based on a conserved transfer mechanism of profilin-actin from FH1 to the barbed end, gated by FH2 as described by a gating parameter, p. Differences between formins are attributed to different parameter values. The main experimental observation, namely the existence of an optimal profilin concentration where elongation rate is a maximum, is another central conclusion of the model. We rationalize (i) how filaments associated with mDia1 elongate more rapidly than formin-free filaments due to the the large number of profilin binding sites and the large gating parameter (p~1) characterizing mDia1 and (ii) how filaments associated with formins whose p values are small, such as mDia2, elongate slowly in the absence of profilin but more rapidly in the presence of profilin. In all cases high enough profilin concentrations suppress elongation rates; in the model this is attributed largely to the saturation of FH1 by free profilin. Consistent with our ADP-actin experiments, the proposed mechanism does not require ATP hydrolysis though we cannot exclude the possibility that formin translocation accelerates ATP hydrolysis for ATP-actin.

1708

**APC2 and Diaphanous Function Together to Organize Actin in *Drosophila* Embryos**

R. L. Webb, J. S. Weinberg, B. M. McCartney; Department of Biological Sciences, Carnegie Mellon University, Pittsburgh, PA

Coordinated assembly and disassembly of actin filaments is a hallmark of cell migration and the orchestrated cell shape changes that occur during morphogenesis. Adenomatous polyposis coli (APC) family proteins associate with actin and microtubules influencing cell migration via actin through IQGAP and a RacGEF, and by promoting microtubule stability downstream of Rho with the formin Diaphanous and the microtubule + TIP protein, EB1. Here we report a novel role for APC2 and Diaphanous in organizing actin in Drosophila syncytial embryos. We have shown previously that Drosophila APC2 localizes to actin structures and the phenotype of mutant syncytial embryos suggested a role for APC2, Drosophila ß-catenin and GSK3ß, in tethering cortical actin to microtubules. To test this hypothesis, we examined embryos null for *APC2* function and observed defects in the actin rings and furrows that develop during syncytial mitoses to separate adjacent mitotic figures. This suggests a role

for APC2 in the assembly or stability of actin-based structures. Diaphanous also plays a role in actin ring and furrow formation in the syncytial embryo. We found that APC2 and Diaphanous colocalize and coimmunoprecipitate from syncytial embryos, suggesting that these proteins form a complex. Further, we showed that reduction of *diaphanous* in *APC2* mutant syncytial embryos enhances the severity of actin defects compared to those in *APC2* mutant embryos alone. To complement the analysis of fixed embryos, we are using live imaging to assess dynamic actin behavior in wild type and mutant embryos. We have observed a variety of actin defects in *APC2* mutant and *dia/+; APC2* mutant embryos consistent with a role for these proteins in actin assembly and stability. We are currently assessing the role of APC2 in the RhoGEF2 and Rho1 regulated actin organization function of Diaphanous in Drosophila.

1709

**Aip1 Accelerates the Turnover of Actin Networks *in vivo* by a Mechanism of Capping ADF/cofilin-severed Actin Filaments**

K. Okada,[1] H. Ravi,[2] E. M. Smith,[1] B. L. Goode[1]; [1]Rosenstiel Basic Medical Research Center, Brandeis University, Waltham, MA, [2]Department of Biochemistry, Brandeis University, Waltham, MA

Actin interacting protein (Aip1) is a highly conserved component of the actin cytoskeleton that has been linked functionally to ADF/cofilin, but its mechanism of action and cellular function has remained poorly understood. Here, we demonstrate that Aip1 and cofilin accelerate the turnover of both actin patches and actin cables in *S. cerevisiae*. Both of these actin structures are highly dynamic, and loss of cofilin and Aip1 functions results in greatly reduced dynamics and loss of cellular functions. To dissect and understand better the Aip1 cellular mechanism, we integrated mutations at 31 conserved residues on its surface and performed genetic, two-hybrid, and biochemical analyses of mutant effects. We identify two distinct and well-separated surfaces on Aip1 that are important for its functions *in vivo* and mediate direct binding to F-actin. Mutations at these sites disrupt Aip1-induced capping and net depolymerization of ADF/cofilin-severed filaments *in vitro*. These same mutations lead to loss of Aip1 localization, thickened actin cables, and genetic interactions with *cof1-22 in vivo*. In addition, these *aip1* mutations reduce rates of actin cable and patch turnover in living cells. Together, these data suggest that the primary cellular function of Aip1 is to accelerate actin turnover by capping cofilin-severed filaments. They also provide the first mechanistic insights into the regulation of yeast actin cable turnover. Our results suggest that Aip1 may have a conserved role in switching the effects of cofilin, from severing filaments to promote new growth in the absence of Aip1 to inducing net depolymerization and turnover of filaments in the presence of Aip1.

1710

**Cofilin-induced Switch from Intramolecular to Intermolecular Cross-linking in Skeletal F-Actin**

M. Phan, Y. Yang, Y. Xie, S. Benchaar, R. R. Ogorzalek Loo, J. A. Loo, E. Reisler; Chemistry & Biochemistry, UCLA, Los Angeles, CA

Actin is believed to assume different conformational states in the monomer and the polymer forms. In turn, these states are altered upon binding ADF/cofilin to actin. Such conformational rearrangements in actin can be identified by using chemical cross-linking methods. Benzophenone-4-maleimide (BPM), an 8Å cross-linking reagent, can be attached to Cys374 of skeletal actin and then photo-actived to cross-link within actin. We confirmed that intramolecular cross-linking with this reagent occurs in F-actin but not in G-actin. Minor intermolecular cross-linking in F-actin has been also detected. Using mass spectrometry methods, the intramolecular cross-link was mapped to Cys374 and Asp11; the intermolecular cross-link was mapped to Cys374 and Met44 on adjacent protomers within the same filament strand. The abundant cross-linking between Cys374 and Asp11 in F-actin, despite their 17.2 Å separation in both G-actin and F-actin (Holmes 1990), provides experimental evidence for a polymerization driven structural change in actin. The binding of cofilin to F-actin abolishes the intramolecular cross-linking and alters the conformation of actin to favor the intermolecular Cys374-Met44 reaction. This intermolecular cross-link locks actin in a conformational state with increased affinity for cofilin. Cofilin appears to be "trapped" on the cross-linked protomers and does not easily dissociate from the actin, even under high salt conditions. Thus, BPM cross-linking from Cys374 to different sites on actin maps some of the conformational changes that occur on actin upon its polymerization and the binding of cofilin.

1711

**Actin Filament Flexibility and Severing by Cofilin and Gelsolin**

D. A. Pavlov, E. Reisler; Chemistry and Biochemistry, UCLA, Los Angeles, CA

Previous studies using differential scanning calorimetry (DSC) showed dual effects of cofilin on F-actin: a stabilization of the occupied protomers and cooperative destabilization of the unoccupied parts of the filament at subsaturating cofilin concentrations. Thus, filaments fully decorated by cofilin are more stable. *In vitro* severing experiments using fluorescent microscopy showed that filaments tethered to the glass surface *via* barbed ends or loosely attached at low densities of heavy meromyosin (HMM) were severed at lower rates, while multipoint-tethered filaments were severed by cofilin at higher rates. Cofilin-induced structural strain in actin filaments facilitates their severing; this strain is dissipated when the number of attachment points is reduced, decreasing cofilin's severing activity. In this study, we contrast the effects of gelsolin on filament stability (in DSC) and the *in vitro* severing with those of cofilin. Differential scanning calorimetry (DSC) showed that monomeric actin was stabilized upon gelsolin, gelsolin segment 1, or cofilin binding. DSC of F-actin showed different structural effects of gelsolin and cofilin binding to F-actin. Actin polymerization caused an increase in $T_{max}$ (8ºC) in DSC experiments. Actin copolymerized with gelsolin (at mole ratios from 3000:1 to 100:1) denatured at lower temperature than intact F-actin; the effect increased with greater amount of incorporated gelsolin, but was detected even at 1:3000 gelsolin to actin ratio. In electron microscopy observations, actin filaments copolymerized with bigger amounts of gelsolin were generally shorter. *In vitro* severing experiments showed that, in contrast to cofilin, increased tethering inhibited actin severing by gelsolin. These results reveal F-actin structure and dynamics dependent differences in filament severing by different proteins.

1713

**Two Region-dependent Functions of PAK: Control of Polymerization by Cofilin Inhibition in the Lamellipodium and of Contraction by Myosin II Activation in the Lamella**

V. D. Delorme,[1] M. Machacek,[2] C. Waterman-Storer,[2] G. Danuser,[2] G. Bokoch[1]; [1]Immunology, The Scripps Research Institute, La Jolla, CA, [2]Cell Biology, The Scripps Research Institute, La Jolla, CA

p21-activated kinases (PAKs) are downstream effectors of Rho-family GTPases that signal to the actin cytoskeleton assembly and actin contraction

machineries. The molecular mechanisms involved in this dual action of PAK remain to be defined. To assess the function of PAK1 at the cell leading edge, we selectively perturbed components of the actin assembly signaling pathway Rac1-PAK1-LIMK-cofilin and the contraction pathway Rac1-PAK1-MLCK/myosinII, respectively. We measured the changes in actin dynamics using quantitative Fluorescent Speckle Microscopy to obtain the actin network velocity (retrograde flow) and assembly and disassembly rates in two regions: the lamellipodium, which is a 1 µm wide region adjacent to the leading edge, and the lamella, which extends from the leading edge several microns into the cell. We tracked the leading edge to assess the changes in rates of protrusion and retraction. We observed the distribution of markers of the lamellipodium (Arp3, cofilin) and the lamellum (tropomyosin, myosin, paxillin). We show that inhibition of PAK1 blocks active RacQ61L-induced actin and protrusion dynamics: inhibition reduces the width of the lamellipodium, possibly by increasing cofilin dephosphorylation and activity. PAK1 inhibition is further associated with a dramatic decrease in the rate of actin retrograde flow in the lamellum. This effect appears to be due to regulation of myosinII-dependent contraction. In contrast, direct enhancement of cofilin activity downstream of PAK1 (via inactive LIMK or non-phosphorylatable cofilin mutants) increases the rate of actin retrograde flow in the lamella. The distribution of biochemical markers indicative of the two regions is also modified. Our results indicate a region-dependent functionality of PAK1: we conclude that PAK1 promotes turnover of the actin network in the lamellipodium and activates myosin II contractility in the lamella.

1714

### The Two *Caenorhabditis elegans* Actin Depolymerizing Factor/Cofilin Proteins Differently Enhance Actin Filament Severing and Depolymerization

S. Yamashiro,[1] K. Mohri,[1,2] S. Ono[1]; [1]Pathology, Emory University, Atlanta, GA, [2]Department of Biophysics, Kyoto University, Kyoto, Japan

Actin depolymerizing factor (ADF)/cofilin is a conserved family of actin-regulatory proteins among eukaryotes that are critical for rapid turnover of actin filaments. Multicellular organisms express multiple ADF/cofilin isoforms in a tissue specific manner, and they have quantitatively different actin-regulatory activities. The *Caenorhabditis elegans unc-60* gene encodes two ADF/cofilin family proteins which are designated as UNC-60A and UNC-60B. Our previous studies suggested that UNC-60A and UNC-60B are functionally differentiated ADF/cofilin isoforms. UNC-60A is expressed in various tissues and required for early embryogenesis, whereas UNC-60B is specifically expressed in body wall muscle and required for myofibril assembly. In steady state assays in vitro UNC-60A causes greater net depolymerization of actin filaments than UNC-60B. Here, we further compared their differences in activities to sever and depolymerize actin filaments using actins from rabbit muscle and *C. elegans*. The non-muscle isoform UNC-60A had greater activities to cause net depolymerization and inhibit polymerization than the muscle specific UNC-60B. Surprisingly, UNC-60B showed much stronger severing activity than UNC-60A. Moreover, UNC-60B induced much faster pointed-end depolymerization of rabbit muscle actin than UNC-60A, while UNC-60A caused slightly faster depolymerization of *C. elegans* actin than UNC-60B. These results suggest that the muscle specific UNC-60B is kinetically more efficient in enhancing actin turnover than the non-muscle isoform UNC-60A, while UNC-60A is suitable for maintaining higher concentrations of monomeric actin. These functional differences might be specifically adapted for different actin dynamics in muscle and non-muscle cells.

1715

### Vav1 Regulates the Activity and Localization of Cofilin-phosphatase Slingshot1L

H. Matsuoka, K. Ohashi, K. Mizuno; Department of Biomolecular Sciences, Graduate School of Life Sciences Tohoku University, Sendai, Japan

Actin cytoskeletal dynamics and reorganization play pivotal roles in a variety of cell activities, including migration, morphological change, polarity formation and cytokinesis. Cofilin, a key regulator of actin filament dynamics, is inactivated by phosphorylation at Ser-3 by LIM-kinase 1/2 (LIMK1/2) and is reactivated by dephosphorylation by a family of protein phosphatases, termed Slingshot1/2/3 (SSH1/2/3). As for the mechanism of regulation of LIMK activity, it is proposed that both Rho-ROCK and Rac-PAK signaling pathways activate LIMK1. However, the mechanism for regulating SSH activation and cofilin dephosphorylation is not well understood. To elucidate the mechanism of regulation and function of SSH1L, we employed proteomic approach comprising tandem affinity purification (TAP) method. Using MALDI-TOF/MS analysis, we identified Vav1 as one of the SSH1L-associated proteins. Vav1 is a guanine nucleotide exchange factor for Rho family GTPases (Rho/Rac). The cell-free and co-precipitation analyses revealed that SSH1L is inactive when it associates with Vav1. Furthermore, microscopic analysis and F-actin co-sedimentation assays suggested that Vav1 controls the localization of SSH1L in response to an extracellular stimulus. Based on these results, we suggest the role of Vav1 in the regulation of SSH1L activity as follows: an extracellular stimulus leads to the activation and membrane translocation of Vav1, which results in the recruitment of SSH1L to the plasma membrane, where SSH1L is released from Vav1 to be activated.

### Molecular Motors in Cells: A Rapid Switch of Biopolymer Organization

D. M. Smith,[1] F. Ziebert,[2] W. Zimmermann,[2] J. A. Käs[1]; [1]Institute for Soft Matter Physics, University of Leipzig, Leipzig, Germany, [2]Physikalisches Institut, Universität Bayreuth, Bayreuth, Germany

All eukaryotic cells rely on self-assembly of protein filaments to form an intracellular cytoskeleton. The necessity of motility and reaction to stimuli additionally requires pathways that reversibly change cytoskeletal organization. While temperature-driven disordering is, from the viewpoint of physics, the most obvious method for dissolving complex cellular structures, this approach would exceed the physiologically viable temperature range. This motif is exemplified in the de-hybridization of DNA, which is temperature-induced in PCR, but achieved by molecular motors in cells. We report another fundamental mechanism whereby changes in the activity of Myosin II induce order-disorder transitions in reconstituted cytoskeletal actin-myosin networks. Bulk activity of the motors, which causes sliding of individual filaments (D. Humphrey et al, *Nature* 2002), maintains a dynamically disordered network. During depletion of the ATP supply, an increasing fraction of molecular motors becomes inactive, crosslinking actin filaments to small clusters. The remaining active motors combined with continually increasing cross-linking foster further growth of these clusters, resulting in a variety of ordered macro-molecular structures such as asters, networks resembling neuronal architectures, and condensed super-precipitates. Experiments with photo-activated motors demonstrate the quick reversible restoration of the disordered state. This nonequilibrium pathway to switch between order and disorder is much faster than any structural changes driven by Brownian motion in thermodynamic equilibrium. This ability for rapid, isothermal motor-induced transitions between different degrees of self-organization indicates that molecular motors, in general, may substantially contribute to dynamic cellular organization.

### Immaturity of Microtubule Networks in Alpha B-crystallin Antisense C2C12 Mouse Myoblast Cells

T. Sakurai, Y. Atomi; Department of Life Sciences, The Graduate School of Arts and Sciences, The University of Tokyo, Tokyo, Japan

Alpha B-Crystallin, one of the small heat shock proteins, has chaperon activity and may protect cytoskeletons under stress conditions and decreases during early skeletal muscle atrophy but not under stretched conditions. We have previously demonstrated interactions between tubulin/microtubules and alpha B-crystallin in cell culture extracts and rat skeletal muscle extracts using immunopresipitation and microtubule sedimentation assay. These data imply an interaction between alpha B-crystallin and tubulin/microtubules in muscle tissues. To investigate a precise role of alpha B-crystallin in vitro, C2C12 mouse myoblast cells transformed with a sense (C2C12SE) or antisense strand (C2C12AS) of alpha B-crystallin cDNA were cultured and observed the microtubule networks by immunofluorescence study. The expression levels of alpha B-crystallin were about 10-fold higher in C2C12SE cells and low in C2C12AS cells. We observed that C2C12WT and C2C12SE cells fused well. Especially, C2C12SE cells formed thick myotube. On the contrary, C2C12AS cells only lined up but could not differentiate into myotube at all. Hoechst staining revealed C2C12WT and C2C12SE cells differentiated into multinucleated myotube, but C2C12AS did not. The microtubule networks in C2C12SE cells developed well, and the dominant direction of the microtubules was longitudinal. On the other hand, the microtubule networks in C2C12AS were thin and spread rather radially than longitudinally. Though alpha B-crystallin may have other rolls because C2C12AS was observed to be too hard to fuse into myotube, these observations imply that alpha B-crystallin is essential for the formation of dense microtubule networks and may keep microtubule reorganization during differentiation. Our previous work that the decrease of alpha B-crystallin increased the rate of nocodazole-induced depolymerization of microtunbules also supports an important roll of alpha B-crystallin for microtubule network maintenance.

1718

### Non-muscle Myosin 2A and 2B are Essential for Myoblast Alignment and Fusion

N. Swailes, P. J. Knight, M. Peckham; University of Leeds, Leeds, United Kingdom

Mononucleated myoblasts form aligned groups of cells prior to fusion, in which the cells have a characteristic bipolar shape, in which the majority of the actin cytoskeleton is organised into a subplasmalemma network, 500nm thick, with mixed polarity (Swailes et al., 2004). Two non-muscle myosin isoforms (2A and 2B) are associated with this network and our objective here was to determine whether they function differently in the formation of aligned groups of myoblasts. Using immuno-electron microscopy we found that the distribution of these two myosins overlaps, but myosin 2A is more tightly associated with the actin network, with the majority of myosin 2A lying within 500nm of the plasma membrane, whereas only 50% of myosin 2B lies within this region. Using an antisense oligonucleotide treatment to knock down the expression levels of either myosin 2A or 2B, we found that both treatments interfered with formation of aligned groups and fusion, but in a different way. 2A knockdown prevented the formation of bipolar cells, and cell-cell adhesion. In contrast 2B knockdown resulted in highly elongated cells, that were double the length of untreated or control cells (treated with sense or scrambled oligonucleotides). Live cell imaging confirmed that this elongation was the result of poor cell retraction. Therefore, both of these myosins play an essential but different role in cell-cell alignment prior to fusion in myoblasts.

1719

### In Vivo Interactions of MyoD, Id1 and E2A Proteins Determined by Acceptor Photobleaching Fluorescence Resonance Energy Transfer

J. Lingbeck; Washington University School of Medicine, St. Louis, MO

MyoD, a skeletal muscle transcription factor, is rapidly degraded by the ubiquitin-proteasome system in both the cell nucleus and the cytoplasm. MyoD interacts with ubiquitously expressed E2A or Id proteins to activate or inhibit transcription, respectively. Furthermore, MyoD has been shown to modulate the ubiquitin-mediated degradation of Id1 and E2A proteins (E12 and E47). E12 and E47 also reduce the rates of degradation of MyoD and Id1 via the ubiquitin-proteasome system, however, the molecular mechanisms governing these events are not clear but are thought to occur via heterodimer formation. Fluorescence resonance energy transfer (FRET) which measures the energy transfer from a donor molecule to an acceptor molecule within 100 Å is a powerful technique for evaluation of protein-protein interactions *in vivo*. Using acceptor photobleaching FRET and chimeric proteins composed of MyoD, Id1, E12, E47, $E12^{NLS}$, or $MyoD^{NLS}$ and either CFP or YFP we show that MyoD, Id1, E12 and E47 each form homodimers within the cell. Furthermore, we show 1) MyoD interacts directly with Id1, 2) E12 and E47 each dimerize with MyoD and with Id1 and 3) E12 interacts with Id1, but not MyoD in the cytoplasm. The FRET results further show stronger binding of Id1 to E12 or to E47 than to MyoD which supports the notion that regulation of MyoD occurs by the sequestration of E2A proteins by Id1 both in the nucleus and in the cytoplasm. It also suggests that heterodimerization is likely responsible for the decreases in the degradation rates of these proteins via the ubiquitin-proteasome system.

1720

### MRF4 is Upstream of MyoD, Myf5, Myogenin in Transactivation Hierarchy during Myogenic Differentiation of Bovine Adult Myoblasts

Y. Matsubara,[1] Y. Hondo,[1] A. Yamaguchi,[1] M. Miyamoto,[1] S. Muroya,[2] K. Maruyama[1]; [1]Department of Life Science, Meiji University, Kawasaki, Japan, [2]Department of Animal Products, National Institute of Livestock and Grassland Science, Ibaraki, Japan

Myogenic regulatory factors (MRFs: MyoD, Myf5, myogenin, and MRF4) control the differentiation of muscle lineage cooperatively. However, the hierarchy of their transactivation and their roles in the lineage determination and differentiation have not been defined. In this study, the interaction among MRFs was investigated in bovine adult myoblasts using RNA interference with a hypothesis that MRF4 was positioned upstream of MyoD, Myf5, and myogenin in transactivation hierarchy. Adult myoblasts were isolated from bovine *Musculus Biceps femoris* and purified to contain desmin-positive cells at more than 95%. Small interfering RNA against respective MRFs: siMyoD, siMyf5, simyogenin, and siMRF4 were designed and custom-synthesized. After the myoblasts were transfected with a single or a combination of siRNAs and differentiation was induced by reducing the amount of FBS in the medium, the MRF expression was detected by real-time reverse-transcription polymerase chain reaction two days later. Myogenic differentiation was analyzed by the monoclonal antibody staining for MyHC and the nuclear staining with Hoechst33258 six days later. The expression of MyoD, Myf5, myogenin, and MRF4 was reduced to 56.4%, 61.5%, 25.7%, and 33.1%,

respectively, by the respective siRNAs. The siMRF4 reduced all MRFs expression. The siMyoD reduced Myf5 and myogenin expression, while increasing MRF4 expression. The simyogenin reduced MyoD and Myf5 expression without affecting MRF4 expression. The siMyf5 reduced only myogenin expression. When myoblasts were transfected with siMyoD and siMyf5, the expression of all but MRF4 was reduced. The fusion index (percentage of nuclear number in the MyHC-positive cell/total nuclear number) was reduced by siMyoD or siMRF4. The siMyoD drastically suppressed the myotube formation. The polynuclear index (the number of nuclei in the MyHC-positive cells) was elevated by siMyf5 and reduced by simyogenin.

1721

**Stage-dependent Protein Degradation via the Ubiquitin Proteasome Pathway Regulates E2A Protein Levels during Muscle Differentiation**

L. Sun,[1] J. S. Trausch-Azar,[1] A. Ciechanover,[2] A. L. Schwartz[1]; [1]Department of Pediatrics and Department of Molecular Biology and Pharmacology, Washington University School of Medicine, St. Louis, MO, [2]Department of Biochemistry and Rappaport Institute for Research in Medical Sciences, Technion-Israel Institute for Technology, Haifa, Israel

The E2A proteins, (i.e. E12 and E47, the two splice variants encoded by the *E2A* gene), are basic helix-loop-helix transcription factors that regulate differentiation and proliferation in many cell types. In muscle cells, the E2A proteins form heterodimers with muscle regulatory factors such as MyoD, which then bind to DNA and up-regulate the transcription of target genes. Hence, regulation of the E2A protein level is likely important for muscle differentiation. In C2C12 cells we show that endogenous E2A proteins are primarily localized in the nucleus in both myoblasts and myotubes, and appear to be degraded by the ubiquitin proteasome system as the proteasome inhibitor, MG132, stabilized E12 and E47 in both myoblasts and myotubes. Cellular abundance of E2A proteins is down regulated during the differentiation from myoblasts to myotubes. The observed reduction in E2A protein levels appears to result from a change in the rate of protein degradation rather than synthesis. Ubiquitin-proteasome-mediated E2A protein degradation is dependent on the muscle differentiation state, with t1/2 ~ 2h in proliferating myoblasts versus t1/2 ~ 7h in differentiated myotubes. No change in E2A mRNA abundance was detected via RT-PCR nor was a change in E2A protein synthesis detected in myoblasts versus myotubes. These results support an important role for E2A protein in the regulation of muscle differentiation, and have implications for the involvement of ubiquitin-proteasome-mediated protein degradation in muscle development under abnormal and pathological conditions.

1722

**Indirect Flight Muscles (ifm) of *Drosophila*: A Model for Human Nemaline Myopathy**

V. Kumar,[1,2] J. C. Sparrow,[2] M. Peckham[1]; [1]The School of Biomedical Sciences, University of Leeds, Leeds, United Kingdom, [2]Biology, University of York, York, United Kingdom

The nemaline myopathies (NM) are a group of human neuromuscular disorders characterized by muscle weakness and the presence of nemaline bodies/rods in skeletal muscle fibres. They are caused by mutations in thin filament proteins (nebulin, actin, troponin and tropomyosin), but actin mutations are the most common. Over 100 mutations in the human skeletal α-actin gene, *ACTA1*, have been identified, of which most are dominant and occur in families with no previous history of the disease (reviewed by Sparrow *et al*., 2003). We investigated how mutations in skeletal actin cause NM using Drosophila indirect flight muscle (IFM) as a model system. IFM specific actin (ACT88F) is highly homologous (93% conserved) to human skeletal α-actin. Using p-element transformation, transgenic flies were generated for three different mutations: G15R, V163L and V163M, that were either heterozygous or homozygous for the mutation. We found that these mutations resulted in a range of phenotypic changes similar to those seen in humans with nemaline myopathy, including variable sarcomere lengths and 'zebra bodies', confirming that the Drosophila IFM system is a good model for this disease. Results from immuno-staining and electron microscopy show that assembly of thin filaments is abnormal during muscle development, and that the filament lengths are highly variable. This suggests that the major defect resulting from the NM mutations is mis-regulation of filament length.

1723

**Domain Function and Genetic Analysis of the *C elegans* ALP/Enigma Gene, *alp-1***

H. Han,[1,2] C. R. McKeown,[2] M. C. Beckerle[1,2]; [1]Oncological Sciences, University of Utah, Salt Lake City, UT, [2]Huntsman Cancer Institute, Salt Lake City, UT

ALP-Enigma proteins are prominently expressed in muscle and display one N-terminal PDZ domain and one or three C-terminal LIM domains. Targeted gene disruption studies in the mouse have suggested that ALP-Enigma proteins are critically important for muscle stability, and deficiencies in this family are associated with muscle disease. To further study these proteins, we identified a single genetic locus, *T11B7.4*, which encodes the entire ALP-Enigma protein family in *Caenorhabditis elegans*. The *alp-1* gene encodes four transcripts that result from alternative splicing. *alp-1a* encodes an ALP homologue, and *alp-1b*, *c*, and *d*, encode Enigma-like proteins. ALP-Enigma proteins are localized at dense bodies and dense plaques, two actin anchorage sites in *C. elegans* muscle. To understand the function of the shared PDZ domain, we generated transgenic worms expressing the ALP-1 PDZ domain under the control of a heat-shock promoter. Our data demonstrate that the ALP-1 PDZ domain is sufficient for localization to dense bodies within muscle cells, but not to dense plaques. To explore ALP-Enigma function *in vivo*, we have characterized two *alp-1* deletion alleles (generated by the *C. elegans* Gene Knockout Consortium and National Bioresource Project). The more severe *alp-1(tm1137)* mutant is predicted to encode a protein in which LIM1 is deleted and premature translational termination occurs. By Western immunoblot analysis, we fail to detect ALP-1A, B or D protein products in the *alp-1(tm1137)*. Although our current reagents cannot detect the expression of ALP-1C, the nature of the *alp-1(tm1137)* mutation suggests that ALP-1C would also be affected by the deletion. Phenotypic analysis demonstrates that the *alp-1* mutants display pharyngeal pumping, locomotion and brood size that are indistinguishable from wild-type. Thus, in contrast with vertebrate systems, muscle function is not compromised in the *C. elegans alp-1* mutants analyzed to date.

1724

**Visualization of Ectopic Calcification in mdx Mouse Skeletal Muscle 2**

N. Kikkawa,[1] M. Shiozuka,[1] T. Kogure,[2] R. Matsuda[1]; [1]The Graduate School of Arts and Sciences, The University of Tokyo, Tokyo, Japan, [2]The Graduate School of Science, The University of Tokyo, Tokyo, Japan

It has been demonstrated that osteogenic differentiation of skeletal muscle cells can be induced by osteogenic factors, such as bone morphogenetic protein-2 (BMP-2), both in vitro and in vivo. One example of spontaneous ectopic calcification was seen in skeletal muscle of mdx mouse, a model of Duchenne muscular dystrophy (DMD). Ectopic calcification was observed by using high-resolution X-ray microtomography Skyscan 1074, which gives resolution of 22um. The compound of this ectopic calcification was revealed to be hydroxyapatite by electron dispersive X-ray spectrometry and X-ray diffraction. Ectopic calcification tended to increase with age in mdx mouse, while no ectopic calcification was observed in skeletal muscle of B10 mouse, which possesses normal dystrophin gene and was used as a negative control. Alkaline phosphatase activity of mdx mouse skeletal muscle was higher than in B10 mouse, but the region of high activity did not overwrap with the calcification. Correlations between muscle degeneration and ectopic calcification were studied by intraperitoneal injection of calcein, tetracycline and Evans blue. The former two were used to monitor calcification, and the last one as a marker of muscle degeneration. Calcified regions and Evans blue positive regions did not coincide, suggesting that calcification does not occur immediately after muscle degeneration.

1725

**Alteration of FHL1 & FHL3 Protein Levels and Localisation in a Congenital Muscle Disease and Hypertrophy**

M. T. Nguyen,[1] J. E. Joya,[1] C. A. Mitchell[2]; [1]Muscle Development Unit, Children's Medical Research Institute, Sydney, Australia, [2]Department of Biochemistry and Molecular Biology, Monash University, Melbourne, Australia

Nemaline myopathy (NM) is a skeletal muscle disease defined by the presence of sarcomeric disruption and electron dense structures within the sarcomere and/ or nucleus of muscle fibers called rods. These rods are thought to be formed by the unchecked expansion of the α-actinin-rich Z-line. Understanding the mechanism of disruption of the filament systems in muscles that causes nemaline myopathy is of great interest. Candidate molecules that could participate in this mechanism are members of the Four and a half LIM (FHL) domain protein family present in skeletal muscle, FHL1 & FHL3. In particular, FHL3 has been shown to disassemble actin fibers in cell cultures and to inhibit α-actinin bundling of actin. Indeed, Affymetrix array analysis of nemaline patients showed an increase in FHL3 mRNA. We have determined that both FHL1 and FHL3 proteins are upregulated in muscles of our mouse model for nemaline myopathy. In normal muscles, the FHLs localize to the mitochondria, Z- and M-line of the myofiber. In NM muscles, FHL1 and FHL3 no longer co-localize with mitochondria. FHL1 translocates to the nucleus, reminiscent of its localization in immature muscle. In contrast, FHL3 is present in nemaline rods, suggesting a possible role in sarcomeric disruption. Additional features of NM are hypertrophy of specific fibers and moderate, segmental regeneration/repair. The presence of FHL1 in the nuclei may reflect a role in these processes. To address this, localisation of FHL1 was assessed in overloaded, hypertrophied plantaris and regenerating EDL muscles. Nuclear localization of FHL1 was detected in both paradigms. Taken together, these data suggest a role for FHL1 in both hypertrophic and regenerative pathways and for FHL3 in sarcomeric disruption in NM.

1726

**Targeted Ablation of the Mouse Smooth Muscle Gamma-Actin Gene in Mice**

J. C. Szucsik,[1] K. Crawford,[1] J. Lorenz,[2] R. Paul,[2] K. Stringer,[3] E. Brunskill,[4] A. G. Lewis,[5] J. L. Lessard[1]; [1]Developmental Biology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, [2]Molecular and Cellular Physiology, University of Cincinnati College of Medicine, Cincinnati, OH, [3]Pathology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, [4]Internal Medicine, The University of Cincinnati College of Medicine, Cincinnati, OH, [5]Pediatric Urology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH

The actins are one of the most highly conserved protein families known. In higher vertebrates the actin gene family consists of at least six members, two cytoplasmic isoforms beta- and gamma-actin, as well as four muscle isoforms: cardiac-, enteric-, skeletal-, and vascular-actin. Here, we report the gene targeting of the enteric or smooth muscle gamma-actin (SMGA) gene in mouse embryonic stem cells and the subsequent generation of SMGA null mice. A gene-targeting construct was created to remove the first 60 amino acids of the gene. The construct was electroporated into embryonic stem (ES) cells and approximately 275 colonies were screened. A single ES cell colony with a correctly targeted SMGA allele was identified, expanded, and cells used for blastocyst injections and the generation of chimeric mice. Germline transmission of the targeted SMGA allele was seen in several chimeras. Matings between SMGA heterozygous mice resulted in the predicted Mendelian inheritance pattern of 1:2:1 of wild-type: heterozygous: null offspring. The SMGA null mice have a normal lifespan and are fertile. Matings between null males and null females resulted in normal size litters. The SMGA null mice are hypertensive and demonstrated a significantly higher mean arterial pressure than wild-type controls. Histological examination of smooth muscle containing tissues did not reveal any morphological differences between the heterozygous or null mice compared to wild-type littermates to account for this finding. Our results indicate that a functional SMGA gene is not required for development or survival, similar to the phenotype of the vascular actin null mice, and in sharp contrast to the lethal phenotype seen in cardiac- and skeletal-actin null mice. Like vascular-actin, SMGA is required for proper blood pressure regulation.

1727

**Generation of a Mouse Lacking the C-Terminal of ε-Sarcoglycan using Poly-A Trap Strategy with a Retrovirus Vector**

M. Imamura,[1] T. Sasaoka,[2] Y. Ishida,[3] S. Takeda[1]; [1]Department of Molecular Therapy, National Institute of Neuroscience, NCNP, Tokyo, Japan, [2]Laboratory of Neurochemistry, National Institute for Basic Biology, Okazaki, Japan, [3]Division of Gene Function in Animals, Graduate School of Biological Sciences, Nara Institute of Science and Technology, Ikoma, Japan

Sarcoglycans (α, β, γ and δ) are transmembrane glycoprotein components of the dystrophin-associated glycoprotein complex, which is critical for the stability of the striated muscle cell membrane. ε-Sarcoglycan (SG) was identified as a homologue of α-SG that is encoded in the causative gene for limb-girdle muscular dystrophy type 2D. However, unlike α-SG, mutations in its gene cause myoclonus-dystonia syndrome but not muscular dystrophy. This indicates the importance of ε-SG for the function in the central nervous system. We found the expression of two ε-SG isoforms in the brain under alternative splicing: one is the conventional type of ε-SG (ε-SG 1) and the other is a brain-specific type (ε-SG2) (Mol. Brain Res. 2004, 125: 1-12). These isoforms are characterized by their different C-terminal sequences and different localization in synaptosomal membranes. Therefore, we hypothesized that these unique structures at the C-terminus are related to individual specific roles at synapses in neuron. To test this, we generated a mouse lacking the C-terminal structures of ε-SGs by poly-A trap strategy. In the bank of gene-trapped mouse ES cells, we found a cell clone having integration of a removable exon trap (RET) retrovirus vector into the *ε-SG* gene (Nucleic Acids Res. 2005, 33: e20) and then generated gene-targeted mice using the ES cell clone. Analysis of genomic DNA of the mice indicated the RET vector integration into intron 11 of

the *ε-SG* gene, resulting in deletion of C-terminal unique sequences of both ε-SG isoforms. Moreover, protein analysis of the mouse brain homogenate also suggested loss of the C-terminal sequences of the isoforms. In conclusion, we have successfully obtained a mouse model for studying the function of ε-SG in the central nervous system.

1728

### *In vitro* and *In vivo* Efficacy of the Cardiac Myosin Activator CK-1827452

R. L. Anderson, S. H. Sueoka, H. M. Rodriquez, K. H. Lee, D. R. Cox, B. P. Morgan, R. Sakowicz, D. J. Morgans, F. Malik, K. A. Elias; Cytokinetics, Inc, South San Francisco, CA

Current inotropic therapies improve contractility by increasing the calcium transient via the adenylyl cyclase pathway, or by delaying cAMP degradation through inhibition of phosphodiesterase (PDE). However, these treatments can be detrimental to patients with heart failure. A preferred approach to improving cardiac contractility may be to directly activate cardiac myosin without changing the calcium transient. Utilizing biochemical assays, we identified compounds (cardiac myosin activators) that directly activate the cardiac myosin ATPase. The cellular mechanism of action, *in vivo* cardiac function in Sprague Dawley (SD) rats, and efficacy in SD rats with defined heart failure to CK-1827452 was then determined. Cellular contractility was quantitated using an edge detection strategy and calcium transient measured using fura-2 loaded adult rat cardiac myocytes. Cellular contractility increased over baseline after exposure to CK-1827452 (0.2 μM) without altering the calcium transient. Combination of CK-1827452 with isoproterenol (β-adrenergic agonist) resulted only in an additive increase in contractility with no further change in the calcium transient demonstrating CK-1827452 is not inhibiting the PDE pathway. *In vivo* contractile function in anesthetized SD rats was quantitated using echocardiography (M-mode) and simultaneous pressure measurements. SD rats were infused with vehicle or CK-1827452 at 0.25 - 2.5 mg/kg/hr. CK-1827452 significantly increased fractional shortening (FS) and ejection fraction (EF) in a dose-dependent manner with no significant change in peripheral blood pressure or heart rate. Rats with defined heart failure induced by left coronary ligation, or sham treated rats had similar and significant increases in FS and EF when treated with CK-1827452. In summary, CK-1827452 increases cardiac contractility without increasing the calcium transient and is efficacious in a rat model of heart failure. These data indicate that CK-1827452 may be a useful therapeutic in the treatment of human heart failure.

1729

### A Multiplexed and Automated Imaging Assay of Cardiac Myocyte Contractility

D. Lenzi, A. Fritsch, G. Alexander, R. Hansen, G. Cong, W. Zink, G. Godinez, A. Pham, J. Trautman, D. Pierce, F. Malik, J. T. Finer; Assay Development, Cytokinetics Inc., South San Francisco, CA

Cardiac myocyte contractility has traditionally been measured using single cell assays. In order to increase throughput and statistical power and facilitate quantitative measurement of the effects of small molecules on cardiomyocyte contractility, we have invented an automated imaging assay that achieves a throughput of more than a thousand cells per experimentalist-day. We took a parallel approach in which multiple cells are measured at once and multiple conditions explored within a computer-controlled experiment. Acutely-dissociated rat ventricular cardiomyocytes are maintained on the stage of an inverted microscope with environmental control in an array of multiple perfusion chambers with integrated electrodes for field stimulation. Imaging is accomplished using a low-magnification objective, and up to 30 contracting cells are imaged per field. Using a motorized stage, multiple fields are imaged per chamber. Custom control software interleaves movie acquisition before and after compound exposure. Movies are taken at high spatial and temporal resolution using a CCD camera and analyzed using custom segmentation and peak-detection algorithms. Distributions of systolic and diastolic lengths are quantified pre and post compound exposure, and dose-response curves computed based on changes in the distributions of contractile behavior. We have successfully used this platform to characterize compounds.

1730

### Hic-5 is a Mediator of Tensional Force, Translocating from Focal Adhesions to Actin Stress Fibers upon Mechanical Stress and Regulating the Contractile Capability of Cells

J. Kim-Kaneyama, M. Shibanuma, K. Nose; Microbiology, Showa University, Tokyo, Japan

Hic-5 is a focal adhesion protein belonging to the paxillin LIM family and shuttling in and out of the nucleus. In the present study, we examined the expression of Hic-5 among mouse tissues by immunohistochemistry and found its exclusive expression in smooth muscle cells in several tissues. This result was consistent with a previous report on adult human tissues and in contrast to the relatively ubiquitous expression of paxillin, the protein most homologous to Hic-5. One factor characterizing smooth muscle cells in vivo is a continuous exposure to mechanical stretch in the organs. To study the involvement of Hic-5 in cellular responses to mechanical stress, we exposed mouse embryo fibroblasts to a uni-axial cyclic stretch and found that Hic-5 was relocalized from focal adhesions to stress fibers through its C-terminal LIM domains during the stress. In sharp contrast, paxillin did not change its focal adhesion-based localization. Among the factors tested including interacting partners of Hic-5, only CRP2, an LIM-only protein expressed in vascular smooth muscle cells, and GIT1 were localized to stress fibers, like Hic-5, during the cyclic stretch. Interestingly, Hic-5 showed a suppressive effect on the contractile capability of cells embedded in three-dimensional collagen gels, and the effect was further augmented by CRP2 co-localized with Hic-5 to fiber structures of those cells. These results suggested that Hic-5 was a mediator of tensional force, translocating directly from focal adhesions to actin stress fibers upon mechanical stress and regulating the contractile capability of cells in the stress fibers.

1731

### Heat Shock-related Protein 20 (hsp20) is a Key Player in Airway Smooth Muscle Relaxation

M. Hinojosa-Kurtzberg, J. Thresher, P. Komalavilas, C. M. Brophy; Bioengineering, Arizona State University, Tempe, AZ

Airway contraction (bronchoconstriction) is a central feature in asthma. Circulating catecholamines and free 5-hydroxytryptamine (5-HT) in the plasma are increased during asthma attacks that correlate with bronchoconstriction and clinical severity. Activation of cyclic nucleotide pathways by nitrovasodilators or $\beta$ -adrenergic agonists leads to phosphorylation of the small heat shock-related protein 20 (HSP20) on Ser 16 mediating vascular smooth muscle relaxation. We have demonstrated earlier that transducible HSP20 phospho- peptides relax vascular smooth muscle from various species after muscarinic and serotonergic agonist-induced contraction. We hypothesized that HSP20 is phosphorylated in response to

increased cyclic nucleotide levels in airway smooth muscle (ASM) mediating relaxation. Bovine airway smooth muscle strips were isolated and treated with contractile agents and vasodilators in a muscle bath followed by biochemical analysis of the phosphorylation of HSP20. Treatment with methacholine ($10^{-8}$-$10^{-5}$M) or 5-HT ($10^{-8}$-$10^{-5}$M) led to a dose dependent contraction of airway SMC. In muscles precontracted with methacholine, isoproterenol (IPT), a β-adrenergic agonist which activates cAMP pathways, induced a dose-dependent relaxation with complete relaxation at $10^{-5}$ M. In ASM precontracted with 5-HT ($10^{-5}$M), sodium nitroprusside, a nitrovasodilator that activates cGMP pathways induced a dose dependent relaxation with complete relaxation at $10^{-}$5 M. There were no increases in the phosphorylation of HSP27 or HSP20 with methacholine or 5-HT induced contractions. However treatment of 5-HT- precontracted airway SMC with IPT was associated with increased HSP20 phosphorylation (72% of total HSP20 protein). Moreover, phosphopeptide analogues of HSP20 led to significant relaxation (63% of maximal contraction) of ASM. These data support a role for HSP20 in mediating airway smooth muscle relaxation and suggest that proteomic approaches may be developed for treatment of asthma.

1732

**Full-length and Peptide Analogs of Phosphorylated HSP20 are Effective Elicitors of a Relaxed Phenotype in Intact Vascular Smooth Muscle and Isolated Cell Systems**

C. R. Flynn,[1] C. Smoke,[1] P. Komalavilas,[1] J. Thresher,[1] M. Guo,[2] R. Penn,[2] C. Brophy[1]; [1]Harrington Department of Bioengineering, Arizona State University, Tempe, AZ, [2]Center for Human Genomics, Wake Forest University Health Science Center, Winston-Salem, NC

We have shown previously that cyclic nucleotide dependent relaxation of vascular smooth muscle is mediated by the small heat-shock-related protein HSP20. This protein is phosphorylated by two different kinases, namely protein kinase A (PKA) and protein kinase G (PKG). In isolated cells phosphorylated (S16) HSP20 (pHSP20) is known to associate with G-actin and other cytoskeletal adapter proteins leading to stellation and a reduction in stress fibers. In intact tissues, pHSP20 inhibits the development of force in response to contractile agonists but does not decrease energy consumption or the phosphorylation of $MLC_{20}$. In this study, transducible HSP20 analogs were generated *ex vivo*, characterized and analyzed for their ability to elicit a relaxed phenotype in both intact tissues and isolated cell systems. cDNAs encoding the catalytic subunit of PKG and HSP20 with an appended amino terminal protein transduction domain (PTD-HSP20) were co-expressed in bacteria and yielded an *in vivo* phosphorylated full-length HSP20 analog as revealed by phospho-specific antibodies and two-dimensional PAGE. A 57% inhibition of a 5-HT-induced contraction of male rat artery was observed after pretreatment with this PTD-pHSP 20. Western blots confirmed the recombinant PTD-pHSP20 was transduced into the vascular strips and that $MLC_{20}$ phosphorylation remained unchanged. Immunofluorescence microscopy of human airway smooth muscle (HASM) cells stably-transfected with a GFP marker and incubated with a peptide mimicking PTD-pHSP20 revealed a time-dependent progression of localization from the cell boundary membrane to the perinuclear region. This localization was commensurate with stellation and a reduction in stress fiber formation. These results support the premise that *ex vivo* synthesized transducible HSP20 analogs are effective in regulating vasomotor tone and do so in a manner downstream of events associated with cyclic nucleotide relaxation.

1733

**Protein Kinase A Inhibition Reverses Forskolin Induced Phosphorylation of Heat Shock-related Protein 20 and Disruption of Stress Fibers in Human Airway Smooth Muscle Cells**

P. Komalavilas,[1] C. R. Flynn,[1] J. Thresher,[1] M. Guo,[2] R. Penn,[2] M. A. Pallero,[3] J. E. Murphy-Ullrich,[3] C. M. Brophy[1]; [1]Harrington Department of Bioengineering, Arizona State University, Tempe, AZ, [2]Center For Human Genomics, Wake Forest University, Winston-Salem, NC, [3]Pathology, University of Alabama at Birmingham, Birmingham, AL

Activation of cyclic nucleotide signaling pathways leads to phosphorylation of the small heat-shock- related protein 20 (HSP20) and actin cytoskeletal changes resulting in the relaxation of vascular smooth muscle. We hypothesized that HSP20 is phosphorylated by protein kinase A (PKA) in response to cAMP elevation in airway smooth muscle cells and leads to disruption of stress fibers. Treatment of human airway smooth muscle (HASM) cells (GFP) with forskolin or isoproterenol that elevate cAMP levels led to increases in HSP20 phosphorylation and loss of stress fibers. HASM cells in which PKA is inhibited (expressing protein kinase inhibitor PKI-GFP), forskolin or isoproterenol failed to increase the phosphorylation of HSP20. There was no disruption of stress fibers in PKA inhibited cells compared to control. Phosphorylation of VASP was also inhibited in cells expressing PKI. Forskolin and isoproterenol decreased phosphorylation of cofilin, the actin depolymerizing protein in control HASM cells, but not in PKA inhibited cells. Forskolin also inhibited focal adhesion formation in control cells but not in PKI-GFP. There was upregulation of HSP20 and protein kinase G in PKA inhibited cells compared to control, however the expression of HSP20 and PKG were lost upon continuous passage of cultures. These results suggest that activation of cAMP pathways leads to phosphorylation of HSP20 and dephosphorylation of cofilin resulting in the disruption of actin stress fibers in HASM and that the effect is mediated by PKA.

## Kinesin I (1734-1748)

1734

**ZBP1 Mediates mRNA Granule Localization Through a Direct Interaction with a Novel Kinesin Light Chain-like Protein in Neurons**

J. B. Dictenberg,[1] K. J. Verhey,[2] R. H. Singer,[3] G. J. Bassell[1]; [1]Neuroscience and Anatomy/Structural Biology, Albert Einstein College of Medicine, Bronx, NY, [2]Cell and Developmental Biology, University of Michigan Medical School, Ann Arbor, MI, [3]Anatomy/Structural Biology, Albert Einstein College of Medicine, Bronx, NY

Subcellular localization of mRNAs and local protein synthesis are important for process outgrowth and plasticity in neurons. However the molecular details of mRNA-motor interactions remain unknown. This report reveals a direct interaction between the microtubule motor kinesin and an integral component of RNA granules, the zipcode-binding protein 1 (ZBP1) which binds to the 53-nt element (zipcode) within the 3'UTR of beta-actin mRNA and localizes in neurites and growth cones in response to synaptic stimulation. ZBP1 associated with microtubules in a nucleotide-sensitive manner. Immunofluorescence microscopy in hippocampal neurons and immunoprecipitations from brain demonstrated that ZBP1 associated with kinesin heavy (KHC) and light chains (KLC) in dendrites and growth cones but not with other kinesin isoforms. Beta-actin but not vinculin mRNA bound to KHC and KLC in a "zipcode"-dependent manner. Yeast two-hybrid analysis revealed ZBP1 bound to kinesin-I through a novel, phylogenetically conserved KLC-like adapter protein that was enriched in mRNA granules localized to growth cones and

dendrites. Domain mapping showed this protein bound to the cargo-binding domain of KLC through a TPR-TPR interaction and to the N-terminus of ZBP1 containing 2 RRM domains. Importantly, inhibition of kinesin-I subunits and this novel KLC-interacting protein in fixed and living hippocampal neurons (using antisense, dominant negative, and RNAi) disrupted BDNF-stimulated ZBP1 and mRNA transport into dendrites and growth cones, while total poly-A mRNA and vesicular cargoes known to interact with KLC (JIP1) were not affected. These data suggest a model by which ZBP1 functions as a receptor within mRNA granules by binding to the motor directly through this novel KLC-like adapter to localize beta-actin mRNA and possibly many other mRNAs to dendrites in response to neurotrophic signals involved in cytoskeletal remodeling.

1735

**Transport of Mitochondria Requires a Complex of Milton and Miro to Recruit Kinesin Heavy Chain, but does not Require Kinesin Light Chain**

E. E. Glater, L. J. Megeath, T. L. Schwarz; Division of Neuroscience, Children's Hospital and Harvard Medical School, Boston, MA

Mitochondria are distributed within cells in order to match local energy demands. Milton, a *Drosophila* protein, is essential for transport of mitochondria. In homozygous *milton* mutant larvae, mitochondria are absent from axons, but other cargoes, such as synaptic vesicles, are present. We now report that milton acts as an adaptor protein that can recruit the heavy chain of conventional kinesin-1 (KHC) to mitochondria. We have mapped the functional domains of milton: an amino-terminal domain (aa 138-450) is required for binding to KHC; a carboxyl-terminal domain (aa 847-1116) is sufficient for milton's localization to the mitochondria. Biochemical and genetic evidence demonstrate that kinesin recruitment and mitochondrial transport are independent of kinesin light chain (KLC): KLC antagonizes milton's association with KHC in immunocytochemistry and co-immunoprecipitation experiments, KLC is absent from milton-KHC complexes, and mitochondria are present in *klc*$^{-/-}$ photoreceptor axons. The recruitment of KHC to mitochondria is in part determined by the amino-terminus splicing variant of milton. All four forms of milton localize to mitochondria, but only three of the four splice variants recruit KHC in transfected cells. The variant (milton-C) that does not recruit KHC does, however, contain the KHC-association domain, suggesting that its amino-terminus can inhibit the association with KHC. In addition, milton was found to bind to miro, a mitochondrial Rho-like GTPase, in a yeast two hybrid screen of the *Drosophila* proteome (Giot *et al.,* 2003 Science 302: 1727-36). We have confirmed this interaction with co-immunoprecipitation experiments from transfected cells and have shown that miro governs the recruitment of milton and hence KHC to mitochondria. Milton and miro thus form an essential protein complex that links KHC to mitochondria for KLC independent, anterograde transport of mitochondria.

1736

**Single Molecule Analysis of Kinesin 1 Activation through Cargo Binding**

C. Huang, B. J. Schnapp; Cell & Developmental Biology, Oregon Health & Science University, Portland, OR

Kinesin 1 is present largely as soluble tetramer of two heavy chains and two light chains that is self-inhibited with respect to ATPase activity and microtubule binding. Self-inhibition depends on folding of the kinesin heavy chains, which allows for an intra-molecular interaction between its C-terminal residues and the N-terminal motor/ neck regions. The kinesin light chains are also needed for full inhibition in vivo. Much less is understood about how Kinesin 1 becomes activated for cargo transport. To address whether activation occurs directly through specific cargo binding, we have examined how the motility of single recombinant GFP-tagged Kinesin 1 tetramer is affected by the binding of defined cargo-linker molecules to its two known cargo binding sites. JIP and SNAP25 recognize and bind to the light chain TPRs and the heavy chain cargo binding domain, respectively. Addition of a JIP-C-terminal peptide increases the frequency of Kinesin 1 motility events without significantly affecting their velocity (~8µm/min). Addition of SNAP25 principally affects velocity. In the presence of SNAP25, the distribution of the velocity of motility events appears to be bimodal with a minor peak at ~20µm/min in addition to the major 8µm/min peak. These findings suggest that each cargo can relieve the self-inhibition of kinesin through different mechanisms. This is parallel to previous reports that light chain inhibits the binding of tetramer to the microtubule and that the tail domain of heavy chain represses motor activity. We conclude that cargo binding itself can activate conventional kinesin activity and that the coordination of light chain and heavy chain cargo binding may be an importlant way of regulating kinesin activities and hence intracellular transport in vivo.

1737

**Fluorescence Resonance Energy Transfer (FRET) Stoichiometry Reveals Kinesin-1 Activation Mechanism in Live Cells**

D. Cai,[1] A. Hoppe,[2] J. Swanson,[2] K. Verhey[1]; [1]Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, [2]Microbiology and Immunology, University of Michigan, Ann Arbor, MI

In the absence of cargo, kinesin-1 is inactive for microtubule-based motility. Previous work has suggested that kinesin-1 is able to adopt distinct conformations *in vitro*. Based on these observations, it has been hypothesized that the inhibited kinein-1 is folded whereas the active kinesin-1 is extended. To reveal kinesin-1 conformational changes upon inhibition-activation in living cells, we used FRET stoichiometry to study Fluorescent Protein-labeled kinesin-1 molecules. When expressed in COS cells, kinesin-1 is not active for microtubule binding and is in a tightly folded conformation. In the absence of kinesin light chain (KLC), the kinesin heavy chain (KHC) dimer is no longer tightly folded and is active for microtubule binding. The two motor domains of the active KHC are closer together, presumably in the right spatial arrangement to bind to adjacent ÃŽÂ²-tubulin subunits of a microtubule protofilament. This implies that KLC polypeptides force the two KHC motor domains apart in the folded inactive motor. Truncation of the KHC tail domain resulted in a molecule that, although folded with the KHC motor domains pushed apart, was active for microtubule binding. Thus, the KHC tail domain contributes to auto-inhibition by blocking the microtubule binding site of the KHC motor domain. These results support the hypothesis that kinesin-1 undergoes a global conformational change *in vivo*, from folded and inhibited to extended and activated. Our results also suggest an important local conformational change between the two KHC motor domains upon activation. We propose that release of both KLC polypeptides and the KHC tail domains from the KHC motor domains is required for activation of motor activity *in vivo.*

1738

**Fasciculation and Elongation Protein ζ-1 (FEZ1) Plays a Role in the Activation of Kinesin-1**

K. Verhey, G. Jih, L. Blasius; Cell and Developmental Biology, University of Michigan, Ann Arbor, MI

In the absence of cargo, kinesin-1 is auto-inhibited due to a direct interaction of the kinesin heavy chain (KHC) tail domain with the KHC motor domain. How kinesin-1 is activated upon cargo binding is unknown. We tested the possibility that cargo binding activates the motor for microtubule-based motility. Binding of kinesin-1 to the cargo molecule JNK Interacting Protein 1 (JIP1) was not sufficient to activate kinesin-1 for microtubule binding. Given these results. we hypothesized that additional proteins may be required for kinesin-1 activation. We identified fasciculation and elongation protein ζ-1 (FEZ1), the mammalian orthologue of *Caenorhabditis elegans* UNC-76, as a binding partner of KHC. FEZ1 binds to the inhibitory coiled region of the KHC tail domain, adjacent to the IAK residues required for auto-inhibition, suggesting that FEZ1 plays a role in regulating kinesin-1 activity. Consistent with this, binding of both JIP1 and FEZ1 to kinesin-1 was sufficient to activate the motor for microtubule binding. These results suggest that FEZ1 plays a role in activation of kinesin-1 upon cargo binding.

1739

**Microtubule Acetylation Dictates Kinesin-1 Binding to Microtubules and Transport in Neuronal Cells**

N. A. Reed,[1] G. W. Jih,[1] J. Gaertig,[2] K. J. Verhey[1]; [1]Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, [2]Department of Cellular Biology, University of Georgia, Athens, GA

Motor proteins use the energy of ATP hydrolysis to ferry cellular cargoes along microtubules and actin filaments. In neurons, the delivery of membrane and cytoplasmic cargoes must be coordinated with the decision of the growth cone to advance, pause or retract. We show using Fluorescent Recovery After Photobleaching (FRAP) that, in differentiating neuronal cells, kinesin-1 (formerly conventional kinesin or Kif5) specifically delivers the cargo molecule JNK-interacting protein 1 (JIP1) to growing neurites but not to retracting neurites. The mechanism for this distinction appears to be a specific post-translational modification (PTM) of microtubule filaments. Kinesin-1 binds *in vitro* selectively to microtubules marked by acetylation of α-tubulin at residue lysine-40 and JIP1 transport *in vivo* is increased by pharmacological treatments that increase microtubule acetylation. These data suggest that microtubule PTMs play an important role in directing protein trafficking to specific subcellular locales.

1740

**Kinesin-1 Heavy Chain Preferentially Binds to and Moves Along Detyrosinated Microtubules in Living Cells**

S. Dunn,[1] H. Musa,[1] E. E. Morrison,[2] M. Peckham[1]; [1]Biomedical Sciences, University of Leeds, Leeds, United Kingdom, [2]CRUK Clinical Research Centre, St James University Hospital, Leeds, United Kingdom

Kinesin-1 (conventional kinesin) is a microtubule-dependent motor involved in the transport of diverse cargoes. We investigated the dynamic properties of kinesin-1 using a GFP-tagged kinesin-1 heavy chain (GFP-Kif5c) *in vivo*. By live cell imaging, we show that GFP-Kif5c is a processive plus-end directed microtubule motor that moves at speeds of up to 1µm $s^{-1}$ *in vivo*, similar to speeds reported *in vitro*. Significantly, GFP-Kif5c only labeled a subset of microtubules that we think are likely to be detyrosinated (Glu-tubes) for the following reasons. First, the appearance and behaviour of these microtubules in live cells suggested that they are stable microtubules. Second, GFP-Kif5c accumulates on and moves along drug-resistant microtubules following nocodazole-induced microtubule depolymerisation in transfected cells. Finally, co-immunostaing suggests that they are composed of detyrosinated tubulin. The function of detyrosinated microtubules inside cells has remained unclear since their discovery over 20 years ago. Our results suggest that the cells may use this biochemically distinct subset of microtubules to direct kinesin-1 dependent trafficking, which in turn could be regulated by signaling pathways.

1741

**Kinesin-1 Transports Phosphorylated and Non-phosphorylated Amyloid-*β* Precursor Protein (APP) by Distinct Pathways**

Z. Muresan, V. Muresan; Physiology and Biophysics, Case Western Reserve University, Cleveland, OH

Kinesin-1 carries the transmembrane protein, APP (the precursor of the amyloid-β peptide that forms the senile plaques in Alzheimer's disease) to the axon terminal. A fraction of the total APP is transported after it is phosphorylated at Thr668 by c-Jun NH2-terminal kinase (JNK), a process that occurs in the cell body and is facilitated by JNK-interacting protein-3 (JIP-3). Using the central nervous system-derived, neuronal cell line, CAD, we show that phosphorylated APP (pAPP), but not non-phosphorylated APP, recruits kinesin-1 via JIP-1, a JNK scaffolding protein unrelated to JIP-3. Thus, pAPP serves as anchoring site and carrier for a large signaling complex that includes JIP-1, JIP-3, activated JNK, and kinesin-1, which becomes localized to the growth cone. By contrast, we find that Fe65, another APP binding protein that binds kinesin-1, forms a complex in the cell body, and is co-transported into neurites strictly with the fraction of APP that is not phosphorylated at Thr668. The two complexes are transported to different sites at the neurite terminal. Consistent with these results, down-regulation of JIP-1 by siRNA specifically impairs transport of pAPP, with no effect on the trafficking of non-phosphorylated APP. In biochemical experiments, we find that JIP-1 preferentially interacts with pAPP, compared to non-phosphorylated APP. By contrast, Fe65 binds with higher affinity to non-phosphorylated APP, compared to pAPP. We show that, in the cellular context, Fe65 prevents JIP-1 from binding to non-phosphorylated APP, but not to pAPP, a result that explains mechanistically the recruitment of kinesin-1 via JIP-1 to pAPP and via Fe65 to non-phosphorylated APP. Thus, APP transport into axons occurs via two separate populations of vesicles that differ in composition, and whose transport is differentially regulated by phosphorylation of APP.

1742

**Regulation of *drosophila* KLP10A Localization and Function by Phosphorylation**

V. Mennella, A. Asenjo, H. Sosa, D. Sharp; Physiology and Biophysics, Albert Einstein College of Medicine, Bronx, NY

Microtubule dynamics must be precisely regulated both in time and in space in order for cells to perform vital functions during the course of their lifespan. A subfamily of kinesins, termed Kinesin 13s (Kin I), have been found to be important effectors of microtubule depolymerization. Recent studies focusing on the cellular functions and dynamics of a Drosophila kinesin 13 family, KLP10A, have revealed complex regulation of this enzyme. Indeed, the targeting and activation of KLP10A appears to vary dramatically through the course of the cell cycle and among distinct subsets of cytoplasmic microtubules. In an effort to understand the underlying mechanism of this regulation, we are mapping the sites of phosphorylation of KLP10A occuring *in vivo*. Of particular interest, ESI mass spectrometry has revealed phosphorylation of a residue that is conserved throughout the entire Kinesin superfamily, suggesting that it may act as a major regulatory switch for several motors with different

functions. In addition, we have generated different cell lines exogenously expressing EGFP-KLP10A which bear mutations in this residue to mimic the phosphorylated or non-phosphorylated states. We are currently characterizing the biological activity of these mutants in an endogenous KLP10A null background generated by RNAi. The biochemical characteristics of KLP10A mutants are also being assessed in vitro.

1743

**The Depolymerizing Kinesin MCAK Undergoes 1D Diffusion to Target the Microtubule Ends**

G. J. Brouhard, J. H. Helenius, Y. Kalaidzidis, S. Diez, J. Howard; Max Planck Institute for Molecular Cell Biology and Genetics, Dresden, Germany

MCAK, a member of the kinesin-13 family of motor proteins, depolymerizes microtubules from both ends and regulates microtubule dynamics in both mitosis and interphase. The depolymerization reaction is fast, reaching a plateau rate of 4 μm/min, equivalent to the removal of 60 tubulin subunits/s per end; and the association rate to the ends is remarkably high, at about 750 x $10^6$ $M^{-1}s^{-1}$. This high rate of targeting to the microtubule ends is not understood, especially considering that MCAK shows no directed motility on the microtubule lattice. To address the question of how MCAK targets the microtubule ends so quickly, we have developed an assay for observing the activity of single MCAK motors using total-internal-reflection-fluorescence microscopy. In this assay, baculovirus-expressed MCAK-EGFP shows an ATP-dependent depolymerization of GMP-CPP microtubules from both ends. Rather than walking along the microtubule lattice, MCAK undergoes a random motion; the diffusion constant of this motion is 0.4 $\mu m^2/s$, and the half-life of lattice binding is 0.6 s, measured for >1000 single molecules. The 1D diffusion of MCAK creates a "reduction in dimensionality" that allows rapid targeting to microtubule ends, with a predicted flux of MCAK to each end on the order of 10 $s^{-1}$ at 10 nM MCAK, or 1000 x $10^6$ $M^{-1}s^{-1}$. This is sufficiently high to account for the association rate to the ends and for the rapid depolymerization of the microtubule.

1744

**MCAK Domains Essential for Microtubule Depolymerization Activity During Spindle Assembly**

S. C. Ems-McClung,[1] K. M. Hertzer,[1] M. W. Miller,[2] C. E. Walczak[1]; [1]Medical Sciences Program, Indiana University, Bloomington, IN, [2]Biological Sciences, Wright State University, Dayton, OH

MCAK, a Kinesin-13, depolymerizes microtubules rather than translocating along them. Similar to other kinesins, MCAK activity is regulated by domains outside of the catalytic domain. While several studies have examined the putative function of these regulatory regions, it remains unclear which domains are most critical to control microtubule depolymerization activity and how this correlates with MCAK activity during spindle assembly. We expressed and purified eight different MCAK deletion and/or catalytic domain point mutation constructs from insect cells and analyzed their depolymerization activity using a dose-response assay. We found that the MCAK neck domain and C-terminal domain are important for robust *in vitro* microtubule depolymerization, whereas the far N-terminus is not necessary. When the far N-terminus and C-terminal domain deletions are combined into our minimal domain construct, depolymerization activity is further compromised. This is in contrast to cellular transfection assays, in which the far N-terminus is important, the C-terminal domain is not important, and minimal domain functions as well as full-length MCAK. Interestingly, our catalytic domain point mutant proteins showed differential depolymerization activities. To ask how *in vitro* depolymerization activity correlates with the MCAK function during spindle assembly, we immunodepleted MCAK from egg extracts and rescued the depletion with each MCAK derivative. Preliminary results suggest that the ability of an MCAK mutant to rescue physiological microtubule aster formation does not necessarily correlate with *in vitro* depolymerization. The MCAK minimal domain protein has a high affinity for tubulin dimer and may not dissociate freely from tubulin during the catalytic cycle, suggesting that domains outside of the catalytic domain contribute to efficient tubulin release. Additional biochemical analyses on the various constructs are underway to determine where in the catalytic cycle these proteins are acting differentially and how this correlates with physiological spindle formation.

1745

**Studies of Single Molecules of the Mitotic Kinesin Eg5**

B. H. Kwok,[1] L. C. Kapitein,[2] J. H. Kim,[1] C. F. Schmidt,[2] E. J. G. Peterman,[2] T. M. Kapoor[1]; [1]Cell Biology & Chemistry, Rockefeller University, New York, NY, [2]Department of Physics and Astronomy, Vrije Universiteit, Amsterdam, The Netherlands

During cell division, a bipolar mitotic spindle is required to equally segregate the genetic material into two daughter cells. Eg5 (kinesin-5), an evolutionarily conserved member of the BimC kinesin family, plays a key role in the assembly of bipolar spindles in eukaryotes. Recently, in controlled *in vitro* experiments, we have shown that full length homotetrameric recombinant Eg5 can crosslink two microtubules and walk on each filament to slide microtubules apart. Based on these studies we predicted that Eg5 is likely to be a doubly processive motor, walking many steps on each microtubule it crosslinks. To test this hypothesis and to directly observe the movements of single Eg5 molecules on microtubules, we have generated and characterized a Eg5-GFP fusion protein. We find this protein to be tetrameric in solution and show that it can functionally substitute for endogenous Eg5 in spindle assembly assays in *Xenopus* egg extracts. Fluorescence microscopy-based analyses of single Eg5 molecules reveal that Eg5 moves processively along microtubules immobilized on a surface. The average velocity of individual Eg5-GFP tetramers was ~2 microns/min and average runlength ~2.5 μm. These results provide essential input to build quantitative models for how individual molecular motor molecules contribute to mitotic spindle assembly and function.

1746

**The Bipolar Mitotic Kinesin Eg5 Moves on Both Microtubules That it Crosslinks**

L. C. Kapitein,[1] E. J. Peterman,[1] B. H. Kwok,[2] J. H. Kim,[2] T. M. Kapoor,[2] C. F. Schmidt[2]; [1]Department of Physics and Astronomy, Vrije Universiteit, Amsterdam, The Netherlands, [2]Laboratory of Chemistry and Cell Biology, Rockefeller University, New York, NY

During cell division, mitotic spindles are assembled by microtubule-based motor proteins. The bipolar organization of spindles is essential for proper segregation of chromosomes and requires plus-end directed homotetrameric motor proteins of the widely conserved kinesin-5 (BimC) family. Models for bipolar spindle formation include the "push-pull mitotic muscle" model in which kinesin-5 and opposing motor proteins act between overlapping microtubules. The precise roles, however, of kinesin-5 during this process are unknown. Using controlled *in vitro* assays, we studied how the vertebrate kinesin-5 Eg5 operates between microtubules. We found that this motor drives sliding of crosslinked microtubules

dependent on their relative orientation. This is possible because Eg5 has the remarkable capability of simultaneously moving at ~20 nm/s towards the plus-ends of each of the two microtubules it crosslinks. For anti-parallel microtubules, this resulted in relative sliding at ~40 nm/s, comparable to spindle pole separation rates *in vivo*. Furthermore, we found that Eg5 can tether microtubule plus-ends, suggesting an additional microtubule-binding mode for Eg5. Currently, we are using single-molecule imaging of Eg5-GFP to test whether single processive motors can establish the observed sliding and end-tethering. These results demonstrate how kinesin-5's are likely to function in mitosis, pushing interpolar microtubules apart, as well as recruiting microtubules into bundles that are subsequently polarized by relative sliding.

1747

**Chemical and Genetic Disruption of *Candida albicans* Kip1p: A Unique Bipolar Kinesin**

D. M. Roof, P. R. Chua, A. L. Tomasi, B. P. Morgan, D. Clarke, D. Morgans, M. Hamilton, R. Sakowicz, D. Pierce, T. Stephens, Y. Lee, M. E. Maxon; Cytokinetics, Inc., South San Francisco, CA

The genome of the pathogenic yeast *Candida albicans* encodes a single member of the bipolar (Kinesin-5) kinesin family, Kip1p. In order to screen for inhibitors of Kip1, we cloned and expressed the *C. albicans* Kip1 motor domain in *E. coli* and obtained a protein with microtubule-stimulated ATPase activity. Screening of a small molecule library and subsequent chemical modifications produced an aminobenzothiazole (ABT) compound which inhibited the Kip1 ATPase activity in an ATP-competitive fashion. This inhibition results in "rigor-like", tight association of Kip1 and microtubules *in vitro*. Upon treatment of *C. albicans* cells with the ABT compound, cell division was blocked and a unique, aberrant spindle morphology was elicited in which multiple spindle poles accumulate in close proximity to each other. Typical of bipolar kinesins in other organisms, we found that *C. albicans* Kip1 localizes to the mitotic spindle. Inducible excision of the Kip1 gene resulted in the transient appearance of a phenotype similar to that induced by the ABT compound. Surprisingly, deletion mutants were able to recover and were viable. The similarity of the effects of genetic and chemical disruption of Kip1p function support the conclusion that the ABT compound has an "on-target" effect on *C. albicans* Kip1 *in vivo*, making it a first in class fungal spindle inhibitor targeted to a mitotic kinesin. In addition, our results suggest that the non-essential nature and implementation of the bipolar motor in *C. albicans* differs from that seen in other organisms.

1748

**Differential Targeting of Related C-terminal Kinesins**

Y. Zhang, K. L. Thompson, R. Wang, A. O. Sperry; Anatomy and Cell Biology, East Carolina Universiy, Greenville, NC

Formation of the spindle pole requires the combined function of numerous structural and motor proteins, including C-terminal kinesins. We have identified a small group of highly related C-terminal kinesin motors in the mouse: KIFC1, KIFC5A, KIFC5B, and KIFC5C. The latter three isoforms are very similar to KIFC1 except for two unique sequence inserts in their tail domain, termed insert 1 and insert 2. Insert 1 of KIFC5A is necessary and sufficient to target this motor to the nucleus and enable it to bind microtubules. We wanted to determine whether the other two isoforms, 5B and 5C, have similar targeting and functional properties as compared to 5A. We propose that the unique sequences present in the B and C isoform might direct these motors to different intracellular locations where they perform distinct functions. Proteins were localized within the cell using isoform specific antibodies and GFP fusion constructs. In order to determine the role of the KIFC5A and 5B isoforms in spindle formation an in vitro microtubule aster assay was used. Our results show that the small changes in tail amino acid sequence targeted the isoforms to different locations within the cell. Also, KIFC5A, and possibly 5C, were found to be important in the formation of asters, while antibodies to KIFC5B had no effect on aster formation in vitro. Taken together, this data supports our hypothesis that minor changes in the tail domain sequences of these motors is sufficient to cause distinct cellular localization and function.

## Microtubule Dynamics & Assembly II (1749-1765)

1749

**Bisphenol A Targets the Microtubule Cytoskeleton in Yeast and Mammalian Cells**

C. Wong, A. C. Ballew, L. Cai, T. Stearns; Biological Sciences, Stanford University, Stanford University, CA

Bisphenol A (BPA) is a synthetic estrogen-related compound that polymerizes into hard, clear polycarbonate plastic that is used widely in consumer products. The BPA polymer is unstable and releases BPA monomers into solutions. BPA and related compounds have been shown to cause meiotic defects in mice, and are cytotoxic to mammalian cells. The mechanism of BPA cytotoxicity is unknown, however, some evidence suggests that BPA might affect the microtubule cytoskeleton. To identify cellular targets of BPA, we performed an induced haploinsufficiency screen in *Saccharomyces cerevisiae*. The heterozygous diploid deletion collection was grown as a pool with or without BPA, and the difference in growth rates between strains was determined using deletion barcode microarrays. The most severely growth-compromised strain was the strain heterozygous for a deletion of the yeast β tubulin, *TUB2*, suggesting that tubulin may be the main target of BPA. Consistent with this hypothesis, BPA also caused an increase in mitotic index and defects in spindle formation in wild-type yeast cells. We also tested the effect of BPA on the microtubule cytoskeleton in human diploid fibroblasts. BPA caused bundling of microtubule filaments and formation of unique ring structures. In an *in vivo* microtubule regrowth assay, BPA inhibited microtubule nucleation at the centrosome, yet enhanced non-centrosomal microtubule growth in the cytoplasm. In an *in vitro* microtubule polymerization assay, BPA caused bundling and branching of microtubules. These results suggest that BPA exerts its cytotoxic effect by altering the structure and dynamic nature of microtubule filaments.

**Resistance to Taxol or to Colcemid Associated with Different Amino Acid Substitutions at P220 of β1-Tubulin**

S. Yin, F. Cabral; Dept. of Integrative Biology and Pharmacology, University of Texas Houston Health Science Center, Houston, TX

Mutations affecting L215 and L217 in the H6/H7 loop of β1-tubulin occur at high frequency in Taxol resistant, but not colcemid resistant cells. To determine whether mutations at other residues in this loop are able to confer drug resistance, saturation mutagenesis of the highly conserved P220 in the loop was carried out. Transfection of a pool of mutagenized β1-tubulin cDNAs with randomized nucleotides at codon 220, followed by selection of the cells in Taxol, resulted in the isolation of cell lines carrying P220L and P220V substitutions. Selection of the transfected cells in colcemid, on the other hand, resulted in the isolation of cells carrying P220C, P220S and P220T. By the use of site-directed mutagenesis and

retransfection, P220L and P220V were confirmed to confer Taxol resistance, while P220C, P220S and P220T were shown to confer colcemid resistance. Consistent with a mechanism of resistance based on changes in microtubule stability, the first set of mutations caused destabilization of microtubules, but the second set caused microtubule stabilization. The results show for the first time that changes in a single amino acid in the H6/H7 loop of β1-tubulin can confer resistance to drugs with opposing actions on microtubule assembly and with distinct binding sites.

1751

**Assembly of β-Tubulin with a 30 Amino Acid Insertion**

H. Yang, F. R. Cabral; Integrative Biology and Pharmacology, University of Texas-Houston Health Science Center, Houston, TX

The N-loop of β-tubulin forms part of the lateral surface of microtubules and protrudes into the microtubule lumen. Prior studies have shown that single mutations in this region can affect microtubule assembly and thus alter the sensitivity of cells to antimitotic drugs. We now report that a 30-amino-acid insertion after residue 63 in the N-loop of class IVa β-tubulin produces a stable protein that is able to incorporate into microtubules. A plasmid containing the mutant βIVa-tubulin cDNA under the control of a tetracycline-regulated promoter was transfected into Chinese hamster ovary cells and stable cell lines with different expression levels were selected. Using immunofluorescence to visualize the microtubule network and biochemical fractionation to separate microtubule polymers from free tubulin dimers, we discovered that the mutant β-tubulin could assemble into microtubules but only at a greatly reduced efficiency. The endogenous β-tubulin assembly was not affected. Cells could tolerate a small amount of the mutant β-tubulin but high expression led to severe growth defects. The results indicate that the mutant β-tubulin folds normally and is able to form heterodimers with α-tubulin. However, mutant heterodimers act as a sink for α-tubulin, thereby lowering the effective concentration of assembly-competent tubulin and the microtubule content of the cell. These studies have identified a region in β-tubulin that can accommodate large insertions, thereby expanding the options for creating assembly-competent tubulin reporter molecules and affinity probes.

**The Protein Kinase MARK/Par-1 is Regulated by the Interaction with the p21-activated Kinase PAK5**

B. Griesshaber, D. Matenia, X. Y. Li, A. Thiessen, J. Jiao, C. Johne, T. Timm, E. Mandelkow, E. M. Mandelkow; Structural Molecular Biology, Max-Planck-Institute, Hamburg, Germany

Protein kinases of MARK/Par-1 family are involved in the development of embryonic polarity, and in neurons they phosphorylate the microtubule-associated protein tau, causing its detachment from microtubules. The target sites of MARK kinases on tau protein occur early in Alzheimer neurodegeneration which prompted us to search for regulatory factors of MARK. A yeast two hybrid screen with the MARK2 isoform yielded several interaction partners, including variants of the scaffolding protein 14-3-3, and the kinase PAK5, a member of the p21-activated kinases which is prominent in brain tissue. Both kinases contain multiple domains, including the typical kinase catalytic domain. A refined two-hybrid search for domain interactions showed that the interaction resides in the two catalytic domains, which are near the N-terminus in the case of MARK2 and near the C-terminus in the case of PAK5. PAK family kinases are activated by small G-proteins (e.g. Rac, Cdc42) and typically regulate the actin cytoskeleton, whereas MARK kinases affect the microtubule network. The interaction of the two kinase domains was confirmed biochemically and by immunoprecipitation from HEK 293 and Sf9 cells. Unexpectedly, the binding of PAK5 strongly inhibited the kinase activity of MARK, but not vice versa. The inhibition of MARK2 was mediated by the binding of PAK5(cat) as such, but not by phosphorylation. This interaction therefore constitutes a possible link between cytoskeletal regulatory pathways affecting the actin and microtubule networks (see Matenia et al., accompanying abstract). - Supported by DFG.

**Ying-Yang of Microfilament and Microtubule Dynamics Regulated by the Interference between PAK and MARK Protein Kinases**

D. Matenia, B. Griesshaber, X. Y. Li, A. Thiessen, J. Jiao, C. Johne, E. M. Mandelkow; Structural Molecular Biology, Max-Planck-Institute, Hamburg, Germany

The dynamics of the microfilament and microtubule cytoskeletons are regulated by multiple pathways including phosphorylation by protein kinases. The PAK family of kinases is known to induce actin-dependent processes (e.g. filopodia, lamellipodia) after activation by small G-proteins of the Rho family. The MARK family of kinases (alias Par-1) plays a role in the generation of cell polarity and in microtubule dynamics (e.g. in neurite outgrowth or growth cone advance). We have recently observed that the brain-specific variant PAK5 binds to MARK family kinases, notably MARK2, and thereby inhibits the kinase activity of MARK2 (see accompanying poster by Griesshaber et al.). Here we report on the cellular effects of this interaction. In transfected CHO cells both kinases show a vesicular distribution with a high degree of colocalization on endosomes containing the adaptor proteins AP1 or 2. Fractionation of vesicle proteins from Sf9 cell expressing MARK2 and PAK5 on an iodixanol gradient revealed colocalization of MARK2 and PAK5 with g-adaptin and b1/b2-adaptin. MARK2 transfected alone destabilizes microtubules since it phosphorylates microtubule-associated proteins, and concomitantly the actin stress fibers are stabilized. By contrast, PAK5 keeps microtubules stable because it downregulates the activity of MARK2, at the same time it destabilizes the F-actin network so that stress fibers and focal adhesions disappear and cells develop filopodia. The results point to an inverse relationship between actin- and microtubule-related signalling by the PAK5 and MARK2 pathways that affect both cytoskeletal networks. - Supported by DFG.

**Microtubule Depolymerization Activity of a Kip3 Kinesin: Results from a Novel High-throughput Microtubule Depolymerization Assay**

R. Baliga, D. Guo, P. Chua, T. Stephens, M. Yu, D. W. Pierce, R. Sakowicz, M. Maxon, J. T. Finer; Assay Development, Cytokinetics, South San Francisco, CA

Kip3 type kinesins are thought to be involved in depolymerization of microtubules (MTs). Consistent with this function, we have discovered that the Kip3 kinesin from *Candida albicans* (CaKip3) is essential, but only at elevated temperatures. Further, in an effort to identify novel inhibitors of fungal kinesins, we cloned and expressed the motor domain of CaKip3 in a bacterial expression system. Using a novel kinetic fluorescence polarization (KFP) assay that enables detection of relatively weak MT depolymerization activity, we found that CaKip3 is able to depolymerize Paclitaxel-stabilized MTs. We miniaturized and automated the KFP assay and screened a ~70000 compound small molecule library for inhibitors of this CaKip3 activity. We identified several modestly potent compounds that stabilize MTs specifically in the presence of CaKip3. In parallel,

using a conventional absorbance-based ATPase screen, we identified inhibitors of the CaKip3 ATPase activity. Interestingly, there is little if any overlap between the two sets of compounds, indicating a possible separation of the ATPase and MT depolymerization activities of this motor. Since CaKip3 is essential in *Candida albicans*, the inhibitors we have identified could provide useful starting points for antifungal drug discovery.

**Two Regulatory Phosphoswitches Control MCAK Function**

X. Zhang,[1] W. Lan,[2] T. Stukenberg,[2] C. E. Walczak[3]; [1]Biology, Indiana University, Bloomington, IN, [2]University of Virginia, Charlottesville, VA, [3]Medical Science, Indiana University, Bloomington, IN

MCAK is a microtubule (MT) depolymerizing enzyme that plays important roles in chromosome alignment and in correcting improper kinetochore-MT attachments. Its activity and localization are regulated by Aurora B kinase. *Xenopus* MCAK is phosphorylated by Aurora B at S196 in the neck region, which results in inhibition of its MT depolymerization activity. We now show that Aurora B phosphorylates T95 in the centromere-targeting domain of MCAK, which regulates its localization to chromosomes. While wild-type GST-NT fusion proteins of MCAK targeted to centromeres, the GST-NT (T95A) mutant assembled large aggregates along chromosomes. These “chromosome nuggets” do not alter the localization of the other kinetochore proteins, such as Ndc80, p150 or CENP E. Interestingly, decreasing the concentration of GST-NT (T95A) added to extracts by 100 fold abolished the formation of these “chromosome nuggets” and instead allowed targeting to centromeres. As a complementary approach, we depleted endogenous MCAK from the extract and added back either full length MCAK or an MCAK-T95A mutant. MCAK-T95A targeted robustly to centromeres when only 10% of the endogenous level of MCAK was added, whereas wt MCAK needed to be added at near endogenous level to target. These results suggest that T95A mutants have a high affinity for the centromere region. We also found that endogenous MCAK associates with chromosome arms. This chromosome arm staining may be mediated by phosphorylation at T95 as a phospho-T95 antibody strongly stains chromosome arms in both extracts and cells, a result confirmed by biochemical analysis of chromatin-coated DNA beads. Our work provides an important example of how a protein can be differentially regulated by multiple site phosphorylation and how these different sites can independently change a protein’s activity.

1756

**Modeling Microtubule Dynamic Instability**

I. V. Gregoretti,[1] A. M. Willis,[2] M. S. Alber,[2] H. V. Goodson[1]; [1]Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN, [2]Department of Mathematics, University of Notre Dame, Notre Dame, IN

Microtubules are dynamic tubular polymers that provide cells with a scaffold for internal organization, vesicle trafficking, and cell division. Key to microtubule function is dynamic instability --stochastic switching between phases of individual polymer growth and shortening, observed both in vivo and in vitro. Although dynamic instability has been studied by many approaches, gaining a predictive understanding of a system of dynamic microtubules requires mathematical modeling. Deterministic modeling efforts have had limited utility because they describe the behavior of the population, not of individual filaments. Existing Monte Carlo models simulate only a single microtubule in isolation or lack the ability to explain how characteristics such as transition frequencies and critical concentration arise as a function of simple parameters. In particular, most models ignore competition between microtubules for tubulin subunits. To address these issues, we have developed a Monte Carlo computer model featuring the essential aspects of this process, including competition between filaments and the existence of system boundaries (a cell edge). Transition frequencies evolve from the simulation rather than being set. Our results show that competition between microtubules for tubulin subunits is key to understanding the dynamic behavior of both individual microtubules and the population. In particular, we find that the processive growth of microtubules observed in vivo is an expected outcome of the increase in free tubulin concentration caused by catastrophe induction at the cell edge --regulatory gradients may influence processive growth but are not required for it. Similarly, the experimental observation that mutations in microtubule nucleation machinery alter microtubule dynamics can potentially be explained by changes in the number of competing microtubules. These simulations should enhance understanding of the emergent properties of systems of dynamic microtubules and provide a foundation for better understanding of the activities of microtubule binding proteins.

1757

**Force Production by Disassembling Microtubules**

K. Grishchuk,[1,2] M. I. Molodtsov,[3] F. I. Ataullakhanov,[3,4] R. McIntosh[1]; [1]MCD Biology, University of Colorado, Boulder, CO, [2]Inst. Gen. Path. & Pathophysiol., Moscow, Russian Federation, [3]National Res. Centre for Haematology, Moscow, Russian Federation, [4]Physics, Moscow State Univ., Moscow, Russian Federation

Microtubules (MTs) are important components of the eukaryotic cytoskeleton; they contribute to cell shape and movement and to the motions of organelles, including mitotic chromosomes. MTs bind motor enzymes that drive many such movements, but MT dynamics can also contribute. It has previously been proposed that MTs could generate force through their unusual mechano-chemistry. These polymers assemble from tubulin dimers that bind GTP and hydrolyse it after polymerisation. The GDP-dimer conformation is bent relative to its GTP-counterpart, but this bend is constrained by MT geometry, so some energy from GTP-hydrolysis is stored within the lattice. During depolymerization, the accumulated stress forces the strands of GDP-dimers, or “protofilaments” (PFs), to arch out in a “ram’s horn” configuration. Thus, each MT is a reservoir of chemical energy that can in principle be harnessed to do mechanical work. Two aspects of this mechanism have gone uncharacterised: the power-stroke that is probably generated by curving PFs and the coupling devices that might convert this energy into motility. Here we conjugated glass microbeads to tubulin polymers via strong, inert linkages, like biotin-avidin. Depolymerizing MTs exerted a brief tug on such beads, as measured with laser tweezers. These interactions have been analysed with a molecular-mechanical model for MT structure and force production. We show that a single depolymerizing MT can generate ~10-times the force developed by a motor enzyme, so this mechanism might be the primary driving force for chromosome motion. Even the simpler coupler used here slows MT disassembly; physiological couplers may therefore modulate MT dynamics in vivo.

1758

**Ethanol-induced Impairment of Hepatic Microtubule and Membrane Dynamics May Be Mediated by the Microtubule Deacetylase,**

**HDAC6**

R. A. Joseph,[1] G. T. Kannarkat,[1] C. A. Cheng,[1] D. J. Tuma,[2] P. L. Tuma[1]; [1]Biology, The Catholic University of America, Washington, DC, [2]Liver Study Unit, Veterans Administration Medical Center, Omaha, NE

Chronic alcohol consumption can lead to serious liver disease. Although the disease progression is clinically well-described, the molecular basis for alcohol-induced hepatotoxicity is not well understood. For these studies, WIF-B cells were used to examine hepatocyte specific defects due to ethanol exposure. These cells are an excellent model for studying alcohol-induced hepatotoxicity; they form highly polarized cells in culture and they metabolize alcohol. Previously, we determined microtubules were more highly acetylated and more stable in ethanol-treated WIF-B cells . We found that increased acetylation required ethanol metabolism and was likely mediated by acetaldehyde. Ethanol treatment is also known to impair the trafficking of numerous hepatic proteins. We propose that increased microtubule acetylation and stability may explain the observed impairments. To test this, the trafficking of selected molecules was examined in cells treated with ethanol or specific inhibitors of microtubule deacetylases, i.e., agents that should increase microtubule acetylation in the absence of ethanol. No increased tubulin acetylation was observed in cells treated with nicotinamide, an inhibitor of Sirtuin T2. However, trichostatin (TSA), an inhibitor of histone deacetylase 6 (HDAC6), induced microtubule acetylation in a time- and dose-dependent manner to the same extent as in ethanol-treated cells (~3-fold). The microtubules in TSA-treated cells were more stable and resembled the shorter, more gnarled microtubules that were observed in ethanol-treated cells. In ethanol and TSA-treated cells, the distributions of endocytic organelles were altered and the basolateral accumulation of selected proteins was observed. Although HDAC6 expression levels did not change in ethanol-treated cells, its solubility in permeabilized cells was increased suggesting impaired association with polymeric tubulin. Thus, one possible mechanism to explain microtubule hyperacetylation in ethanol-treated cells is decreased microtubule association of HDAC6 leading to decreased tubulin deacetylation.

1759

**Benomyl Suppresses Microtubule Dynamics, Decreases Tension Across Kinetochore Pairs and Induces Apoptosis in Cancer Cells**

K. Rathinasamy, D. Panda; School of Biosciences and Bioengineering, Indian Institute of Technology, Mumbai, India

Benomyl, an antifungal drug, has been found to arrest mammalian cells at mitosis in parallel with its ability to inhibit cell proliferation. We found that benomyl inhibited microtubule assembly dynamics in mammalian cells, which encouraged us to examine the mechanism by which benomyl arrests mammalian cells at mitosis and induces apoptosis. Cells treated with 5 μM benomyl, a drug concentration that inhibited HeLa cell proliferation by 45 %, arrested HeLa cells at mitosis with nearly normal bipolar spindles with most of the chromosomes aligned at the metaphase plate, and a few chromosomes were scattered near the poles. Cells treated with 20 μM benomyl showed mutipolar mitosis and the chromosomes were not compactly aligned at the metaphase plate. Benomyl (5 μM) decreased intercentrosomal distance in mitotic HeLa cells by 28% from 11.8 ± 1.6 μm to 8.3 ± 1.6 μm and it also perturbed spindle microtubule-kinetochore attachment in the mitotically arrested cells. Benomyl significantly decreased the distance between the sister kinetochore pairs in metaphase cells indicating that the drug impaired the tension across the kinetochores. Further, benomyl induced bcl2 hyper-phosphorylation, reduced the association of bcl2 and bax, and induced apoptosis, which was confirmed by the cleavage of the enzyme poly ADP-ribose polymerase and fragmentation of DNA. Our results showed that benomyl inhibits mitosis by suppressing microtubule dynamics and reducing tension across the kinetochore pairs. Thus, benomyl may be used to study microtubule-mediated alterations in the functions of centrosomes and tension at kinetochores and to understand events leading to apoptosis in tumor cell lines. Supported by Department of Biotechnology, India.

**Microtubule Sliding Powers Proplatelet Elongation from Megakaryocytes during Platelet Production**

S. R. Patel,[1] J. Richardson,[1] H. Schulze,[2] E. Kahle,[1] N. Galjart,[3] K. Drabek,[3] R. Shivdasani,[2] J. H. Hartwig,[1] J. E. Italiano[1]; [1]Hematology, Brigham and Women's Hospital, Boston, MA, [2]Dana Farber Cancer Institute, Boston, MA, [3]Cell Biology and Genetics, Erasmus University, Rotterdam, The Netherlands

Blood platelet formation is powered by a dramatic reorganization of the microtubule cytoskeleton. During platelet biogenesis, terminally differentiated megakaryocytes use microtubule-based forces to convert their cytoplasm into long psuedopodia, called proplatelets, which remodel into blood platelets. Microtubule bundles line proplatelets and occasionally diverge, forming platelet-sized swellings along the proplatelet shaft. A nascent platelet assembles within the bulbous tip at each proplatelet terminus. Proplatelets elongate at an average rate of 0.85 μm/min. Addition of rhodamine-tubulin to permeabilized proplatelets, immunofluorescence microscopy of the microtubule plus-end marker EB3, and time-lapsed fluorescence microscopy of EB3-GFP expressing megakaryocytes reveal that microtubules continuously polymerize throughout the proplatelet and organize into a bipolar array. EB3-GFP movements indicate that centrosomal nucleation of microtubules predominates in immature megakaryocytes lacking proplatelets, where plus-end growth rates range from 8.9-12.3 μm/min. As megakaryocytes mature and begin to form proplatelets, centrosomal nucleation ceases and microtubule polymerization occurs throughout proplatelets. In contrast to immature megakaryocytes, plus-end growth rates within proplatelets are highly variable, ranging from 1.5-23.5 μm/min. Despite arrest of net microtubule assembly, proplatelets continue to elongate. An alternative mechanism for force generation is microtubule sliding. Upon addition of ATP, Triton X-100 permeabilized proplatelets elongate at a rate of 0.65 μm/min in the absence of microtubule polymerization, indicative of an inherent microtubule sliding mechanism. Immunofluorescence microscopy studies demonstrate that the microtubule-based molecular motor, cytoplasmic dynein, and its regulatory complex, dynactin, are situated along the length of proplatelets and remain after Triton X-100 permeabilization. Furthermore, retroviral expression of dynamitin (p50), which disrupts dynactin-dynein function, inhibits proplatelet elongation. These findings suggest that dynein powers microtubule sliding during proplatelet elongation. We conclude that while continuous microtubule polymerization is necessary to support the enlarging proplatelet mass, the sliding of overlapping microtubules is a vital component of proplatelet elongation.

1761

**Creation of a Computational Model for Cooperativity in Single-stranded Polymers**

A. Bartholomew,[1] R. Ganetzky,[1] P. J. Thomas,[2] L. Romberg[3]; [1]Computer Science, Oberlin College, Oberlin, OH, [2]Mathematics, Oberlin College, Oberlin, OH, [3]Biology, Oberlin College, Oberlin, OH

FtsZ, a bacterial homolog of tubulin, forms single-stranded polymers that assemble cooperatively (Chen et al, 2004). Models for cooperative

polymerization traditionally require polymers to be multistranded, suggesting that new models are now needed. Potentially, cooperativity might emerge if a subunit changes from a low to a high affinity conformation when in contact with adjacent subunits in the polymer. Computer programs that model chemical reactions could determine whether such models for single-stranded polymers produce the lags and critical concentrations indicative of cooperativity. However, conventional programs are difficult to apply to polymers because an unlimited number of different polymer species may exist, whereas these programs require discretely defined species. Additionally, conventional programs cannot efficiently track spatial relationships between subunits within a filament or make rate constants dependent upon them. We are developing a computer program that tracks the behavior of 10,000 subunits based on probabilities of reaction per unit time. The modeling strategy uses a stochastic reaction event generator (Gillespie, 1977). To validate the algorithm, we successfully simulated mathematically solvable polymerization schemes, including isodesmic polymerization and the model for double-stranded polymerization used to fit FtsZ data (Chen et al, 2004). Our program is robust, eliminating feedback loops that can occur in deterministic models in which all long polymers are combined into one chemical class. Additionally, our program successfully simulates polymerization models not easily solved with conventional methods, including systems in which polymers anneal and fragment. We are determining the effects of annealing on polymerization kinetics and polymer length distribution. We are also extending the program to determine whether linking a subunit's reaction rates to the chemical states of its neighbors can explain cooperativity in single-stranded FtsZ polymers.

1762

**Comparative Time Series Analysis of Single Kinetochore Microtubule Dynamics in Yeast**

K. Jaqaman,[1] J. F. Dorn,[1] G. S. Jelson,[2] P. K. Sorger,[2] G. Danuser[1]; [1]Department of Cell Biology, The Scripps Research Institute, La Jolla, CA, [2]Department of Biology, Massachusetts Institute of Technology, Cambridge, MA

We want to elucidate the role of kinetochore proteins in regulating kinetochore microtubule (kMT) dynamics and consequently ensuring proper chromosome segregation. We take budding yeast as a model system because of its relative simplicity and powerful genetics, and because in yeast we can track single kMTs by labeling a centromere-proximal region. However, kMT dynamics in yeast are fast and kMT trajectories obtained by 3D time-lapse microscopy suffer from undersampling. Thus the analysis of kMT dynamics is a challenging task, both because of extrinsic stochasticity introduced by undersampling and because of the intrinsic stochasticity of kMT trajectories. Changes in kMT behavior induced by mutations are often comparable in magnitude to the inherent variability of the dynamics in wildtype, even when the mutations are lethal. Therefore, to analyze and compare kMT behavior under different conditions, and to calibrate mathematical models of the molecular-level processes that underlie the observed dynamics, sensitive descriptors that properly characterize kMT trajectories must be employed. Here we propose the use of autoregressive moving average (ARMA) models for that purpose. ARMA models extract the dependence of a stochastic variable on its history and on a related white noise series which embodies the probabilistic nature of the underlying process. ARMA models yield a detailed description of kMT dynamics: In addition to capturing the traditionally employed kMT growth and shrinkage speeds and rescue and catastrophe frequencies, they also reveal the time correlation in kMT trajectories. ARMA descriptors distinguish between G1 kMT behaviors resulting from kinetochore protein mutations, provide the means to distinguish between changes in kMT dynamics due to differential regulation and those due to equilibrium shifts within one regulatory regime, and provide necessary insight for devising mathematical models of the molecular-level processes that underlie the observed kMT dynamics.

1763

**Coordination of Microtubule Employing HVEM of the Adult Retinal Cells in *Drosophila melanogaster***

J. Mun,[1] K. Lee,[1] T. Arii,[2] K. Hama,[2] H. Kwon,[3] D. Studer,[4] S. HAN[1]; [1]Korea University, Seoul, Republic of Korea, [2]National Institute for Physiological Sciences, Okazaki, Japan, [3]Division of Nano-Material and Environmental Science, Daejeon, Republic of Korea, [4]Institute of Anatomy, Bern, Switzerland

The study of structure in *Drosophila melanogaster*'s photoreceptor cells using electron microscopy were carried in detail by Waddington (1962), Farquhar and Palade (1963), and Perry (1968). But, these results can have limitation because of two-dimensional structure. High voltage electron microscopy (HVEM) has been a natural outgrowth of the desire to obtain 3-dimensional information due to problems related to interpretations of 3-dimensional images from 2-dimensional electron microscophs are numerous. In this study, the adult retina of *Drosophila melanogaster* was investigated using fast-freezing, chemical fixation, serial sections, and electron tomogram. The technique of fixation by fast-freezing offers significant advantages over conventional methods. The retinular cell fixed by fast-freezing had smoother cell membranes than that fixed by chemicals. Furthermore, subcellular organelles were preserved well. Therefore we could acquire accurate 3-D models. The distribution of retinular cells, cross-section microtubules and nuclei was observed by their contours of 21 ~ 30 μm, 35 ~ 40 μm, 50 ~ 55 μm, 60 ~ 65 μm, and 73 ~ 79 μm range below distal region. Microtubules are appeared at basal and distal side mainly. And in each range, they existed mainly near mitochondria. After that, the polarity of microtubule in each range of retinal cells was observed. The current data provide us more precise the organization and distribution of microtubule in retinal cell organization in new dimension.

**Thermal Fluctuations of Grafted Microtubules Provide Evidence of a Length Dependent Persistence Length**

F. Pampaloni,[1] G. Lattanzi,[2] A. Jonas,[3] E. Frey,[4] E. Florin[3]; [1]Cell Biology and Biophysics, EMBL, Heidelberg, Germany, [2]Department of Medical Biochemistry, Universita di Bari, Bari, Italy, [3]Center for Nonlinear Dynamics and Department of Physics, University of Texas at Austin, Austin, TX, [4]Department of Physics, Ludwig-Maximilians-Universitat München, Munich, Germany

Microtubules are hollow cylindrical structures that constitute one of the three ma jor classes of cytoskeletal filaments. On the mesoscopic length scale of a cell, their material properties are characterized by a single stiffness parameter, the persistence length Lp . Its value, in general, depends on the microscopic interactions between the constituent globular proteins and the architecture of the microtubule. Here, we use single-particle tracking methods combined with a fluctuation analysis to systematically study the dependence of Lp on the total filament length L. Microtubules are grafted to a substrate with one end free to fluctuate in three dimensions. In living cells, microtubules usually irradiate from a microtubule organizing center toward the cell cortex, hence the boundary conditions adopted in our assay might be close to MT configurations in cells. A fluorescent bead is attached proximally to the free tip and is used to record the thermal fluctuations of the microtubule’s end. The position

distribution functions obtained with this assay allow the precise measurement of Lp for microtubules of different contour length L. Upon varying L between 2.6 and 47.5 μm, we find a systematic sigmoidal increase of Lp from 110 μm to 5035 μm. At the same time we verify that, for a given filament length, the persistence length is constant over the filament within the experimental accuracy. We interpret this length dependence as a consequence of a non-negligible shear deflection determined by subnanometer relative sliding of the protofilaments. Our results may shine new light on the function of microtubules as sophisticated nanometer-sized molecular machines and give a unified explanation of seemingly uncorrelated spreading of microtubules' stiffness previously reported in literature.

1765

### *Toxoplasma gondii*, an Obligate Intracellular Pathgen, Hijacks and Redirects Host Cell Microtubules

J. Hornick, E. Hinchliffe, K. M. Hager; Biological Sciences, University of Notre Dame, Notre Dame, IN

*Toxoplasma gondii* is a pathogen that is profoundly dependent upon the ability to create an intracellular niche safeguarded from host defenses while maintaining accessibility to host nutrients. **We hypothesize that *T. gondii* remodels the host cell cytoskeleton in order to establish an intracellular niche favorable for survival and growth.** *T. gondii* mediates these changes by regulating both host microtubule proteins and host microtubule (MT) transcripts using secreted parasite proteins. Our hypothesis is based on the following electron microscopy, immunofluorescence assay (IFA) and videomicrocopy data. **First**, the parasite actively recruits host cell organelles such as the endoplasmic reticulum and mitochondria to its vacuole membrane. Nocodazole disruption of the host cell MTs decreases the delivery of host mitochondria to the parasite vacuole membrane (PVM). Following drug washout, host MT reform around the PVM. **Second**, infection is correlated with an induction of host microtubule transcription. **Third**, we observe tight MT structures surrounding each PVM. Time-lapse video microscopy of host cells expressing GFP-tubulin reveals that the MTs surrounding each PVM are host-cell derived. **Fourth**, Gamma-tubulin, a MT-organizing center (MTOCs) component, also surrounds each PVM. Gamma-tubulin concentrations are 5-fold higher in infected versus uninfected host cell monolayers. **Fifth**, we observe by videomicroscopy that when superinfected cells undergo mitosis, MTOCs are associated with each of the vacuoles. During exit from mitosis, the MTOCs and the vacuoles themselves coalesce and host cell division is blocked. These observations are important because they suggest both a mechanism for, and the function of, MT remodeling. We conclude that the parasite uses gamma-tubulin as a scaffold to remodel the host cytoskeleton, resulting in the delivery of nutrients and the creation of a stable environment free from the disruptions of cell division.

## Cell Motility III (1766-1793)

1766

### Directing Cell Migration and Proliferation with Engineered Two-Dimensional Spatial Patterns of FGF-2

E. D. Miller,[1] G. W. Fisher,[2] K. Li,[3] L. E. Weiss,[4] L. M. Walker,[5] T. Kanade,[4] P. G. Campbell[6]; [1]Department of Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA, [2]Molecular Biosensor and Imaging Center, Carnegie Mellon University, Pittsburgh, PA, [3]Department of Electrical and Computer Engineering, Carnegie Mellon University, Pittsburgh, PA, [4]The Robotics Institute, Carnegie Mellon University, Pittsburgh, PA, [5]Department of Chemical Engineering, Carnegie Mellon University, Pittsburgh, PA, [6]Institute for Complex Engineered Systems, Carnegie Mellon University, Pittsburgh, PA

Spatial patterns of extracellular signaling molecules, hormones, direct cell organizational behavior by providing positional information required for embryonic morphogenesis and post-embryonic tissue repair or regeneration. Engineering arbitrary and persistent spatial hormone patterns to study and control biological patterning relevant to tissue morphogenesis, homeostasis, and repair is vital to understanding tissue development. We have developed an inkjet printing method to create two-dimensional concentration modulated patterns of hormones which direct cellular function including migration and proliferation. We demonstrate this methodology using a model hormone, fibroblast growth factor-2 (FGF-2), naturally immobilized onto a fibrin substrate. Accuracy of the printed patterns was verified using a bioink consisting of native FGF-2 and FGF-2 labeled with a fluorescent dye. Retention of patterned FGF-2 on the fibrin surface *in vitro* was quantified using iodinated FGF-2. Uniform square array patterns and concentration gradients of FGF-2 were printed on fibrin-coated glass slides followed by seeding of the slides with MG-63 human osteosarcoma cells. The cells proliferated in register with the printed patterns demonstrating that the immobilized FGF-2 was biologically active. Cell counts on the patterns indicated that the cells proliferated in a dose-dependent manner up to a level of saturation where increased FGF-2 surface concentrations did not result in increased cell density. Linear concentration gradients and uniform concentration control patterns of FGF-2 were also printed and Swiss3T3 fibroblasts were seeded at the "starting line" at one end of the patterns. The gradient of increasing concentration from the cell source was shown to direct cell migration further than the control patterns with gradient steepness and design influencing the level of cellular response. This growth factor patterning methodology is not limited to FGF-2 and fibrin but is readily extensible to other extracellular matrix substrates and hormones.

### Emergent Properties of the Dendritic Nucleation/Array Treadmilling Model

T. E. Schaus, E. W. Taylor, G. G. Borisy; Cell and Molecular Biology, Northwestern University, Chicago, IL

The dendritic nucleation / array treadmilling model provides a conceptual framework for the actin network driving protrusive cell motility. However, the large number of interacting and self-organizing elements present complexities that defy ready analysis. Such "complex systems" may be studied by computer models to demonstrate emergent properties that are not easily intuited from their component parts. To this end, we have developed a 2-D, stochastic computer model of branching actin polymerization. Sub-models of essential dendritic nucleation mechanisms were incorporated, including discretized actin monomer diffusion, Monte-Carlo filament kinetics, and a bending-resistant flexible plasma membrane. We show that a flexible plasma membrane, while varying over ~100 nm scales, allows the leading edge to conform to network shape and maintain even filament density, but remain remarkably straight over ~1000 nm scales. Despite the flexibility of the leading edge and the stochastic nature of filament polymerization, the model generated a robust self-organization of filaments in which they favored orientations with respect to the leading edge normal of +/- ½ the branch angle. Varying the branch angle did not preclude this development, nor did it affect protrusion rates. Limiting branching of filaments toward the direction of protrusion had a negligible effect on the build-up of backward-facing filament mass or protrusion rates. Protrusion rates were weak functions of the number of free barbed ends within the physiological range of filament densities. Protrusion rates

instead depended critically on work-sharing among polymerizing filaments, a novel aspect of which involves the self-organizing distribution of barbed ends with distance from the leading edge. This permits otherwise thermodynamically-implausible filament extension and has implications for biophysical models of protrusion. We acknowledge funding by the NIH (GM 62431 to GGB) and the Feinberg Pulmonary and Critical Care Division (T32 to TES).

**Probing the Molecular Mechanism in Cell Migration by Cytoskeleton Continuum Mechanics**

L. Ji, J. Lim, K. Hu, C. Waterman-Storer, G. Danuser; Cell Biology, The Scripps Research Institute, La Jolla, CA

Cell movement is mediated by generation of molecular forces acting on the cytoskeleton which by itself undergoes constant assembly and disassembly of actin and microtubule polymers. Whereas many of the molecular constituents of this machinery have been identified on molecule-by-molecule basis, little is understood about how the actions of these many diverse molecular machineries at the system level converge to produce directed motion of whole cells. At the length and time scales of light microscopy, the actin cytoskeleton can be treated as a visco-elastic continuum through which motion-generating forces are transmitted in a highly regulated fashion. To understand how plasticity and changes of the cytoskeleton architecture and the adhesive coupling of the cytoskeleton to the extra-cellular matrix alter cell behavior at the microscopic scale, we established a continuum mechanical model of the actin cytoskeleton mediating protrusive activity at the leading edge of migrating epithelial cells. We developed an algorithm to identify intracellular forces by fitting the partial differential equations describing the relationship between force generation and cytoskeleton deformation to high-resolution of cytoskeleton displacement data sets. These data are extracted from fluorescent speckle microscopy (FSM) images of living cells. We also devised rules to separate contraction forces from adhesion resistance forces. This allows us for the first time to watch the time modulated interplay between contraction and adhesive force distributions inside a cell and to correlate it with the movement of the cell edge. To validate our model, we correlated the reconstructed cellular forces with the spatial distribution of myosin-II and adhesion complexes in multi-spectral FSM of F-actin and myosin or one adhesion protein.

1769

**A Continuum Finite Element Model Predicting Cell Motility**

B. Flaherty, J. P. McGarry, B. P. Murphy, P. E. McHugh; Mechanical and Biomedical Engineering, National University of Ireland, Galway, Galway, Ireland

This research is concerned with the development of a continuum Finite Element (FE) model of a motile cell that includes all major biomechanical and biochemical factors experimentally observed. The development of an FE model to describe a biological process, such as cell motility, represents a major advancement in the use of the finite element method. Constitutive laws, used previously in purely mechanistic applications, will be adapted to include the characteristics seen in a motile cell. The inclusion of biochemical stimuli, which are integral to the generation of forces required for cell movement, represent another major challenge in this work. While a commercially available finite element solver will be used to generate the final results, much work developing code that allows the inclusion of the above constituents will have to be undertaken. The results to date include the generation of accurate cellular geometry from images taken by a confocal microscope. Also a User Material Subroutine (UMAT) was developed. This allows the creation of an active material which in turn generates the asymmetric force that drives a motile cell. Also a User Surface Interaction Subroutine (UINTER) that describes the interfacial behaviour between the cell and substrate has been included. In conclusion, by incorporating the aforementioned components in a two dimensional finite element model of a cell sitting on a substrate, it is possible to model cell movement under the influence of the asymmetric driving force and also mimic the cell/substrate interfacial behaviour, needed to facilitate cell movement.

**Cell Migration in 3D: Sterics, Stiffness and Signals**

M. H. Zaman,[1] L. M. Trapani,[2] A. Siemeski,[1] R. D. Kamm,[1] A. Wells,[3] D. A. Lauffenburger,[1] P. T. Matsudaira[4]; [1]Biological Engineering, MIT, Cambridge, MA, [2]Wellesley College, Wellesley, MA, [3]Pathology, University of Pittsburgh, School of Medicine, Pittsburgh, PA, [4]Whitehead Institute, Cambridge, MA

Most of our current knowledge of cell motility and migration comes from *in vitro* studies carried out on two-dimensional substrates which provide only limited powers of observation. Moving to a 3D environment offers a superior range of observation, however the 3D experiments carried out to date have not studied the effect of matrix properties or cell-matrix interactions on cell migration. In order to fully understand the underlying mechanisms by which cells migrate *in vivo*, it is critical that we study the movement of cells in 3D environments that mimic the properties of the ECM *in vivo*. Using a combination of computer simulations, high resolution imaging and rheology studies, we study the role of adhesion, mechanics, stiffness and matrix proteolysis in cell migration in 3D matrices. Our computational approaches combine novel techniques in ODE based modeling to calculate the forces acting on the cell during migration, Monte Carlo Simulations to study persistence and MD simulations to understand integrin-ECM interactions. Our techniques allow us to quantitatively map the cell migration landscape at various length and time scales. The results from our simulations and experiments show a simultaneous dependence of cell migration behavior on both chemical signals in the ECM and mechanical properties of the cell and the ECM. A complete understanding of this complex process requires that both the mechanics of the matrix and chemical signals be taken into account, as ignoring either of the two key components will lead to incomplete and inaccurate understanding of migration in 3D environments. The novel computational methods developed in our group show good agreement with the experimental studies in predicting the overall behavior of cells migrating in 3D and have provided useful insights in understanding the molecular basis of migration, contact guidance and persistence in 3D environments.

1771

**Identification of Novel Genes that Regulate Cell Motility Using a High Throughput siRNA Screening Approach**

K. J. Simpson, L. M. Selfors, J. Bui, J. S. Brugge; Cell Biology, Harvard Medical School, Boston, MA

Cell migration is a complex process requiring coordinated interactions of many proteins throughout the cell. A comprehensive understanding of the protein networks and their functional relationships requires a broad, system-level analysis of these processes. In conjunction with the Cell

Migration Consortium, we have developed a high throughput assay to screen large collections of siRNAs to identify genes that positively or negatively regulate cell migration. This screen, is based on the well-established wound healing assay for cell motility, employing a robotic pin to generate the wound and automated microscopy to capture the entire wound in a single image. Our screen of 1100 human genes includes all protein phosphatase and kinase family members and a selected set of genes implicated in regulation of cell motility in normal tissues and tumours from diverse origins. We use the mammary epithelial cell line MCF10A and derivatives over-expressing wildtype or constitutively active ErbB2 to identify genes that (a) regulate the response of epithelial cells to a motogen, (b) enhance migration in the "sensitized" background of a non-migratory cell line, and (c) inhibit aberrant cell-autonomous migration of a transformed cell line. Cells are robotically transfected with Dharmacon SMARTpool siRNAs, wounded 52 hours post-transfection, then fixed and stained with rhodamine-phalloidin. Cell viability is determined prior to wounding to assess the impact of the siRNAs on general cell metabolism and proliferation. Motility is scored by the amount of cleared area remaining in the wound space, together with gross cell morphology and actin cytoskeletal alterations. Pilot studies confirm the assay is robust, with migration phenotypes consistent with the literature for RhoA, RhoB and RhoC and Rac1 and Cdc42. We will present preliminary data on the hits from the phosphatase screen that is currently in progress.

1772

**Genome-wide RNAi Analysis Identifies a Network of Proteins Necessary for Caenorhabditis Elegans Distal Tip Cell Migration**

E. J. Cram, H. Shang, J. Schwarzbauer; Molecular Biology, Princeton University, Princeton, NJ

Integrin receptors for extracellular matrix transmit mechanical and biochemical information through molecular connections to the actin cytoskeleton and to a number of intracellular signaling pathways. In *C. elegans*, integrins are essential for embryonic development, muscle cell adhesion and contraction, and migration of nerve cell axons and gonadal distal tip cells. To identify key components involved in integrin signaling and distal tip cell migration in general, we are using an RNA interference (RNAi)-based genetic screen for deformities in gonad morphogenesis caused by aberrant DTC migration. We have surveyed an RNAi library of 16,750 *C. elegans* open reading frames, each contained in a vector optimized for bacterial-mediated RNAi. Of these, 100 clones caused DTC migration defects in > 30% of treated animals. Our analysis indicates that tubulins, other cytoskeletal elements, and signaling proteins are significantly over-represented among the genes isolated in our screen. Using published protein-protein interaction data, we have assembled 38 of these genes into a network. This network has *pat-3*/β integrin as one of its hubs with spokes that link to genes encoding actin, *mig-15*/NIK kinase, the focal adhesion proteins *unc-112* and *unc-35*/talin, and a LIM-domain protein *unc-97*. On the basis of predicted protein interactions within this network, novel candidate genes have been identified and their effects on DTC migration are being determined. This screen has identified a network of interacting proteins that regulate distal tip cell migration, and has identified novel proteins necessary for cell migration in vivo.

1773

**Lateral Membrane Waves Constitute a Universal Dynamic Pattern of Motile Cells**

H. G. Doebereiner,[1,2] B. J. Dubin-Thaler,[1] J. Hofman,[3] H. S. Xenias,[1] T. N. Sims,[4] G. Giannone,[1] M. L. Dustin,[4] C. Wiggins,[3,5] M. P. Sheetz[1]; [1]Biological Sciences, Columbia University, New York, NY, [2]Physics, Columbia University, New York, NY, [3]Applied Physics, Columbia University, New York, NY, [4]Skirball Institute of Biomolecular Medicine, New York University School of Medicine, New York, NY, [5]Center for Computational Biology and Bioinformatics, Columbia University, New York, NY

Cell motility is driven by actin polymerization and myosin motor activity. We have monitored active movements of the cell circumference using quantitative DIC and TIRF microscopy. Spreading and motility essays were done on specifically adhesive substrates for a variety of cells including mouse embryonic fibroblasts and T-cells, as well as wing disk cells from drosophila melanogaster. Cultured fibroblasts (RPTPalpha+/+) and wing disk cells (S2R+) were plated on fibronectin and/or vitronectin coated glass slides, respectively. Primary naive T-cells were derived from lymph node and spleen of mice and allowed to adhere on supported bilayers containing ICAM-1 and MHC-peptide complexes. Despite their functional diversity, all those cell types exhibit similar dynamic patterns in their normal membrane velocity. In particular, we found that protrusion and retraction activity is organized in lateral waves running along the cell circumference. We find wave speeds on the order of 100 nm/s. Remarkably, these wave patterns show both spatial and temporal long-range periodic correlations reflecting a corresponding organization of the actomyosin gel.

1774

**Real-time Single Sperm Tracking and Laser Trapping: "Track and Trap"**

L. Shi, E. Botvinick, J. Vinson, M. W. Berns; Bioengineering, University of California, San Diego, La Jolla, CA

Single sperm motility is studied using a novel real-time sperm tracking and laser trapping algorithm. The user is allowed to pick a moving sperm of interest. The algorithm can extract the location of the tracked sperm from a noisy background or when it is out of focus. The stage of the microscope is automatically moved when the tracked sperm is moving toward to the edge of the acquiring screen. The algorithm also has the feature to distinguish the tracked sperm from sperm that it collides with based on the average VCL, traveling distance, and direction of movement after the collision. After enough sperm motility information is collected (length of track), the laser is automatically turned on to trap (capture) the tracked sperm for a predefined time frames. This sperm is continually tracked after the laser is tuned off until the user stops the tracking. Meanwhile, the trajectory, the track speed (VCL) and average VCL of the sperm are saved to the hard disk. The stage movement of the microscope, the image acquisition from the CCD camera and the real-time tracking/trapping algorithm are fast enough to keep the frame rate at 30 frames/second. The fastest sperm tracked in the experiment was 133 microns/second. Unlike other sperm motility software, the real-time single sperm tracking and laser trapping algorithm has no limit on the maximum tracking frames. It can be used not only as a tool to study the effect of laser trapping, but also as an objective and analytical measurement of the sperm motility.

1775

**Statistical Analysis of Phototoxic Effects of Fluorescent Markers on Cell Motility**

W. Timp,[1] S. Hopp,[2] J. G. Evans,[3] P. Matsudaira[2]; [1]Electrical Engineering and Computer Science, MIT, Cambridge, MA, [2]Biology, MIT, Cambridge, MA, [3]Bioimaging Center, MIT, Cambridge, MA

Fluorescent stains are widely used to detect cell proliferation and position, as well as morphology and internal structure. With the advent of new

imaging systems, complete with environmental chambers, it is now possible to image cells over hours, or even days. This long time-lapse data allows us to gather dynamic information about cell motility, but is limited by two problems, photobleaching and phototoxicity. Photobleaching is the gradual fading of the fluorescent dye due to light induced oxidative damage accumulated over time. The far more serious problem is phototoxicity - the effect that these bleached dyes cause in the cell. We wanted to quantitatively determine the effect of phototoxicity on cell motility, comparing different cell types and anti-oxidant additives. It has been suspected for years that these molecules may perturb the cell state - even producing toxic effects, through the combination of intense light and photoreactive species. Effectively, the fluorescent stains are generating free radicals and other oxidative and reactive species after their bombardment with intense light. These free radicals then cause random damage throughout the cell. Different cell types demonstrate different degrees of susceptibility to photodamage. Anti-oxidants are able to ameliorate this effect, allowing the fluorescent stains to be used. We demonstrate this through an analysis of cell speed, calculated using a long term time-lapse scan on a microscope with an environmental chamber. We used brightfield images as a control, assuming that brightfield is the least destructive method of imaging. We then performed the same analysis on the cells with various fluorescent chemical stains, as well as with GFP transfection. Finally, we used the same fluorescent stains in conjunction with anti-oxidants such as Trolox and vitamin C.

1776

**An Automated Phase-contrast Based Live Cell Microscopy Assay of Metastatic Cell Behavior**

D. Loerke,[1] J. De Rooij,[1,2] A. Kerstens,[1] C. Waterman-Storer,[1] G. Danuser[1]; [1]Department of Cell Biology, The Scripps Research Institute, La Jolla, CA, [2]Department of Cell Biology, Netherlands Cancer Institute, Amsterdam, The Netherlands

The scattering of MDCK cells in response to HGF *in vitro* is a model system that captures key aspects of the transformation of human epithelial cells into metastasizing tumor cells *in vivo*, as cells lose epithelial cell-cell junctions and acquire a motile phenotype. In MDCK cells, both the loss of cell-cell adhesion and the induction of migration occur within 24 hours, which enables us to follow the complete process by live-cell microscopy. For automated analysis of the resulting time-lapse image series, we have developed ScatterTrack, a customized software that automatically detects and tracks individual cells in phase-contrast images. While computationally very demanding for reliable cell detection, the use of phase contrast imaging allows us to analyze long time series by avoiding any phototoxic effects of fluorescence dyes and the signal decay associated with photobleaching. Quantitative analysis of the spatial clustering dynamics of cell distributions allows us to independently evaluate the change in motility and cell-cell adhesion properties, thus separating these two distinct components of the scattering process. In a small-scale drug screen, we have used this software to characterize several pharmacological inhibitors for their capacity to specifically modify either of these components. We find that most described drugs (e.g. SU6656, SB203580) reduce scattering through effects on cell motility rather than cell-cell adhesion, while a minority of inhibitors (e.g. PD98095, PP2) specifically prevent the disruption of cell-cell adhesion. Consequently, selecting drugs on the basis of altered motility alone is not efficient in identifying potent scattering inhibitors. We conclude that our novel live-cell microscopy-based assay allows the differential characterization of the cell-cell adhesion and migration aspects of metastatic cell behavior of HGF-treated MDCK cells, and is a reliable tool for screening new potential pharmacological agents against tumor invasion.

1777

**Viscoelasticity of Actin Networks Growing Under Load**

O. Chaudhuri, S. H. Parekh, D. A. Fletcher; Bioengineering, UCSF/UC Berkeley Joint Graduate Group, University of California at Berkeley and San Francisco; Department of Bioengineering, University of California at Berkeley, Berkeley, CA

Actin filament networks are a major component of eukaryotic cell cytoskeletons that provide mechanical integrity to the cell and drive cell protrusions during crawling motility. The ability of branched actin networks to generate force for motility has been extensively studied with *in vitro* bead motility assays, but the mechanical properties of these networks are not well understood. We reconstituted growing actin networks in a modified atomic force microscope and measured the viscoelastic properties of the branched networks as they grew against increasing loads through stall. Using AFM-based microrheometry, we found that the elasticity of the network increased with increasing load, and we hypothesize that this result is due to an increased number of working filaments at high loads.

1778

**Identification of Novel Tyrosine Substrates in FAK Signaling Pathways**

A. E. Kisailus,[1] E. Shaefer,[2] I. Gelman[1]; [1]Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY, [2]Biosource International, Camarillo, CA

Focal adhesion kinase (FAK) is a non-receptor tyrosine kinase that plays an essential role in cell migration. Integrin activation by extracellular matrix (ECM) proteins triggers FAK activation via auto-phosphorylation enabling an SH2-dependent interaction with and subsequent activation of the Src tyrosine kinase. The FAK/Src signaling complex plays a role in motility by recruiting and phosphorylating cytoskeletal proteins involved in focal adhesion formation and turnover. A role for FAK in cancer is suggested by its Src-substrate status in tumor cells and by correlations of increased FAK expression/activation levels with increased malignancy. Although a distinctive role for FAK in cell migration, growth, and survival has been implicated, it is unclear whether these functions are encoded by its kinase or protein-scaffolding activities. Furthermore, most FAK substrates identified to date, such as paxillin, CAS, and α-actinin, are also targets of Src phosphorylation. Thus, to identify FAK-specific tyrosine substrates, we used purified, active, recombinant, human FAK to screen a human cDNA expression library. Our *in situ* kinase screen was adapted from previous methods via novel application of a highly sensitive phospho-tyrosine detection system, which used an immunoconjugated infrared-excitable fluor. Controls included overlays with kinase-deficient FAK397F, no kinase (to exclude autophosphorylation by cDNAs encoding tyrosine kinases) and active Src. Using this improved method, we identified 16 new FAK-specific phosphorylation targets. The FAK-dependency of these substrates was verified by immunoprecipitation/anti-phosphotyrosine blotting of FAK+/+ and FAK-/- cell lysates adhered to fibronectin-coated dishes (versus in suspension). The potential substrates are involved in a variety of functions including cell migration, gene transcription, stress response, and metabolism. Study of FAK phosphoryation on these newly identified substrates, such as Trio and RhoGDI2, regulators of Rho-family small GTPases, will further our understanding of how FAK mediates cytoskeletal remodeling and migration.

1779

**Dual Protein Display Technique for Investigating Cell Motility, Cell Adhesion, and Signal Integration**

S. J. Hunt, W. J. Nelson; Molecular and Cellular Physiology, Stanford University School of Medicine, Stanford, CA

Many of the pathways by which extracellular signals provided by cell-cell and cell-matrix adhesion are transduced into changes in intracellular physiology remain to be determined. Particularly lacking in our knowledge of such systems is how the multiple, and often disparate, signals arising from the different forms of cell adhesion are integrated into characteristic cellular responses. An example of such signal integration is found in polarized epithelial cells, which must respond to signaling pathways downstream from both integrin-mediated adhesion to the extracellular matrix (e.g., Rho), and signals arising from E-Cadherin-mediated cell-cell adhesion (e.g., Rac, Cdc42). We have developed a micropatterning technique for displaying two substrates simultaneously on a surface, which we are using to examine the interaction of these two pathways in MDCK cells. We present evidence of signal integration and extinction in our experimental system, as well as examining downstream effects on cellular systems including morphology, actin dynamics, and cell motility.

1780

**Cell Spreading and Migration on Surfaces of Variable Mechanical Stiffness**

R. A. Desai, S. Raghavan, M. T. Yang, C. S. Chen; Bioengineering, University of Pennsylvania, Philadelphia, PA

Initiation of cell migration is crucial to diverse processes such as embryonic development, tissue maintenance and repair, and tumor metastasis. While much is known about the binding interactions between integrins and the extracellular matrix (ECM) that trigger migration, little is known about the role of ECM mechanics in mediating these effects. Here, we investigated how mechanical stiffness of the underlying substrate regulates the transition of cells from a stationary to a migratory state. We developed a surface micropatterning technique in which cells are initially restricted to small adhesive patches surrounded by a nonadhesive background. The nonadhesive regions are then chemically switched to become adhesive, thereby uncaging cells and allowing them to migrate away from prior geometric constraints. We then applied this technique to cells cultured on substrates presenting a bed of vertical cantilevers of different heights. Altering cantilever height enables control over substrate stiffness independent from changes to surface chemistry or ECM presentation to the cell. Preliminary results suggest stiffness of the substrate modulates the ability of cells to develop stress fibers, and initiate cell spreading and migration upon release from micropatterned constraints. We are investigating the interaction between substrate mechanics and cell mechanics, and the subsequent mechanochemical signaling that may underlie these processes. Understanding the mechanochemical phenomena underlying cell-substrate interactions, cell spreading and migration will likely yield a more complete model of how cells probe their physical environment.

1781

**Quantitative Elucidation of a Unique Spatial Gradient Sensing Mechanism in Fibroblasts**

I. Schneider, J. Haugh, E. Parrish; Chemical and Biomolecular Engineering, North Carolina State University, Raleigh, NC

During wound healing, fibroblast migration is biased by extracellular gradients of platelet-derived growth factor (PDGF). As in other chemotactic cells, such as neutrophils and *Dictyostelium discoideum*, spatial gradient sensing in fibroblasts is mediated by receptor activation of phosphoinositide (PI) 3-kinases and the localized production of 3' PIs in the plasma membrane. However, the responses of these cell types to uniform stimulation suggest fundamental differences in their respective spatial sensing mechanisms. Indeed, while shallow chemoattractant gradients yield robust, "all-or-none" polarization of 3' PI signaling in *Dicty* and neutrophils, we postulated that the gradient sensitivity in fibroblasts depends much more on the average PDGF concentration. Using total internal reflection fluorescence microscopy to quantitatively monitor 3' PI levels in fibroblasts expressing the GFP-AktPH probe, in conjunction with mathematical modeling of the underlying kinetics and spatial 3' PI pattern, we report that fibroblasts possess three distinct regimes of PDGF gradient sensitivity. In response to PDGF gradients with low midpoint concentrations, the 3' PI gradient is roughly proportional to the change in receptor occupancy across the cell. Gradients with intermediate midpoint concentrations, sufficient to recruit most intracellular PI 3-kinase without saturating receptor occupancy, elicit maximal 3' PI gradient sensitivity. At high midpoint concentrations, receptors are saturated, and the response is indistinguishable from that seen after uniform stimulation. We also found that the morphological polarity of the cell imposes an intrinsic bias to the 3' PI pattern. Peripheral, leading-edge regions of the contact area were consistently found to be 'hot spots' of 3' PI lipid concentration, and quantitative analyses revealed that these regions harbor both locally enhanced PI 3-kinase activation and reduced 3' PI turnover. Hot spots enhance or oppose the initial sensing of a PDGF gradient depending on its orientation relative to the cell.

1782

**Distinguishing Models of Eukaryotic Gradient Sensing**

W. Losert,[1] R. Skupsky,[2] R. Nossal,[2] C. Parent,[3] E. Rericha[1]; [1]Dept of Physics, IPST, and IREAP, University of Maryland, College Park, MD, [2]Laboratory of Integrative and Medical Biophysics, NICHD, NIH, Bethesda, MD, [3]NCI, NIH, Bethesda, MD

How can one critically evaluate models of signaling pathways, such as the 3'phosphoinositide pathway for gradient sensing in *Dictyostelium discoideum*, even though there are uncertainties in rate constants and potential interactions with unidentified proteins? We present a modular model of gradient sensing in eukaryotic cells, and new experimental tools to critically test this model. The model describes phosphoinositide (PI)-mediated sensing of cAMP at an intermediate level of detail - we focus on the spatial distribution 3'PIs and a subset of molecules involved in its regulation. We identify two coupled positive feedback loops involving substrate delivery and enzymatic feedback through PI3K and PTEN, and a global inhibitory mechanism through phosphorylation of PI3K. Our analysis indicates that a single signaling pathway can lead to qualitatively different gradient sensing mechanisms. Changing the relative strength of the feedback loops (e.g. by changing concentrations of signaling molecules or values of rate constants) yields four variants with characteristics that resemble different models of gradient sensing in the literature. We find that the model variants may best be distinguished based on the characteristics of the transition from efficient gradient detection to failure. Such transitions to failure occur (1) at low cAMP gradients, and (2) in gradients that change quickly with time. We show new experimental tools to study the transition from efficient gradient detection to failure in single cells: stable small gradients of cAMP of a few percent or less across a cell are generated with a microfluidics device. A new optical micromanipulation technique allows us to generate time dependent gradients by varying the orientation and position of multiple cells in a stationary chemical gradient at speeds of several microns/sec and rotation rates of less than one

rotation/sec. This work was supported by NSF-MRSEC and NIH.

1783

**Modulation of Chemotactic Behavior by Cues from Substrate Topography**

M. M. VanDuijn, D. Fletcher; Dept of Bioengineering, UC Berkeley, Berkeley, CA

Chemotaxis is an important process controlling the migration of cells. It has been the subject of extensive studies, in particular the migration of neutrophils in response to gradients of formylated peptides like fMLP. While such cells are usually studied on a flat substrate, chemotaxis of neutrophils *in vivo* typically involves migration through complex three dimensional tissue. Under these conditions, cells cannot migrate along a straight path along the chemical gradient, but need to circumnavigate other cells and components of the extracellular matrix. Thus, chemical gradients may lead cells in a direction they are physically unable to follow. Here we investigate the interplay of structural and chemical cues on the navigation of chemotactic cells. HL-60 cells were differentiated with DMSO to until they showed neutrophils-like chemotactic properties, and were then allowed to migrate on coverslips decorated with paths and obstacles that were microfabricated from SU8. A chemotactic gradient was delivered from a micropipette with a constant backpressure, and cell movements were tracked. The data suggest that structural features on the substrate can override cues from the chemical gradient, leading to cells crawling on a tangent or even away from a source of fMLP. This shows that cells are not stringently directed by the local chemical gradient, but can combine different sources of information to guide their movement.

1784

**Biochemical Mechanics of Nematode Spermatozoon Crawling**

M. Zajac, C. W. Wolgemuth; Cell Biology, UConn Health Center, Farmington, CT

Cell crawling requires three main processes: polymerization at the leading edge, adhesion to the substrate, and retraction at the rear. The objective of this work is an extensible model to describe the biochemical regulation of the cytoskeletal deformation and reorganization that drives motility in crawling cells. Recent experiments using nematode spermatozoa and spermatozoon extracts reveal that the Major Sperm Protein (MSP) cytoskeleton in these cells drives locomotion in a similar fashion as has been observed in the more familiar translocation of actin-based cells. However, the MSP system is simpler and therefore more amenable to modeling. Our simulation method uses two-phase gel mechanics which treats the cytoskeleton as a deformable elastic meshwork and also accounts for the fluid motion of the cytosol. The thermodynamic underpinnings of this model capture elastic, ionic, entropic, electrostatic and hydrophobic interactions between cytosolic and cytoskeletal matter. Explicit treatment of cytosolic flow allows competition or collaboration between advection and diffusion as mechanism for intracellular transport. Level set methods facilitate robust treatment of moving cell boundaries where cytoskeletal assembly converts between the liquid (cytosolic) and solid (cytoskeletal) phases as monomers enter or leave solution and also provide an algorithm for computing lateral diffusion along the deforming cell membrane, thereby enabling the simulation of cytoskeletal nucleation by membrane bound proteins. Simulation results realistically predict the polymerization rate at the leading edge of the cell and the force generated by the deforming cytoskeleton and illustrate the potentially catastrophic feedback between changing cell geometry and intracellular processes, both chemical and physical. In conclusion, initial simulations suggest that gel mechanics and level set methods may provide an adaptable basis for wholistic reconstruction of cell motility, starting from experimental measurements of individual components.

1785

***Spiroplasma* Swim by a Processive Change in Body Helicity**

J. W. Shaevitz,[1] J. Y. Lee,[2] D. A. Fletcher[3]; [1]Integrative Biology, U.C. Berkeley, Berkeley, CA, [2]Plant and Microbial Biology, U.C. Berkeley, Berkeley, CA, [3]Bioengineering, U.C. Berkeley, Berkeley, CA

Microscopic organisms must rely on very different strategies than their macroscopic counterparts to swim through liquid. To date, the best understood method for prokaryotic swimming employs the rotation of flagella. Here, we show that *Spiroplasma melliferum*, tiny helical bacteria that infect plants and insects, use a very different approach. By measuring cell kinematics during free swimming, we find that propulsion is generated by the propagation of kink pairs down the length of the cell body. A processive change in the helicity of the body creates these waves and enables directional movement in a viscous environment.

1786

**Transient Adhesion-mediated PKA Activation at the Leading Edge of Migrating Cells**

L. E. Goldfinger,[1] K. H. Kain,[1] J. Zhang,[2] R. Y. Tsien,[3] M. H. Ginsberg[1]; [1]Medicine, University of California, San Diego, La Jolla, CA, [2]Department of Pharmacology and Molecular Sciences and Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD, [3]Departments of Pharmacology and Chemistry and Biochemistry, University of California, San Diego, La Jolla, CA

cAMP-dependent protein kinase A (PKA) is important in directional cell migration and axonal pathfinding. Activation and deactivation of endogenous PKA can be imaged by fluorescence resonance energy transfer within AKAR2.2, comprising monomeric cyan and yellow fluorescent proteins linked by a pThr-binding domain and a Thr-containing PKA substrate. When targeted to the plasma membrane, AKAR2.2 revealed transient integrin-mediated activation of PKA at the leading edge of migrating CHO cells. Leading edge PKA activation was seen with two different integrins and was required for efficient forward protrusion at the cell front. PI3-kinase has been proposed as the initiator of polarization of migrating cells; however, polarized PKA activation was PI3-kinase-independent and is therefore an autonomous, early, and critical directional signal in cell migration. Thus we describe a novel, compartment-specific PKA activation biosensor and utilize it to identify a new, PI3-kinase-independent, cellular compass.

1787

**Integrin α6β4 Promotes Expression of Autotaxin/ENPP2 Autocrine Motility Factor**

M. Chen, K. O'Connor; Department of Surgery and the Sealy Center for Cancer Cell Biology, University of Texas Medical Branch, Galveston, TX

In advanced breast carcinomas, the α6β4 integrin is associated with a migratory and invasive phenotype. In our current study, we show that expression of the α6β4 integrin in MDA-MB-435 breast carcinoma cells leads to increased expression of the autocrine motility factor autotaxin, as determined by Affymetrix gene chip, real time quantitative RT-PCR and immunoblot analyses. We further demonstrate that increased autotaxin

secretion from integrin α6β4 expressing cells acts to enhance chemotaxis through its ability to convert lysophosphatidylcholine (LPC) to lysophosphatidic acid (LPA). We determine that integrin α6β4-dependent overexpression of autotaxin in MDA-MB-435 cells is mediated by NFAT1, but not NFAT5, through the use of siRNAs that specifically target autotaxin, integrin β4, NFAT1 and NFAT5. Finally, we show by electrophoretic mobility shift assays that three consensus NFAT binding site found in the autotaxin promotor specifically binds NFAT1 from integrin α6β4 expressing cells and is sensitive to calcineurin inhibition. In summary, we find that the α6β4 integrin potentiates autotaxin expression through the upregulation and activation of NFAT1. These observations highlight for the first time a mechanism by which NFAT transcription factors can facilitate an invasive and motile phenotype downstream of integrin α6β4 signaling.

**Myosin Activity is Required for Symmetry Breaking and Motility Initiation in Keratocytes**

P. T. Yam,[1] J. A. Theriot[2]; [1]Biochemistry, Stanford University School of Medicine, Stanford University, CA, [2]Biochemistry and Microbiology and Immunology, Stanford University School of Medicine, Stanford University, CA

We have observed the spontaneous initiation of actin-based motility in keratocytes, a rapidly moving fish epithelial cell. This motility initiation was accompanied by changes in the symmetry (from radial to bilateral), shape, and cytoskeletal dynamics of the cell. Individual stationary keratocytes were circular, while motile keratocytes had a half-moon shape. We have found that the F-actin meshwork in stationary keratocytes flows centripetally from the leading edge to the cell body, in contrast to motile keratocytes, where the F-actin meshwork remains mostly stationary with respect to the substrate as the cells move. Over time, circular stationary keratocytes were observed to break symmetry spontaneously and generate a well-defined and persistent structural polarity in the absence of extrinsic spatial cues. We wished to determine whether spontaneous polarity was generated by specification of the leading edge (as in chemotaxis) or specification of the trailing edge. Time-lapse phase contrast microscopy indicated that during spontaneous motility initiation the rear of the cell retracted first, followed by forward translocation of the cell body and finally the front cell margin, over a period of ~200-400 seconds. Rear retraction was accompanied by a decrease in lamellipodial thickness at the rear, and an increase in the rate of centripetal actin flow at the rear, suggesting that spontaneous motility initiation in keratocytes first involves changes in the rear of the cell. Depolymerization of microtubules with nocodazole did not inhibit motility initiation. Inhibition of myosin II with blebbistatin decreased the frequency of motility initiation. The blebbistatin phenotype was mimicked by the Rho kinase inhibitor Y-27632 but not the myosin light chain kinase inhibitor ML-7, suggesting that an increase in actin network contractility at the rear of the cell regulated by myosin and Rho kinase is important for symmetry breaking.

1789

**Local Application of PDGF Induces Rapid Spreading and Tractional Force Generation by Isolated Cells Inside 3-D Collagen Matrices**

W. M. Petroll, L. Ma; Ophthalmology, University of Texas Southwestern Medical Center, Dallas, TX

We have previously studied cell-matrix mechanical interactions within 3-D collagen matrices using high magnification time-lapse imaging. The goal of this study was to extend this model to allow local application of growth factors or other reagents near isolated cells. Human corneal fibroblasts were plated at low density inside 100 μm thick fibrillar collagen matrices and cultured for 1 to 2 days in serum-free media. Following 1 hour of time-lapse DIC imaging, a glass microneedle (Femtotip) loaded with either PDGF or vehicle control solution was inserted axially into the ECM, approximately 20 μm from the leading edge of an isolated cell of interest. The loaded solution was then injected into the matrix, and time-lapse imaging was continued for another 1-2 hours. Changes in cell morphology and extracellular matrix (ECM) deformation were assessed using MetaMorph. Insertion of microneedles was generally achieved without significant disruption or deformation of the ECM. Cells randomly extended and retracted cell processes both before and after needle insertion; similar behavior was observed following control injections. In contrast, injection of PDGF induced rapid cell spreading toward the microneedle tip, with both extension of existing pseudopodia and formation of new processes. Tractional force was generated during PDGF-induced spreading, as indicated by pulling in of individual collagen fibrils in front of pseudopodia. Overall, the ability to apply reagents adjacent to individual cells should be a useful tool for studying cell motility within 3-D matrices. In this study, rapid cell spreading and tractional force generation was demonstrated in response to PDGF, presumably through upregulation of Rac. By moving the needle laterally following insertion, the additional effects of local mechanical perturbation on cell behavior could potentially be assessed using this system.

1790

**Comparison of Light-induced Direction Change in Three Diatom Species**

S. A. Cohn, K. R. Monroe, M. P. Wemhoff; Biological Sciences, DePaul University, Chicago, IL

Previous work from our lab indicated that diatom motility is light sensitive, with the direction of cell movement being responsive to light irradiance at the tips of the cells. Exposure to high irradiance light at cell tips can induce a reversal of cell direction (*Diat. Res.* **19**:167) and several different diatom species, including *Craticula cuspidata*, *Stauroneis phoenicenteron*, and *Pinnularia viridis* (*J. Phycol.* **32**:928) have shown a characteristic spectral sensitivity with respect to light attraction. Our current work has investigated these three species for their spectral sensitivity to direction changes induced by high-irradiance light. The leading ends of moving cells were irradiated with high irradiance light ($\geq 10^5$ μmol/m$^2$sec) at either 470, 550, or 650 nm (blue, green or red light, respectively), and observed to determine the time it took for cells to change direction. We found that each species displayed different spectral sensitivities. For example, using 1 sec irradiations, *Craticula* cells were about equally sensitive to blue and green light (changing direction 11±1 and 15±4 sec after irradiation, respectively), while irradiations with red light showed no significant response compared to unirradiated control cells (changing direction 44±6 and 56±6 sec after irradiation, respectively). In contrast, *Stauroneis* cells were responsive to all three light wavelengths, showing greatest sensitivity to blue and red light. *Pinnularia* cells were only responsive to blue light, showing no significant sensitivity to either green or red light. These spectral sensitivities correlate well with those seen for the attraction of these cells into light at low irradiance, suggesting that the low light (into the light) and high light (away from the light) responses are using the same light detection mechanism. This work was supported by DePaul University Research Council, College of Liberal Arts & Sciences, and NSF Grant IBN-9982897.

**A Nocodazole-Sensitive Novel Immune Cell in the Sea Urchin, *Lytichinus variegatus*: Increased Abundance during Spawning**

J. R. Cahlander, B. M. Johnson, S. Amy, L. Winslow; Biology, Northwestern College, St. Paul, MN

Coelomic fluid of the sea urchin *Lytichinus variegatus* has been reported to contain petalloid, red spherule, colorless spherule and migratory coelomocytes. We observed a cell type, typically low in abundance, that increased significantly during the sea urchin's spawning seasons. The level of coelomic fluid and overall number of immune cells during spawning decreases since the coelomic cavity is consumed with swollen gonads containing gametes. Cell counts were performed from September through May, including two spawning seasons (November and March). Our results showed a 50% increase in the unidentified cell type during spawning seasons while ratios of all other coelomocytes remained constant. After spawning, the numbers of these cells precipitously dropped. The cells show a striking resemblance to red spherule coelomocytes in both morphology and motility but are not pigmented. The cells appear multi-lobed, extend and retract blebs in three dimensions but do not appear to translocate linearly. Using digital-enhanced video microscopy, the rate of motility and cell surface bleb formation showed accelerated and more fluid movements than those observed in the red spherule cells. Bleb formation was demonstrated to be dependent on the acto-myosin cytoskeleton based on perfusion experiments using phalloidin, cytochalasin B and blebbistatin. The microtubule disruption drug, taxol, had no effect on cell shape or motility. However, cells treated with the microtubule disruption drug, nocodazole, lysed within seconds of exposure. We thus refer to these cells as Nocodazole Sensitive Cells or NSCs. The unique function of NSCs in sea urchin immunity is presently unknown, but may indicate a complex mechanism of sea urchin immunocompetence where a specific immune defense, needed during sea urchin spawning, is accomplished by NSCs.

1792

***cnr15*, a *Dictyostelium* Cell Number Regulation Gene, is Required for Size Regulation Mediated by Counting Factor**

Y. Tang,[1] T. Gao,[2] D. Hatton,[2] R. Gomer[2,1]; [1]Department of Biochemistry & Cell Biology, Rice University, Houston, TX, [2]Howard Hughes Medical Institute, Houston, TX

Unicellular *Dictyostelium* cells aggregate to form multicellular fruiting bodies during development triggered by the lack of food. Counting factor (CF), a secreted protein complex, was previously found to regulate aggregate size. High levels of CF induce the formation of small aggregates and low levels of CF cause the formation of big aggregates. To understand the molecular mechanisms of CF's regulation of aggregate size, a second-site suppressor screen was conducted to find the components of the CF signal transduction pathway. *cnr15*, one of the cell number regulation (cnr) genes identified in this screen, was found to affect aggregate size. *cnr15* is predicted to encode a Ser/Thr and Tyr dual specificity phosphatase, sharing 40% identity to *Dictyostelium* 3'-phosphoinositide phosphatase known as PTEN. *cnr15*$^-$ cells, generated by homologous recombination in wild-type Ax2 cells, formed smaller fruiting bodies in comparison with those formed by Ax2 cells. *cnr15*$^-$ cells exhibited a higher random cell motility and a slightly lower cell-cell adhesion than Ax2 cells do, which is consistent with previous observations that higher random cell motility and lower cell-cell adhesion lead to smaller aggregates in *Dictyostelium*. *cnr15*$^-$ cells showed a higher level of polymerized actin and a lower level of assembled myosin II in response to cAMP stimulation, indicating Cnr15 regulates cell motility via regulating cytoskeleton proteins. *cnr15*$^-$ cells were insensitive to addition or depletion of CF, indicating that loss of *cnr15* abrogates CF's size regulation effects. Our results suggested that Cnr15 is required for *Dictyostelium* aggregate size regulation mediated by CF.

1793

**HEI10, E3 Ubiquitin ligase, Negatively Regulates Cell Motility**

M. K. Singh,[1] E. Nicolas,[1] W. Gherraby,[1] D. Dadke,[1] S. R. Lessin,[2] E. A. Golemis[1]; [1]Basic Sciences, Fox Chase Cancer Center, Philadelphia, PA, [2]Medical Sciences, Fox Chase Cancer Center, Philadelphia, PA

HEI10 defines a novel class of RING finger protein that regulates the passage through G2. Previously, we have shown that HEI10 functions as an E3 ubiquitin ligase to promote the proteolysis of cyclin B, such that overexpression of HEI10 extends the G2 phase of cell cycle. HEI10 is itself subject to cell-cycle-controlled changes in expression and localization, and is an *in vitro* substrate for cyclin B/cdc2, implying a feedback circuit between the HEI10 protein and the cell cycle machinery. Given that HEI10 localizes in part to focal adhesions, and the HEI10 mRNA has been reported to be particularly abundant in aggressive melanomas, we wished to delineate the functional role of HEI10 in cancer with following aims: 1) Does depletion of HEI10 cause changes in cell migration and attachment, compatible with a role in metastasis, and 2) Is HEI10 more abundant in aggressive versus non-aggressive tumors, and if so, is this difference specific to melanoma? Using live cell imaging and Boyden chamber assays, we have found that siRNA-mediated depletion of HEI10 increases cell motility. HEI10 depleted cells spread over a greater area than control-depleted cells, although the rate of cell reattachment following trypsinization was not altered. HEI10-depleted cells also ceased to proliferate, with a reduced number of cells observed in G2. HEI10 depletion did not affect cellular invasion through Matrigel. Similar results were obtained in both the U2OS (osteosarcoma), and MCF7 (breast adenocarcinoma) cell lines. These data indicate that HEI10 negatively regulates cell motility, perhaps through promoting the degradation of a pro-motility signaling protein. Separately, we have found that HEI10 is not particularly abundant in malignant melanomas, but is well-expressed in many primary tissues and cell lines. Investigation of the mechanism of HEI10 action in control of cell migration is in progress.

## Cytoskeleton-Membrane Interactions II (1794-1807)

1794

**Genetic Evidence that the PH Domain of Beta Spectrin is Responsible for Spectrin Targeting**

A. Das, C. Base, R. Dubreuil; Biological Sciences, Univ. of Ill. Chicago, Chicago, IL

We used a transgene replacement strategy to examine the contributions of the putative ankyrin binding domain and the pleckstrin homology (PH) domain to β spectrin function in the *Drosophila* midgut epithelium. A control myc-epitope-tagged wild type transgene rescued a lethal β spectrin mutation and the myc-tagged protein was correctly targeted in midgut copper cells. Transgenic β spectrin colocalized with endogenous α spectrin at the septate junction and in the basolateral plasma membrane domain below the level of the septate junction, but not in the apical domain. One mutant transgene in which the putative ankyrin binding repeat domain was replaced with an irrelevant repeat domain from α spectrin was also

targeted correctly in copper cells and efficiently rescued mutants to adulthood. This result indicates that either the ankyrin binding site is located elsewhere in β spectrin or that ankyrin binding is dispensible for spectrin function. In contrast, a truncated β spectrin transgene lacking the C-terminal PH domain (ΔPH) was not correctly targeted in copper cells and it exhibited a poor efficiency of mutant rescue. Interestingly the ΔPH protein was targeted only to the septate junction in a wild type background and even that targeting activity was lost in the absence of wild type β spectrin. The results suggest that there are two different mechanisms operating in copper cells to target spectrin to the septate junction and to the subjunctional basolateral domain. Remarkably, a very small number of ΔPH-spectrin-expressing mutants were rescued to adulthood. These flies appeared normal except that they were approximately half the size of their wild type siblings. Mutants without the ΔPH transgene always died before larval hatching. Thus there are additional essential functions of spectrin that are independent of the PH domain.

1795

**CAMSAP1 - A Calcium/Calmodulin-Regulated Spectrin-Associated Protein That is Required for Neurite Outgrowth from PC12 Cells**

M. D. A. King,[1] G. W. Phillips,[1] P. A. Bignone,[1] P. M. Taylor-Harris,[2] A. M. Maggs,[2] J. C. Pinder,[2] M. J. Allen,[1] A. J. Baines[1]; [1]Biosciences, University of Kent, Canterbury, United Kingdom, [2]Randall Division of Cell and Molecular Biophysics, King's College, London, United Kingdom

We describe CAMSAP1, a calmodulin-regulated spectrin-associated protein. The human CAMSAP1 gene is on chromosome 9 at q34.3. In vitro, CAMSAP1 binds $Ca^{2+}$/calmodulin and brain spectrin. The binding site for CAMSAP1 in spectrin is located in betaII-sigma1-spectrin within the linker between the last triple helical repeat and the pleckstrin homology domain. The splice variant betaII-sigma2, that shares only part of this region, does not bind CAMSAP1 in vitro. Native complexes of betaII-sigma1-containing spectrin co-immunoprecipitate with CAMSAP1 from rat brain extracts in EGTA. $Ca^{2+}$ inhibited immunoprecipitation but in $Ca^{2+}$/trifluoperazine, immunoprecipitation was restored indicating that calmodulin regulates CAMSAP1-spectrin interaction. Immunofluorescence on PC12 neurons demonstrated CAMSAP1 in cell bodies, neurites and growth cones in close association with spectrin. To investigate the function of CAMSAP1 in PC12 cells, we knocked down its expression with siRNA. 24 hours after siRNA transfection, CAMSAP1 was undetectable by immunofluorescence, but unchanged in controls. Importantly, knocked-down cells did not respond to NGF by extending neurites, even though ERK was activated. CAMSAP1 evidently has a role in adult brain too: it is abundant in cerebellar granule neurons. CAMSAP1 is one of three related genes in vertebrates; single copies exist in the genomes of invertebrate animals. All these proteins contain a calponin homology domain and a novel C-terminal domain. We have extended our analysis of CAMSAP1 by investigating the Drosophila homolog (dCAMSAP). Two alleles containing P-element insertions in the dCAMSAP gene are embryonic recessive lethal at approximately stage 16; the trans-heterozygotes are also lethal. They show severe defects in both the peripheral and central nervous systems. We conclude that CAMSAP1 plays a direct role in formation of the nervous system, and that it links the established spectrin and calmodulin pathways in this process downstream of ERK.

1796

**Isoform Specificity of Ankyrin-B: A Site in the Divergent C-Terminal Domain is Required for Intramolecular Association**

K. M. Abdi,[1] J. Q. Davis,[1] P. J. Mohler,[2] V. Bennett[1]; [1]Cell Biology, Duke University, Durham, NC, [2]Department of Pathology, Vanderbilt University, Nashville, TN

Ankyrins provide a direct link for integral membrane proteins to the underlying spectrin/actin cytoskeleton. The three major ankyrin gene products, ankyrins R, B, and G contain significant amino acid identity and are co-expressed in many cell types, but maintain unique functions *in vivo*. Recent studies have identified the highly divergent C-terminal regulatory domain in ankyrin-B as the key domain for driving ankyrin-B-specific functions in mouse neonatal cardiomyocytes. The structural basis for this C-terminal domain driven specificity was evaluated in this study. Here we describe an intramolecular interaction between the C-terminal domain and the membrane-binding domain of ankyrin-B using pure proteins in solution and the yeast two-hybrid assay. Through extensive deletion and alanine scanning mutagenesis, we have mapped key residues for interaction in both domains. Amino acids 1597EED1599 located in the ankyrin-B C-terminal domain are necessary for interaction with the membrane-binding domain and are required for localization of InsP3-receptors in cardiomyocytes. Amino acids 37R/40R located in the first ankyrin repeats of the membrane-binding domain are also required for interaction in yeast two-hybrid assays. Physical properties of the ankyrin-B C-terminal domain, determined by circular dichroism spectroscopy and hydrodynamic parameters, reveal it is unstructured and highly extended in solution. Similar structural studies performed on full-length 220 kDa ankyrin-B harboring alanine substitutions, 1597AAA1599, reveal an increased frictional ratio when compared to wild type ankyrin-B. Taken together these results suggest a model of an extended and unstructured C-terminal domain folding back to bind and regulate the membrane-binding domain of ankyrin-B. They also provide a mechanism of intramolecular interaction as a means to drive ankyrin-B functional specificity in-vivo.

1797

**Study of the Effect of Bradykinin and Thrombin on the Cytoskeleton by Atomic Force Microscopy**

C. Cuerrier, F. Gobeil, M. Grandbois; Department of Pharmacologie, Université de Sherbrooke, Sherbrooke, PQ, Canada

Thrombin (TB) and Bradykinin (BK) are important in the maintenance of vascular homeostasis. Indeed, their cellular effects induce important physiologic responses by activating specific receptors (PAR-1 and $B_2$) that induce intracellular signaling and lead to cytoskeletal reorganization. In the present study, we have quantified the effects of these agonists on cytoskeletal reorganization, by measuring the interaction forces between the cell membrane and cytoskeleton by atomic force microscopy (AFM) and by fluorescent microscopy using a phalloidin probe. Membrane tethers (MT) can be extracted from individual HUVEC cells by the establishment of physical contact between the cell and an AFM cantilever. Retraction of the cantilever induces MT formation, characterized by a constant elongation force. These force measurements can be used to monitor the cytoskeletal reorganization induced by BK and TB signaling pathways. Time course analysis of TB (10 nM) and BK (1 µM) activities indicate a significant increase in elongation forces (47 and 51 pN, respectively) after 30 to 45 minutes in comparison to the control (39 pN), suggesting an increase in membrane-cytoskeleton interaction and clearly indicating an important biomechanical response of the cell to these treatments. These AFM results on the TB and BK - induced cytoskeletal reorganization were confirmed by fluorescence imaging. Our results show that it is possible to mechanically and temporally quantify structural changes in the cytoskeleton by AFM. This new experimental model could be used to study the implication of cytoskeleton reorganization in physiological processes such as endothelium permeability and cell motility.

1798

**Vinculin is Activated by Coordinated Action of Talin and F-actin**

H. Chen, D. Choudhury, S. W. Craig; Biological Chemistry, Johns Hopkins University School of Medicine, Baltimore, MD

Published data demonstrate that vinculin is maintained in its high affinity autoinhibited state by cooperation between two lower affinity intramolecular interfaces, D1/Vt and D4/Vt. This finding, together with the inability of talin rod domain to bind full length vinculin in solution, suggest a model in which two ligands cooperate to activate vinculin by disrupting both intramolecular interfaces. However, crystal structures of D1 and VBS-3, a talin binding peptide, and of the 4-helix domain of talin that contains VBS-3, indicate that talin itself must undergo activation to present the VBS-3 peptide to vinculin. Once activated, talin alone may be capable of activating vinculin. To discriminate between these models we first examined the solution binding of TAMRA-labeled VBS-3 peptide to D1, D1-D4 (Vh), and vinculin. Whereas VBS3 binds to D1 and Vh with ~100nM affinity, binding to native vinculin was undetectable. We conclude that the VBS-3 binding site on autoinhibited vinculin is kinetically inaccessible. We used a new vinculin FRET probe to assay the ability of ligands to activate vinculin. Neither F-actin, a ligand for vinculin tail domain, nor talin rod domain, a ligand for D1, were able to activate the FRET probe in lysates of HEK293 cells. However, in the presence of 5uM F-actin, talin rod domain (0-2uM) induced dose-dependent activation of the vinculin FRET probe. This and other data lead us to propose that ligands for D1 may bind to vinculin when Vt momentarily dissociates from D1, but are quickly displaced by Vt unless Vt is bound by another ligand or otherwise modified. Our findings support a dual-ligand activation model, and also suggest a mechanism for controlling how long vinculin remains activated.

1799

**Suramin Effects on *Trypanosoma cruzi*: Cytochemical and Immunocytochemical Evidences of Changes on the Flagellum-Cell Body Adhesion Region**

D. F. R. Bisaggio,[1] L. Campanati,[2] R. C. V. Pinto,[1] T. Souto-Padrón[1]; [1]Instituto de Microbiologia Prof. Paulo de Góes, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil, [2]Instituto de Biofísica Carlos Chagas Filho, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Suramin has been previously reported to inhibit distinct cell enzymes besides the effects on synthesis and distribution of cytoskeleton proteins. Our study indicates that long lasting incubation of *Trypanosoma cruzi* in the presence of suramin caused a partial or complete detachment of the flagellum from the cell body besides an accentuated decrease on parasite motility. Immunofluorescence analysis of the region of adhesion between the cell body and the flagellum on suramin treated trypomastigotes did not show any difference in the localization of FAZ antigens recognized by 4D9 and L3B2 monoclonal antibodies despite the presence of a detached flagellum. On the other hand, suramin caused a significant change on the surface expression of FRA antigen, which was observed throughout the surface of trypomastigotes. Cytochemical localization of cationized ferritin showed that anionic particles gain access to the space between the cell and flagellar membranes as well as to the flagellar pocket in suramin treated parasites indicating alterations on extracellular components of the region of adhesion between the cell body and the flagellum.

1800

**A Novel Microtubule Binding and Bundling Domain in a Coiled-coil ER Protein, p180/Ribosome Receptor**

K. Ogawa-Goto,[1,2,3] T. Ueno,[1] K. Tanaka,[1] K. Tanaka,[2] T. Sata,[2] S. Irie[1,3]; [1]Nippi Research Institute of Biomatrix, Tokyo, Japan, [2]NIID, Tokyo, Japan, [3]Japan Institute of Leather Research, Tokyo, Japan

**Introduction**: The ER uses microtubules (MT) as a framework for extending its reticular network, while mechanism by which the ER maintains this structure in vivo remains unclear. Here we present data that 180/ribosome receptor, a coiled-coil protein on the ER membrane, has novel MT binding domains, and could contribute spatial positioning of the ER along the MT. **Results**: As overexpression of p180 modified the MT arrays in cultured cells, we determined whether p180 binding to MT is direct and which domain is responsible for this interaction. By *in vitro* co-sedimentation assays, we identified a novel MT-binding domain in the coiled-coil region of p180, which induced MT bundling both in vitro and in vivo. Bacterially expressed full-length p180 interacted with MT efficiently. To address a possible role of p180 on the ER organization, we examined siRNA treatment of 180 in human diploid fibroblasts containing abundant endogenous p180. Depletion of p180 is sufficient to alter their normal ER distribution to retract around the nucleus, while expression levels of other ER markers were not changed. Differing degrees of p180 depletion were coincidentally associated with severity of the ER retraction. In these si-RNA transfected cells, re-distribution of MTs occurred. **Conclusions**: Our data indicate that p180 could function as a direct linker between the ER and MT, and seems to affect their spatial distributions in the cultured cells.

1801

**Tubulin Detyrosination Affects Microtubule Tips Protein Complex: Implication in Spindle Position and Neuronal Organisation**

L. Peris,[1] A. Andrieux,[1] M. Thery,[2] J. Fauré,[1] J. Wehland,[3] M. Bornens,[2] D. Job[1]; [1]Rhone Alpes, DRDC-CS CEA INSERM U366, Grenoble, France, [2]Institut Curie UMR144 CNRS, Paris, France, [3]German Research Center of Biotechnology, Braunschweig, Germany

Tubulin is subject to a special cycle of detyrosination/tyrosination in which the C-terminal tyrosine of α-tubulin is cyclically removed by a carboxypeptidase and readded by a tubulin-tyrosine-ligase (TTL). This tyrosination cycle is conserved in evolution, yet its physiological importance is a matter of conjecture. TTL suppression in mice causes perinatal death due to severe brain disorganization. Spindle positioning in neuronal progenitors was perturbed with resulting imbalance of proliferation/differentiation events. In addition, mitotic spindle orientation was also altered in cultured TTL null fibroblasts grown in special restrictive micropatterns. In culture, TTL null neurons display morphogenetic anomalies including an accelerated and erratic time course of neurite outgrowth and a premature axonal differentiation. CLIP family proteins (CLIP170, CLIP 115 and p150Glued), which links microtubule ends to the cell cortex, failed to associate with microtubule tips in TTL null cells and showed a reduced interaction with detyrosinated microtubules *in vitro.* We propose that the tyrosination cycle is required for the control of microtubule interactions with the cell cortex and is thereby critical for mitotic spindle orientation and neurogenesis.

1802

**Mitotic Spindle Oscillations**

S. W. Grill,[1,2,3] K. Kruse,[2] J. C. Roeper,[3] J. Pecreaux,[3] A. A. Hyman,[3] J. Howard,[3] F. Jülicher[2]; [1]Physics, University of California, Berkeley, CA,

[2]Max Planck Institute for the Physics of Complex Systems, Dresden, Germany, [3]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany

During unequal cell division the mitotic spindle is positioned away from the center of the cell before cell cleavage, which in many biological systems is accompanied by oscillatory movement of the spindle. We present a simple theoretical description for mitotic spindle oscillations. We show that the cooperative attachment and detachment of cortical force generators to astral microtubules generally leads to spontaneous oscillations beyond a critical number of force generators. This mechanism can quantitatively describe the spindle oscillations observed during unequal division of the one cell stage Caenorhabditis elegans embryo. Finally, we measure the oscillation threshold by RNA mediated interference of the G-protein regulator gpr-1/2.

1803

**Cytoskeletal Dynamics Influence S100A8 and S100A9 Localization and Movement**

A. Broome, R. L. Eckert; Physiology & Biophysics, Case Western Reserve University, Cleveland, OH

Epidermal hyperproliferation, premature cell death, and epidermal remodeling lead to a psoriatic architecture. As proliferative keratinocytes (HKc) lose contact with the ECM, cells undergo a type of apoptosis termed anoikis. Apoptotic cell death generates modified proteins that induce inflammatory responses. S100 proteins are suggested as HKc-derived mediators of inflammation. In psoriasis, S100A8/S100A9 expression is markedly elevated and aberrant expression is detected in the epidermal layers. We examine how inflammatory agents such as okadaic acid (OA), a phosphatase inhibitor, influence the distribution and promote formation of vesicles containing S100A8/S100A9 in HKc. We propose that formation of these membrane structures involve cytoskeletal proteins, such as tubulin and actin. Our studies show that S100A8/S100A9 assume a cytoplasmic distribution in resting cells. Instead of linear actin bundles typical for HKc, circular arrays of actin bundles formed in the cortical cytoplasm of OA-treated HKc. OA treatment causes S100A8/S100A9 movement to the cell periphery via intact microtubules and localization within the cortical actin ring followed by the formation of S100-positive membrane blebs that protrude from the apical surface. The blebs are ringed by F-actin, which sequesters the S100 protein-containing cytoplasm. OA induces F-actin depolymerization in HKc. Disruption of the F-actin network by OA, as quantified by a decrease in the F/G-actin ratio, does not alter the spatial distribution or formation of the membrane blebs. Bleb integrity is maintained even under increased osmotic force physical stress as measured by FM 1-43 dye incorporation. Cytochalasin D, an F-actin polymerization inhibitor, prevents the formation of blebs observed in OA-treated HKc. Sustained treatment with OA results in apoptosis. The majority of HKc detach from the substrata; only cell debris and intact blebs remain. We propose that S100 protein-containing blebs may then be engulfed by phagocytic cells and invoke the inflammatory response.

1804

**Ezrin Forms a Link Between Signaling and Vesicular Membrane Trafficking in Gastric Acid Secretion**

F. WU,[1] H. Deng,[1] R. Zhou,[2] Z. Guo,[3] Z. Fan,[1] K. Yuan,[1] X. Cao,[1] J. Forte,[2] X. Yao[3]; [1]Division of Cell Dynamics, Hefei National Laboratory, Anhui, China, [2]Molecular & Cell Biology, University of California, Berkeley, CA, [3]Physiology, Morehouse School of Medicine, Atlanta, GA

Stimulation of acid secretion in gastric parietal cells typically involves an initial elevation of intracellular calcium and/or cAMP followed by activation of a cAMP-dependent protein kinase cascade that triggers the translocation and insertion of the proton pump enzyme, H,K-ATPase, into the apical plasma membrane of parietal cells. Our recent studies have revealed PKA-mediated phosphorylation site on ezrin and the importance of such phospho-regulation in gastric acid secretion (J. Biol. Chem. 2003. 278, 35651). However, little is known about the cAMP-dependent signaling events and the role of the actin cytoskeleton in supporting the apical pole remodeling associated with parietal cell activation. Using phospho-mimicking ezrin as bait, we have identified a dozen positive clones including a novel ARF GTPase-activating protein (ARF-GAP). This novel ARF-GAP contains a PH domain and displays a PIP2-dependent GAP activity *in vitro*. The ARF-GAP interacts with ezrin *in vivo* and *in vitro*, and co-distributes with ezrin to the apical membrane of gastric parietal cells. To determine the inter-relationship of ezrin-ARF-GAP localization to the apical membrane, we carried siRNA experiment to suppress ezrin protein level. The apical localization of ARF-GAP is minimized in the absence of ezrin, suggesting the role of ezrin in targeting and/or maintaining ARF-GAP to the apex. Moreover, the translocation of H,K-ATPase to the apical membrane is disrupted in the ezrin-deficient cells. Currently, we are evaluating how ezrin-ARF-GAP interaction orchestrates ARF6 and H,K-ATPase trafficking cycle in parietal cell acid secretion.

**Phosphorylation of Ezrin on T567 is Not Involved in Membrane Recruitment and Activation of Parietal Cells**

R. Zhou, J. Forte; Molecular & Cell Biology, University of California, Berkeley, CA

The ERM protein family (ezrin/radixin/moesin) participates in linking functional activities of the plasma membrane to the actin cytoskeleton, and are regulated via phosphorylation on several potential sites. Phosphorylation of the conserved threonine residue near the C-terminus (T567, ezrin; T558, moesin; T564, radixin) is under the control of the small GTPase Rho, and has been shown to alter N/C oligomerization of ezrin and promote formation of actin-rich surface projections in many cells. In previous work using the gastric parietal cell model for secretory activation we compared wild type T567 ezrin (WT) and mutant forms, including the non-phosphorylatable T567A and one mimicking permanent phosphorylation, T567D. The most striking result was that expression of T567D (in contrast to WT and T567A) produced a great elaboration of cytoplasmic extensions, but principally at the basolateral surface, and these cells did not respond to secretory stimuli. We concluded that T567 phosphorylation may direct ezrin to membrane-cytoskeletal activity away from apical secretory surface. Here we show that the elaborate basolateral actin- and ezrin-rich extensions induced by T567D mutant ezrin "parasitizes" many membrane sources for the requisite increase in area that must occur, including H pump-rich tubulovesicles and even apical membrane. Using a site-specific antibody we show that a fraction of total ezrin is phosphorylated at T567 in resting, non-stimulated, parietal cells, and that there is no significant change in the level of T567 ezrin (or T558 moesin) when the cells are maximally stimulated to secrete acid. These data support the hypothesis that the Rho signaling pathway and T567 phosphorylation are not involved in membrane recruitment and secretory activation at the apical plasma membrane of the parietal cell, but probably function to support membrane-cytoskeletal interaction at the basolateral surface.

1806

**Missense Mutations in the Merlin Protein Cause a Loss of Association with Lipid Rafts**

J. L. Ovesen, J. Stickney, L. Foster, W. Ip; Cell Biology, University Of Cincinnati, Cincinnati, OH

Neurofibromatosis type 2 (NF2) is an autosomal dominant disorder affecting 1:40,000 live births. NF2 results from loss of heterozygosity at the *NF2* locus and the accompanying loss of functional gene product, the canonical tumor suppressor merlin. Loss of functional merlin leads to formation of schwanommas of the 8$^{th}$ cranial nerve and other nervous system tumors. Merlin is related to the ERM (ezrin-radixin-moesin) family of cytoskeleton-membrane linker proteins. Despite the fact that merlin lacks the C-terminal F-actin binding site that is conserved in the ERM proteins it is insoluble in non-ionic detergents such as Triton X-100 (TX-100), a characteristic often attributed to cytoskeleton-associated proteins. However, our recent observation that merlin resides in lipid rafts, Triton-insoluble membrane microdomains rich in cholesterol and sphingolipids, led us to hypothesize that the detergent solubility properties of merlin result mainly from its localization to rafts with limited contribution from binding to the F-actin network. We tested this hypothesis by investigating the TX-100 solubility and raft localization of *NF2* missense mutations K79E, L360P, and L535P. As shown previously, all of these mutations encode merlin proteins with greater detergent solubility than wild type merlin. Biochemical and immunofluorescence studies further revealed that all three mutations cause a dramatic loss of lipid raft association. Future studies will probe whether re-targeting of these mutations to rafts using lipid anchors can restore their growth-suppressive function and will test our central hypothesis that lipid raft localization of merlin is necessary for its function. Supported by the NIH, the NNFF, and the DOD.

**Filamin-Caveolin Interactions in Caveolae-Mediated Endocytosis**

M. Sverdlov, R. D. Minshall; Pharmacology, University of Illinois at Chicago, Chicago, IL

The F-actin cross-linking protein filamin A also binds to caveolin-1, the primary coat protein of caveolae (Stahlhut and van Deurs, MBC 11:325-337, 2000). This interaction is thought to mediate the physical association between caveolae and actin filaments. In the present study, we tested the functional importance of filamin A in caveolae-mediated endocytosis. Filamin A co-fractionated with caveolin-1 in lipid raft-enriched fractions of human lung microvascular endothelial cells. In addition, caveolin-1 co-immunoprecipitated with filamin A suggesting that these proteins are associated *in vivo*. Expression of a filamin A fragment containing the caveolin-1 binding site (repeats 22-24) prevented the association of caveolin-1 with endogenous filamin A and significantly reduced albumin endocytosis. We next determined if caveolin-filamin interactions are regulated by caveolin-1 phosphorylation on Tyr 14, which is *Src*-dependent. mSIRK, an activator of Gβγ, which in turn induces *Src* activation (Shajahan et al., JBC 279:48055-48062, 2004), or sodium orthovanadate, an inhibitor of tyrosine phosphatases, induced caveolin-1 phosphorylation and its association with filamin. The increase in caveolin-filamin binding was blocked by PP2, a specific inhibitor of *Src*-family tyrosine kinases. Furthermore, we found that filamin A associates to a greater extent with the phosphorylation-mimicking caveolin-1 mutant, Y14D, compared to the phosphorylation-defective caveolin-1 mutant, Y14F. Thus, our results indicate that caveolin-1 phosphorylation positively regulates the interaction between filamin A and caveolin-1. This interaction is now shown to be required for *Src*-dependent, caveolae-mediated endocytosis in endothelial cells.

## Extracellular Matrix & Cell Behavior I (1808-1823)

1808

**Laminin Isoforms Regulate Trophoblast Cell Behavior During Mouse Embryo Implantation**

E. J. Klaffky,[1] I. M. Gonzales,[1] J. Miner,[2] F. J. De Mayo,[3] J. P. Lydon,[3] A. E. Sutherland[1]; [1]Cell Biology, University of Virginia, Charlottesville, VA, [2]Internal Medicine, Washington University, St. Louis, MO, [3]Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX

Extracellular matrix has specific effects on cell behavior which influence many aspects of early development. In the early postimplantation mouse embryo dynamic patterns of laminin (Ln) 1in the embryo and Ln 10/11 expression in the surrounding decidua correlate with the progression of implantation. These two Ln isoforms have distinct effects on trophoblast cell behavior : Ln 1 promotes random migration and decreases spreading, whereas Ln 10/11 promotes both spreading and persistent migration. When presented as adjacent substrates however, cells recognize the boundary and do not enter the region containing Ln 1. Lns 1 and 10/11 also have differential effects on cell-cell adhesion, with Ln 1 decreasing and Ln 10/11 promoting intercellular adhesion. Trophoblast cells interact with Ln 1 through beta 1 integrins, whereas they interact with Ln 10/11 with a combination of beta 1 and beta 3 integrins. The effects of each Ln isoform on cell behavior and the localization of Ln 1 in Reichert's membrane and Ln 10/11 in the surrounding decidual matrix suggest that they may influence the progress of implantation. To test this possibility we generated a decidual knockout of Ln 10/11 by crossing a floxed Ln alpha 5 mouse with one carrying Cre under the control of the progesterone receptor promoter. Females homozygous for the conditional locus and carrying the Cre gene are fertile, although the decidual matrix completely lacks Ln 10/11. Embryos are able to initiate implantation, however, the pattern of trophoblast invasion and morphogenesis of the yolk sac placenta are abnormal. These results suggest that the spatial distribution of Ln isoforms is a key factor regulating the direction and quality of invasion of trophoblast cells during implantation, and that decidual Ln 10/11 provides epigenetic cues that drive the morphogenesis of the yolk sac placenta.

1809

**Detection of Tenascin-W in Patient Sera and in Cancer Tissue**

M. Degen,[1] C. Rüegg,[2] P. Schraml,[3] R. Simon,[3] R. Kain,[4] R. Chiquet-Ehrismann[1]; [1]Friedrich Miescher Institute for Biomedical Research, Basel, Switzerland, [2]Centre Pluridisciplinaire d'Oncologie, University of Lausanne, Lausanne, Switzerland, [3]Institute of Pathology, University of Basel, Basel, Switzerland, [4]Department of Ultrastructural Pathology and Cell Biology, University of Vienna, Vienna, Austria

It is well recognized that extracellular matrix proteins such as tenascins are present during the development of an organism as wells as in pathological situations. However, the functional impact of their presence is not very well understood so far. Tenascin-W (TN-W), the fourth member of the tenascin family remains the least well characterized one. In our study we aim to determine serum TN-W levels in cancer patients evaluating its diagnostic significance, and to investigate its expression in tumors. To measure serum TN-W levels, a sensitive sandwich ELISA was established by the use of two anti-human TN-W antibodies and the purified protein as a standard. With our assay, concentrations as low as 0.005 mg/l are detectable, making it sufficiently sensitive for the determination of serum TN-W levels. TN-W concentrations in sera of patients with

breast cancer were not increased compared to healthy volunteers (normal: 0.424 +/- 0.13 mg/l; breast cancer: 0.370 +/- 0.173 mg/l). However, TN-W concentrations in colon cancer patients were elevated (colon cancer: 0.904 +/- 0.34 mg/l). Furthermore, we analyzed TN-W expression in human breast tumor extracts by western blotting. Interestingly, we found TN-W expression in tumor tissues (carcinomas as well as benign tumors), but no expression in the normal mammary parenchyma. 74% of the tumor samples were TN-W positive and 82% showed expression of TN-C. However, TN-W and TN-C amounts vary greatly between tumors and some contain either TN-W or TN-C exclusively, indicating independent mechanisms regulating TN-W and TN-C expression. We conclude that TN-W might be an important protein with diagnostic value in cancer patients.

1810

**Multivalent Action of NG2 Proteoglycan in Cell-Microenvironment Interactions Involved in Tumor Growth and Metastasis**

S. Cattaruzza,[1,2] E. De Lorenzo,[1] W. Stallcup,[3] A. Colombatti,[1] P. Braghetta,[4] P. Bonaldo,[4] R. Perris[1,2]; [1]Division for Experimental Oncology 2, The National Cancer Institute CRO IRCCS, Aviano (PN), Italy, [2]Department Evolutionary and Functional Biology, University of Parma, Parma, Italy, [3]The Burnham Institute, LaJolla, CA, [4]Department of Medical Biotechnology, University of Padua, Padua, Italy

Using cells derived from knock-out mice and a combined RNAi and gene transfer approach in human mesenchymal tumor cells we find that NG2 proteoglycan is critically involved in the cells' autocrine and paracrine response to several FGF family members. The proteoglycan contributes to the control of FGF signalling by specifically associating, in a ligand-independent manner, with FGFR1/3 and by sequestering and activating FGFs on the cell surface. Contemporary, we also confirm that NG2 serves as a integrin-independent receptor for collagen type VI and that it promotes tumor cell motility on this substrate through the activation of cytoskeleton-mediated signal transduction cascades. A phospho-proteomic approach has been adopted to dissect these pathways and determine the extention to which they converge with those elicited by growth factors. To further clarify the transcriptional regulation underlying this phenomenon, we are pursuing a global gene profiling by DNA microarray in cells overexpressing NG2. Similar NG2-rich melanoma cells, sarcoma cells in which the constitutive PG levels have been knocked-down by RNAi, and dominant-negative mutant cells are examined in motility assays in vitro and for their ability to grow and metastasise in wild type and collagen type VI knock-out animals. These studies are complemented by trans-endothelial migration assays in vitro, involving primary haematic and lymphatic cells, which are aimed at defining the molecular mechanisms responsible for the ability of NG2 to confer metastatic potential to transformed cells by affecting their intra- and extravasation capacities.

1811

**β1,4-*N*-Acetylglucosaminyltransferase III Antagonizes the Effect of β1,6-*N*-Acetylglucosaminyltransferase V on α3β1 Integrin-mediated Cell Migration**

Y. Zhao,[1] J. Gu,[1] T. Nakagawa,[2] E. Miyoshi,[1] Y. Kariya,[3] K. Miyazaki,[3] A. Kondo,[2] N. Taniguchi[1]; [1]Department of Biochemistry, Osaka University Graduate School of Medicine, Osaka, Japan, [2]Department of Glycotherapeutics, Osaka University Graduate School of Medicine, Osaka, Japan, [3]Division of Cell Biology, Kihara Institute for Biological Research, Yokohama City University, Yokohama, Japan

β1,6-*N*-acetylglucosaminyltransferase V (GnT-V) is required in the biosynthesis of β1,6GlcNAc-branched *N*-linked glycans attached to cell surface and secreted glycoproteins. Malignant transformation is accompanied by increased β1,6GlcNAc-branching of *N*-glycans. β1,4-*N*-acetylglucosaminyltransferase III(GnT-III) catalyzes the formation of a bisecting GlcNAc structure in *N*-glycans, resulting in the suppression of further processing and the elongation of *N*-glycans catalyzed by GnT-V in vitro, since it is not able to use the bisected oligosaccharide as its substrate. It has long been hypothesized that the suppression of β1,6GlcNAc branching by the inhibition of GnT-V would be possible based on substrate specificity studies. To test this, we drew a comparison among MKN45 cells(a human gastric cancer cell line), which were transfected with GnT-III, GnT-V, or both, respectively. We found that α3β1 integrin-mediated cell migration on Laminin5 was greatly enhanced in GnT-V transfectant. Such enhancement of cell migration was significantly blocked after introduction of GnT-III. Interestingly an increase in the bisected GlcNAc but a decrease in β1,6 GlcNAc branched *N*-glycans on α3 integrin was observed in these double transfectants. Consistent with that, the overexpression of GnT-III inactive mutant failed to induce all changes above. On the other hand, the introduction of GnT-III had no effects on both GnT-V'activities and expression level of α3 integrin. Our results clearly demonstrate for the first time that GnT-III and GnT-V can modify the same target glycoprotein positively and negatively respectively, by regulating sugar chains on it and the priority of GnT-III for modification of α3 integrin maybe one of the reasons why GnT-III inhibits GnT-V induced cell migration.

1812

**Beclin/ATG6 Regulates Proliferation and Survival During 3D Morphogenesis and Anoikis**

J. Debnath,[1] G. Gao[2]; [1]Department of Pathology, University of California San Francisco, San Francisco, CA, [2]Department of Cell Biology, Harvard Medical School, Boston, MA

The individual units (acini) comprising glandular epithelium possess a hollow lumen that is filled during early oncogenesis. We have been investigating the generation of luminal space in epithelial acini using an *in vitro* 3D MCF-10A cell culture model. Lumen formation involves the selective apoptosis of centrally-located cells within developing acini. However, the hollow lumen still forms when classical apoptosis is blocked via Bcl-2 overexpression, indicating additional processes contribute to luminal clearance. During lumen formation, the central cells in both normal and Bcl-2 expressing acini contain numerous autophagic vacuoles, suggesting autophagy, an adaptive catabolic process in which a cell digests its own contents, may influence cell fate in the lumen. To elucidate the role of autophagy in epithelial cells, we are examining how autophagy regulatory molecules (called ATGs) influence 3D morphogenesis. Remarkably, RNAi-mediated downregulation of Beclin/ATG6 (a tumor suppressor) enhances proliferation in developing acini. Although the resulting acini grow larger in size, they exhibit luminal apoptosis and remain hollow. Surprisingly, Beclin/ATG6 knockdown does not cooperate with Bcl-2 mediated apoptotic inhibition to fill the lumen, despite the decreased autophagy and increased proliferation in these structures. Because cells in the lumen lack contact with extracellular matrix, we have further investigated how autophagy influences cell death upon matrix detachment (*anoikis*). Matrix detachment strongly induces autophagy, confirmed by electron microscopy and the relocation of light-chain 3 (LC3/ATG8) to autophagosomes. Importantly, matrix-detached cells still exhibit autophagy when apoptosis is blocked by Bcl-2 overexpression. In contrast, Beclin/ATG6 knockdown inhibits autophagy and attenuates the cytoprotective effects of Bcl-2 during *anoikis*. Hence, autophagy may actually promote cell survival during matrix detachment. We are now investigating if these prosurvival functions of Beclin/ATG6 influence luminal cell fate and how other ATGs regulate epithelial proliferation and survival during 3D

morphogenesis and *anoikis*.

**Gene Expression Patterns in Aging Human Discs Show Quiescent and Transcriptionally Active Cells**

H. E. Gruber, J. A. Ingram, E. N. Hanley; Orthopaedic Surgery, Carolinas Medical Center, Charlotte, NC

Gene expression patterns in aging human discs show quiescent and transcriptionally active cells Disc cell functions include appropriate gene expression of tissue-specific extracellular matrix (ECM), ECM remodeling, and cell maintenance. Aging/degeneration introduce radical changes in disc physiology. Our objective was to assess global gene expression (using gene arrays) and cellular gene expression (using in situ hybridization) in healthy and degenerating discs in Human Subjects Institutional Review Board-approved protocols. Human disc tissue, Thompson grades II-IV, was obtained from surgeries or control donors. Laser capture microdissection harvested cells for microarray analysis to obtain global expression profiles (9 lumbar, 2 cervical specimens; 4 grade II discs, mean age 34.7 yrs; 4 grade III discs, mean age 41.5 yrs, and 3 grade IV discs, mean age 62.3 yrs) using Affymetrix arrays. In situ hybridization identified expression of selected genes at the cellular level. Strong expression signals were found for collagen type I alpha 2, pro-alpha I type II collagen, fibronectin 1, SPARC, aggrecan, SOX9, MMP3, TIMP3, chondroitin-6-keratan sulfotransferase 1, latent TGF-ß binding protein 2ß, IGF binding protein 7, pro-apoptotic caspases 3 and 8, and anti-apoptotic BCL-2 beta protein. SPARC expression correlated with age ($p=0.04$, $r^2= 0.451$). Pro-alpha 1 collagen II gene expression correlated with age ($p=0.04$, $r^2= 0.447$). Unexpectedly, in situ hybridization analysis revealed that not all cells were transcriptionally active for a given gene product. Inability of adjacent cells to coordinate gene expression is an important finding which would have been missed with only global gene expression profiling. Possible explanations are that with aging/degeneration: a) cells become fewer in number and loose ability to coordinate gene expression, b) loss of signals/cytokines requisite for coordinated gene expression, c) quiescent cells are at different levels of differentiation or senescence.

1814

**Alterations and Functional Consequences of Changes in Laminin Composition of the Extracellular Matrix Induced by the Senescence Program in Prostate Epithelium**

C. C. Sprenger; Medicine, University of Washington, Seattle, WA

The microenvironment in which cells reside appears to play a role in determining behavior of those cells. Several studies support the importance of a changing microenvironment in both aging of an organism as well as in the progression of various cancers. The ability of cells to stop replicating but remain metabolically active is termed senescence. In young organisms, senescence may prevent epithelial cancers by stopping replication of damaged cells, but increase the incident of such cancers in old organisms, in part, by altering the tissue microenvironment. Currently, only senescent epithelial cells have been detected in human prostate. Yet, the role senescent epithelial cells play in the alteration of the microenvironment and prostate cancer progression remains to be elucidated. We hypothesized that as part of the senescent program in prostate epithelial cells, a change in the laminin component of the ECM occurred, which, in part, altered the microenvironment such that growth and migration of the epithelial cells was altered. Senescent prostate epithelial cells express high levels of mac25; overexpressing this protein in the metastatic M12 prostate cancer cell line led to cell senescence, a delay in G1, and decreased growth/tumorigenicity in vivo. We demonstrated a shift in laminin production from laminin 5 ($\alpha3, \beta3, \gamma2$) and some laminin 8 ($\alpha4, \beta1, \gamma1$) in the M12 cells to laminin 9 ($\alpha4, \beta2, \gamma1$) in the M12mac25 cells. Further, matrix from M12mac25 cells reduced the migratory and invasive behavior of the M12 cells in vitro. In conclusion, senescence in prostate epithelial cells induced by the senescence-associated gene mac25 altered the laminin composition of the matrix and this M12mac25 matrix reduced migration and invasion of the metastatic M12 prostate cancer cell line.

1815

**Histological Studies Demonstrating the Effect of a Collagen-Like Peptide on ECM Molecules Synthesis in Human Skin**

C. Dal Farra, A. Perrin, E. Bauza, N. Domloge; Vincience, Sophia antipolis, France

Recent studies have shown that, in addition to improving *ex vivo* skin morphology, the newly developed synthetic oligo collagen-like peptide enhances cultured cell adhesion and differentiation. In these studies, we carried out histological analysis of the effects of a collagen-like peptide and compared it with vitamin C, which is known for its ability to enhance the synthesis of ECM molecules such as collagen. We performed time course studies and immunostaining analysis on human *ex vivo* skin samples treated with 1% collagen-like peptide for 16h to 72h. Parallel experiments with vitamin C at 20 µg/ml were also conducted. Immunostaining analysis included evaluations of collagen I, III, IV, laminin 5, beta 1 integrin, filaggrin and pan keratin. Our findings revealed that application of collagen-like peptide enhanced the synthesis of these ECM molecules, and this effect was seen as early as 16h after application for some molecules such as laminin 5, collagen III, IV and pan keratin. The expression of the other molecules increased after different periods of time of application of the peptide. Interestingly, the synthesis response of some ECM molecules, such as laminin 5, collagen III, IV and pan keratin, was greater and more rapid when prompted by collagen-like peptide than by vitamin C. The findings also revealed that both active ingredients stimulated ECM molecules synthesis to a similar degree when evaluations were made after a longer period of time. A few proteins, such as collagen IV and beta 1 integrin maintained a superior synthesis after a longer period of time in response to the peptide. Within the context of anti-aging and photoaging skin care products, these histological studies reveal that collagen-like peptide's stimulating effect on ECM molecule synthesis can be of great use.

1816

**Substrate Geometry and Chemistry Co-Regulate Growth and Differentiation of Nerve, Schwann, and Muscle Cells**

O. Kolotushkina,[1] M. R. Hynd,[2] W. Shain,[2] B. L. Patton[1]; [1]CROET, Oregon Health & Science Univ., Portland, OR, [2]Wadsworth Center, New York Department of Health, Albany, NY

Genetic studies have confirmed an array of extracellular matrix proteins influence growth and differentiation of muscle cells, Schwann cells, and axons in the developing neuromuscular system. Matrix proteins have restricted distributions in endodneurial and muscle basal laminae, and are thought to have synergistic effects on cellular differentiation. However, in vitro assays have been limited to uniform culture substrates and micropatterning of single components. To begin to assess information encoded in the spatial complexity of multicomponent substrates, we adapted microcontact printing methods to derivitized polyacrylamide "hydrogel" substrates. Matrix proteins double-labeled with fluorescent chromophore

and biotin were stamped at non-saturating levels on streptavidin-conjugated hydrogels. Complexity was increased by serial deposition of multiple proteins, in distinct patterns. Cells (hippocampal neurons; C2C12 myoblasts; primary Schwann cells) adhered poorly (neurons) or not at all to bare hydrogel. Thus, behaviors resulted predominantly from interactions with bound proteins and soluble factors. Schwann and muscle cells proliferate at high rates and move apart from each other on uniform laminin-1 substrates. Cell proliferation was significantly reduced on linear (10 micron-wide) substrate geometries, and cells became aligned, similar to arrangements in vivo. The results suggest availability of embryonic matrix surfaces may limit proliferation, and promote myofiber alignment. Neurons extend processes without orientation on unpatterned substrates. In contrast, neurons on crossed linear patterns of polylysine and laminin-2 appeared to preferentially form axons on laminin-2, and dendrites on polylysine. Axonal preferences were not observed on laminin-1/polylysine patterns. The results suggest that matrix chemistry and geometry have independent and co-dependent roles in regulating tissue formation, possibly including orientation of neuronal polarity. Nerves and muscles regenerate imperfectly following injury in adults. Combinatorial micropatterned substrates may increase the efficacy of cellular guides in tissue engineering. *Supported by Nanobiotechnology Center (NBTC), NSF*.

1817

**Vitronectin is Essential for the Differentiation of Cultured Mouse Cerebellar Granule Cell Precursors**

Y. Miyamoto,[1] T. Saitou,[1] H. Ambe,[1] M. Takeda,[1] S. Murase[2]; [1]Department of Biology, Ochanomizu University, Tokyo, Japan, [2]Department of Cell Biology, Univiersity of Virginia, Charlottesville, VA

Proliferation and neuronal differentiation of granule cell precursors (GCPs) are regulated spatially and temporally in the postnatal cerebellum. The proliferating activity of GCPs is regulated by the Sonic hedgehog protein (Shh), however, it is not fully understood why the GCPs stop proliferation and begin to extend their neurites at the molecular layer in the cerebellum. It has been reported that an extracellular matrix protein, vitronectin, is important for the cerebellar morphogenesis in chick and rat, and one of the vitronectin receptors, αvβ5 integrin heterodimer, plays a critical role for the neurite elongation. Our recent results showed that vitronectin arrests the Shh-dependent proliferation of GCPs, and suggested that one of the immunoglobulin superfamily proteins, nectin-like protein-5 (Necl-5), plays a role in the differentiation of GCPs. In this study, we examined the effect of vitronectin or Necl-5 on the differentiation of mouse GCPs using primary culture system. First, we observed the increased expression level of β5 integrin subunit in the differentiating GCPs. To examine the effect of vitronectin or Necl-5 on the β5 expression, GCP cells was plated on vitronectin-coated dishes or cultured with the existence of anti-Necl-5 function blocking antibody. Obtained results showed that vitronectin increased the expression level of β5 subunit and anti-Necl-5 antibody suppressed its expression. Finally, to confirm the function of vitronectin for the GCPs differentiation, GCPs from vitronectin knockout mice were cultured with or without exogenous vitronectin. The vitronectin$^{-/-}$ GCPs did not differentiate into the mature granule cells, and the extent of their neurite elongation was smaller than that of wild-type GCPs. These defects were recovered by culturing the vitronectin$^{-/-}$ GCPs on vitronectin-coated dishes. These results demonstrate that vitronectin is essential for the differentiation of cultured GCPs.

1818

**Differential Sulfation Pattern of Chondroitin Regulates Axonal Guidance**

Y. Katagiri, H. Wang, H. M. Geller; NHLBI, NIH, Bethesda, MD

Failure of injured axon to regenerate within the CNS after injury has been attributed to inhibitory properties of the glia scar. Others and we showed the presence of chondroitin sulfate proteoglycans (CSPG) forms a barrier to axon outgrowth. Recent studies in vivo demonstrated that removal of CSPG glycosaminoglycan (GAG) chains by chondroitinase ABC treatment promotes functional recovery after injury, indicating GAG chains are essential for the activity. To evaluate functional roles of GAG chains, we have used immobilized GAG chains as well as CSPG to form an interface on poly-L-lysine coated glass coverslips and checked whether axons can cross its boundary. We found that CS-A GAG chains, mainly consisting of 4-sulfated GalNAc in the disaccharide unit, repelled axonal outgrowth of mouse cerebellar granule neurons. In contrast, CS-C consisting of 6-sulfated GalNac, showed no activity. Treatment of GAG chains with 4- sulfatases abolished their inhibitory effect. These results are consistent with the fact showing that inhibition of sulfation in cultured astrocytes by several drugs reduced the inhibitory activity in glia scar model. Further, exposure to CS-A as well as CSPG, but not CS-C, induced RhoA activation in PC12 cells. This finding revealed that the sulfation pattern of chondroitin is pivotal for its inhibitory activity and downstream signal transduction and demonstrates the importance of 4-sulfation on CSPG in axon regeneration.

1819

**Human-, Mouse, and Rat-Laminin-5 May Have Differing Effects on Oral Squamous Cell Carcinoma Proliferation *In Vitro***

T. Vinh, S. O'Malley, K. Kingsley; Biomedical Sciences, University of Nevada, Las Vegas School of Dental Medicine, Las Vegas, NV

The majority of oral cavity cancers are squamous cell carcinomas. Even though they represent only about 3% of all cancers in the United States, they are disproportionately important because half result in death within five years. Because of their asymptomatic progression, they have usually metastasized by the time the primary lesion is discovered. Therefore, detection of oral squamous cell carcinoma (OSCC) before metastasis is critical for a hopeful diagnosis. Laminin-5 is a key extracellular matrix (ECM) protein that is preferentially produced by OSCC, and cleaved by matrix metalloproteinases (MMPs) secreted by OSCC in order to metastasize through the ECM. This study examines the extent to which Laminin-5 affects OSCC behaviors, such as proliferation, *in vitro*. Collagen Type I and Fibronectin were used as positive controls, and poly-L-lysine and untreated plastic as negative controls, all of which were used in OSCC 0, 1, 2, and 3-day proliferation assays. Current literature surveys reveal experimentation using mouse and rat Laminin-5 with human OSCC despite significant differences between their amino acid sequences. Our results suggest that human Laminin-5 positively influences OSCC proliferation *in vitro* significantly over mouse Laminin-5. This research is part of the foundation for our understanding of OSCC behaviors, such as proliferation, and the subsequent metastasis in oral cancers.

1820

**The Globular Domains of Human and Rat Laminin-5 Alpha3,Beta3, and Gamma2 Subunits May Contain Distinct Alpha3Beta1 Integrin Binding Sites that Influence *In Vitro* Adhesion of Oral Squamous Cell Carcinoma Cells**

G. Koontz, K. Kingsley; Biomedical Sciences, University of Nevada, Las Vegas School of Dental Medicine, Las Vegas, NV

Laminin-5 is an extracellular matrix glycoprotein involved in modulating cellular behaviors, such as adhesion and migration. Many studies currently use rat-derived laminin-5 to examine human cell adhesion, tissue remodeling, and migration *in vitro*. Our study objective is to understand the structural and functional relationships between alpha3 beta1 and alpha6 beta4 integrins that modulate adhesion to, and migration on, laminin-5 and different laminin-5 sources through a comprehensive analysis of the sequence similarities and differences between the human- and rat-derived laminin-5 subunits. Using BLAST2 analysis software, we show the primary amino acid sequences from the National Center for Biotechnology Information (NCBI) of human and rat laminin-5 alpha3-subunits contain specific, homologous alpha3 beta1 integrin-binding domains. We also report distinct alpha3 beta1 integrin-binding domains not shared between rat and human alpha3-subunits of laminin-5. In addition, using ProtScale and MultiCoil software, differences in coiled-coil formation and hydrophobicity between the globular domains of these subunits were found. We conclude these domains may be capable of supporting integrin ligation and may therefore represent functional differences between rat and human alpha3-subunits of laminin-5 that modulate specific cellular responses, such as adhesion and migration.

1821

**Biochemical Cleavage of Laminin-5 by Matrix Metalloproteinases May Alter Specific Integrin Binding Sites on Specific Laminin Subunits**

C. L. Neilson, S. O'Malley, K. Kingsley; Biomedical Sciences, University of Nevada, Las Vegas School of Dental Medicine, Las Vegas, NV

Laminin-5 is an extracellular matrix glycoprotein involved in modulating cellular behaviors, such as adhesion and migration. Many studies demonstrate that specific laminin-5 subunits, such as gamma-2 are cleaved by matrix metalloproteinases (MMPs), such as MT1-MMP. Our study objectives are (1) to understand the relationship between the release of specific matrix metalloproteinases from Oral Squamous Cell Carcinomas (OSCC), (2) the specific cleavage sites of laminin-5 subunits by these matrix metalloproteinases and (3) the relationship of this OSCC-mediated MMP-cleavage to OSCC adhesion *in vitro*. We hypothesize that primary amino acid sequences from the National Center for Biotechnology Information (NCBI) of laminin-5 subunits contain specific sequences that are known cleavage sites of MMPs. Using BLAST2 analysis software, we report distinct enzymatic cleavage sites that may be responsible for the altered phenotypes between normal and proteolyzed laminin-5 that modulate specific cellular responses, such as adhesion and possibly cell migration in OSCC.

**The Laminin Derived Peptide YIGSR Modulates Adhesion Molecules in an Adenoid Cystic Carcinoma Cell Line**

R. Jaeger,[1] E. Oliveira,[1] C. Furuse,[2] V. Araujo,[2] V. Freitas[1]; [1]Cell and Developmental Biology, ICB-USP, Sao Paulo, Brazil, [2]Sao Leopoldo Mandic Research Institute, Sao Paulo, Brazil

Adenoid cystic carcinoma is a malignant salivary gland neoplasm with high level of recurrence and distant metastasis. We have demonstrated that laminin-1 modulates the phenotype of a cell line (CAC2) derived from human adenoid cystic carcinoma. We are currently studying the expression of a non-integrin laminin receptor, the 32/67kDa laminin-binding protein (LBP), in adenoid cystic carcinoma. Immunohistochemistry showed the presence of LBP in adenoid cystic carcinoma cells in vivo and in vitro. The LBP binds a sequence of laminin beta 1 chain, the YIGSR peptide. This peptide promotes cell attachment and migration. We decided to study the role played by the peptide YIGSR and its ligand, the LBP receptor, in CAC2 cells. These cells were grown inside either laminin-1 (control) or laminin-1 enriched with YIGSR (treated). Cells treated by YIGSR appeared non-cohesive, with fibroblastic-like morphology, while control cells were epithelioid and closely packed. This result suggested decrease of adhesion molecules induced by YIGSR. Thus, we decided to study the role played by the peptide YIGSR, and the LBP receptor, on the expression of adhesion molecules in CAC2 cells. Samples were analyzed by immunoblot to detect E-cadherin and beta-catenin. YIGSR decreased the amount of these proteins in CAC2 cells, when compared to controls. Pretreatment of cells with anti-LBP restored adhesion molecules expression. The result was confirmed by whole mount immunofluorescence. Cells grown inside laminin-1 exhibited E-cadherin and beta-catenin as a linear staining located at cell boundaries. Cells treated by YIGSR were non-cohesive, with a discrete punctate label. Blockage of LBP restored the linear pattern of E-cadherin and beta-catenin. Our results suggested that YIGSR, and its ligand the 32/67kDa LBP regulate the expression of adhesion molecules in an human adenoid cystic carcinoma cell line

1823

**Cleavage of Laminin-5 by Matrix Metalloproteinase-2 May Alter Specific Integrin Binding Sites on Laminin Subunits**

L. A. Trerice, S. O'Malley, K. Kingsley; Biomedical Sciences, University of Nevada, Las Vegas School of Dental Medicine, Las Vegas, NV

Laminin-5 is an extracellular matrix glycoprotein involved in modulating cellular behaviors, such as adhesion and migration. Previous research has shown that laminin-5 subunits, such as gamma-2 are cleaved by specific matrix metalloproteinases (MMPs), such as MMP-2. Our study objectives are (1) to identify MMPs that are capable of performing enzymatic cleavage of laminin-5 subunits and (2) identifying the specific cleavage sites of the laminin-5 subunits that may be acted upon by these MMPs and (3) characterizing the enzymatic cleavage and the effect on cellular adhesion *in vitro*. We hypothesize that primary amino acid sequences from the National Center for Biotechnology Information (NCBI) of laminin-5 subunits contain specific sequences that are known cleavage sites of MMPs. Using BLAST2 analysis software, we propose alternative enzymatic cleavage sites that may be responsible for the observed altered phenotypes between normal and proteolyzed laminin-5 that modulate specific cellular responses, such as adhesion and possibly cell migration in OSCC.

## Extracellular Matrix & Morphogenesis (1824-1839)

1824

**Human Mesenchymal Stem Cells Enhance Angiogenesis within Denser 3D Fibrin Matrices via Initial MMP-9 and pro-MMP-2 Upregulation**

C. M. Ghajar,[1] S. C. George,[1] A. J. Putnam[2]; [1]Biomedical Engineering, University of California, Irvine, Irvine, CA, [2]Biomedical Engineering and Chemical Engineering and Materials Science, University of California, Irvine, Irvine, CA

The diffusion limitation is the most prominent obstacle to developing thick, engineered tissues. To overcome this hurdle, our lab has developed a 3D fibrin-based extracellular matrix in which embedded human umbilical vein endothelial cells rapidly form a vascular-like network when cultured in optimal conditions. One limitation of this system is that the fibrin matrix lacks the mechanical integrity necessary for its intended application.

The purpose of this project is to understand how enhancing the mechanical properties of the fibrin gel affect the angiogenic process. Fibrin stiffness was modified by varying the initial concentration of fibrinogen from 2.5-10.0 mg/ml. Compressive moduli were obtained for these conditions, and accompanying changes in the network structure were visualized via confocal microscopy by utilizing Oregon Green-488 conjugated fibrinogen. For each condition, total capillary length was quantified at separate time points (days 7, 14, and 21). The resulting data demonstrates that increasing matrix stiffness significantly decreases the total length of these networks. Adding an exogenous inhibitor (GM6001) of secreted matrix metalloproteinases (MMPs; specifically MMP-2 and -9) to the low stiffness culture duplicated the effect of increased matrix stiffness on total network length. This led to the hypothesis that enhancing the expression of these MMPs within stiffer matrices would abrogate the effect of matrix stiffness on capillary morphogenesis. Adding human mesenchymal stem cells throughout denser fibrin matrices achieved this end (as assayed via gelatin zymography) and led to a significant increase in sprouting by day 21. The notion that this result is MMP-dependent was validated by adding GM6001 to these cultures and observing a subsequent decrease in total network formation. These results delve into the biological processes and engineering design principles that regulate vascularization of tissues in three dimensions.

**Fibroblast Growth Factor (FGF) Signaling Regulates the Expression and the Activity of Matrix Metalloproteases (MMPs) during Mouse Submandibular Gland (SMG) Branching Morphogenesis**

I. T. Rebustini, M. P. Hoffman; MMU-CDBRB, NIDCR-NIH-DHHS, Bethesda, MD

SMGs develop by branching morphogenesis that involves extracellular matrix (ECM) remodeling. FGF signaling plays a key role in ECM remodeling by regulating the expression of ECM proteins and proteases such as MMPs. However, the roles of specific MMPs during SMG morphogenesis are not well understood, therefore we have investigated how FGF signaling regulates the expression and the activity of MMPs. We use embryonic, post-natal and adult mouse SMG to generate developmental profiles of gene expression by real-time PCR, and we found that soluble MMP2 and 9, transmembrane MMP14, 15 and 16, ADAM (A Desintegrin and MMP) 8, 9, 10, 12, 15, 17 and 19, and TIMP (Tissue Inhibitor of MMP) 1, 2 and 3 increase their expression during the early stages of SMG development. Blocking MMP activity using the broad spectrum MMP-inhibitor GM6001 decreases branching morphogenesis in SMG organ cultures. The knockdown of FGFRs by siRNAs downregulates MMP2 expression and activity, suggesting that MMP2 is regulated by FGF signaling. The knockdown of multiple MMPs is required to decrease branching morphogenesis in organ cultures. FGF7 and FGF10 induce distinct epithelial morphologies therefore we analyzed the changes on the FGFRs and MMPs expression in SMG epithelial cultures. FGFRs increase after 6h with FGF7 or FGF10 treatments, whereas MMP2, 14 and 16 peak after 18 hours. MMP2 and MMP16 show similar expression profiles in FGF7-epithelial cultures indicating that they are closely regulated. Also, siRNA knockdown of FGFRs in epithelial cultures downregulates MMP2. In conclusion, FGF signaling regulates the expression and the activity of MMPs during SMG branching morphogenesis.

1826

**Membrane Type 1 Matrix Metalloproteinase (MT1-MMP) Regulates Mammary Gland Development Through Synergy Between Two Substrates, Collagen Type I and Matrix Metalloproteinase-2**

M. Egeblad,[1] B. S. Wiseman,[1] M. D. Sternlicht,[1] H. Kouros-Mehr,[1] K. A. Green,[2] H. Mananzan,[1] K. Holmbeck,[3] H. Birkedal-Hansen,[3] M. J. Bissell,[4] L. M. Coussens,[5] L. R. Lund,[2] Z. Werb[1]; [1]Anatomy, University of California, San Francisco, San Francisco, CA, [2]The Finsen Laboratory, Rigshospitalet, Copenhagen, Denmark, [3]National Institute for Dental and Craniofacial Research, NIH, Bethesda, MD, [4]Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, [5]The Cancer Research Institute and Comprehensive Cancer Center, University of California, San Francisco, San Francisco, CA

Branching morphogenesis is the process of epithelial ductal invasion and branching into stromal tissue and it requires stromal remodeling, which can be regulated by matrix metalloproteinases (MMPs). We show here that branching morphogenesis of the mouse mammary gland requires MMP-14 (MT1-MMP), its activation of MMP-2 and the cleavage of type I collagen by both enzymes. Mammary glands from mice deficient in MMP-14 had severely reduced epithelial branching, abnormal terminal end bud morphology and extensive collagen deposition. In keeping with MMP-14's ability to activate MMP-2 (gelatinase A) and cleave type I collagen, mammary glands from mice deficient in MMP-2 or with mutated type I collagen genes resistant to collagenolytic MMPs, including MMP-14, also had delayed mammary gland development. However, only composite mutant mammary glands, deficient for MMP-2 and with MMP-14 resistant collagen, had the same pronounced collagen deposition as the MMP-14 deficient mammary glands, suggesting synergy between cleavage of collagen by MMP-14 and MMP-2. Although ductal elongation was diminished in all these cases, proliferation of epithelial cells in the terminal end buds was normal or even increased, suggesting accelerated programmed cell death and lack of generation of a survival signal. Indeed, mice with mutated type I collagen hypersensitive to proteinase degradation also had delayed mammary gland development, suggesting a role for specific type I collagen cleavage fragments in addition to simple removal of collagen. Together, the data suggest that MMP-14 generates specific collagen fragments that mediate survival signals and that the further degradation of collagen by MMP-14-activated MMP-2 is important for path-clearing. We propose that this coordinated degradation of type I collagen by MMPs plays a central role in branching morphogenesis.

1827

**Membrane Type 1 Matrix Metalloproteinase (MT1-MMP) is a Path-Generating Collagenase in Mammary Gland Branching Morphogenesis**

H. Mori, J. Alcaraz, C. M. Nelson, M. J. Bissell; Life Science Division, Lawrence Berkeley National Laboratory, Berkeley, CA

Proper mammary gland morphogenesis and differentiation requires strict temporal and spatial control of cellular function. These processes are coordinated by changes in the structure and composition of the surrounding extracellular matrix (ECM), orchestrated in large part through the action of matrix metalloproteinases (MMPs), which play a key role in degradation and reorganization of ECM as essential components of cell proliferation and migration. MT1-MMP has been shown to play a key molecule in cancer cell invasion and metastasis. During mammary gland development, ductal elongation and branching morphogenesis involve epithelial cell invasion into a collagen- and laminin-rich mammary fad pad, and MT1-MMP is expected to play a role. To dissect the role of MT1-MMP, we used three-dimensional collagen I gels and EpH4 mouse mammary epithelial cells. Whereas stable expression of MT1-MMP enhanced tubular elongation and side branching, its hemopexin domain inhibited

branching presumably by interfering with dimerization of MT1-MMP. Reduction of endogenous MT1-MMP by RNAi expression inhibited both tubular elongation and side branching. Using collagen gels of different stiffness, we show that collagenous activity per se is not essential for branching. In gels with lower stiffness, EpH4 cells branch without MMP activity, but at higher gel stiffness, EpH4 branching requires MMP activity. We thus propose that in vivo, MT1-MMP activity is required for branching mainly to reduce the stiffness of the surrounding matrix to allow the growing end bud to invade the stroma.

1828

**Identification of the Key Control Mechanisms of Mammary Epithelial Branching Morphogenesis**

C. M. Nelson,[1] M. van Duijn,[2] J. L. Inman,[1] D. A. Fletcher,[2] M. J. Bissell[1]; [1]Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, [2]Department of Bioengineering, University of California, Berkeley, CA

Branching morphogenesis, the formation of branched epithelial tubes from a preexisting structure, is common throughout development and is responsible for generating the complex architectures of lung airways, kidney collecting ducts, and the salivary and mammary glands. The most fundamental step of branching morphogenesis, branch site initiation, has been found to be regulated by a number of cues, including growth factors, proteases, and morphogens. To determine how these cues are integrated spatially to result in characteristic, organ-specific patterns of branching, we have developed a quantitative three-dimensional micropatterned assay of mammary epithelial branching morphogenesis to define the signals that control the position of branch site initiation. Mouse mammary epithelial cells were engineered to form precisely defined multicellular duct-like structures within gels of collagen type I. Onset of branching morphogenesis was controlled temporally by the exogenous addition of growth factors to stimulate the morphogenic program. We found that these structures branched in characteristic, highly reproducible patterns from specific locations depending on the local microenvironment and the initial geometry of the multicellular structure. We identified the key alterations in signaling and gene expression at sites of branch initiation and found transient upregulation of genes associated with the mesenchymal phenotype. We show that the form of the duct-like structures coordinates signaling from growth factors and morphogens to regulate the position of branch initiation.

1829

**Fibronectin Modulates Mammary Epithelial Cell Morphology during Acinar Differentiation**

C. M. Williams, J. E. Schwarzbauer; Molecular Biology, Princeton University, Princeton, NJ

Mammary epithelial cells (MECs) *in vivo* form branching ducts that end in hollow acini surrounded by a basement membrane. Breast cancer results in derangement of tissue architecture and increased amounts of fibronectin, an extracellular matrix protein normally absent from mammary tissue, is found in the stroma. This correlation between a fibronectin-rich extracellular matrix and aberrant proliferation and morphology may point to a role for fibronectin signaling in early stages of breast oncogenesis. The non-tumorigenic mammary epithelial cell line, MCF-10A, is capable of differentiating into acini *in vitro* when cultured on Matrigel, a reconstituted basement membrane matrix. Unlike MECs *in vivo*, MCF-10A cells express fibronectin and its α5β1 integrin receptor and assemble a fibronectin matrix in monolayer culture. Fibronectin is absent from mammary tissue *in vivo* suggesting that its expression must be down-regulated as acini form. However, fibronectin appears to play a role in the early stages of acini formation since knock-down of endogenous MCF-10A fibronectin using small interfering-RNAs perturbed acinar polarity and lumen formation. Analysis of developing acini by immunofluorescence staining with anti-fibronectin antibodies localized fibronectin to the basal cell surface, on the outside of the acini. Growth on Matrigel, which does not contain fibronectin, resulted in down-regulation of fibronectin production by MCF-10A cells. Within 3 days of plating, little if any secreted fibronectin was detected. To mimic the primary breast tumor microenvironment, fibronectin was added to the Matrigel. In this environment, cells maintained fibronectin expression and formed large, poorly polarized acini that failed to form a hollow lumen. These data show that failure to down-regulate fibronectin expression prevents normal acinar morphogenesis. During cancer progression, increased stromal fibronectin may provide a microenvironment that modulates epithelial cell morphology and disrupts signals required for maintenance of the differentiated state.

1830

**Force-dependent Apoptosis Resistance and Breast Tumorigenesis**

J. L. Leight,[1] N. Zahir,[1] J. N. Lakins,[2] J. Y. Wong,[3] V. M. Weaver[2]; [1]Bioengineering, University of Pennsylvania, Philadelphia, PA, [2]Pathology, University of Pennsylvania, Philadelphia, PA, [3]Biomedical Engineering, Boston University, Boston, MA

Apoptosis resistance plays a key role in malignant transformation and metastasis of the breast. Because cell-extracellular matrix (ECM) interactions regulate mammary epithelial cell (MEC) survival, we have been studying how the ECM could influence malignant transformation and treatment responsiveness of breast tumors. Previously we identified α6β4 integrin dependent activation of NFκB as a key apoptosis resistance mechanism that is up regulated in breast cancers. We showed that the efficacy of NFκB-mediated breast cancer survival is greatly enhanced when MECs are grown within a compliant ECM to form a three-dimensional (3D) tissue-like structure. To test the hypothesis that three-dimensionality and matrix compliance regulate apoptosis resistance and to delineate the underlying mechanisms, we used reconstituted basement membrane cross-linked polyacrylamide gels of defined elastic moduli onto which we cultured MECs as 3D structures. Here we report that MECs form organized acini-like structures on a compliant matrix (140 Pa) and exhibit a markedly enhanced survival phenotype to chemotherapeutic agents and immune receptor activators within 5-6 days. In contrast, on a stiff matrix (60 kPa) MECs fail to undergo morphogenesis and undergo apoptosis readily in response to exogenous death stimuli, even after formation of non-differentiated multi-cellular structures. 3D compliant MEC structures acquire apoptosis resistance coincident with tissue polarity and a blunted ability to stimulate the stress genes AP-1 and SRE. Because we showed that compliance-dependent apoptosis resistance correlates with a failure to induce stress genes in response to apoptotic insults, we conclude that matrix compliance regulates stress-dependent gene expression. Using synthetic 2D and 3D gels of calibrated stiffness we are currently exploring the mechanism whereby matrix compliance and three-dimensionality could regulate stress gene expression to modulate tissue polarity and apoptosis resistance. 1831

**The Role of Rab27b in Breast Cancer Development**

W. Westbroek,[1] O. De Wever,[2] A. Helip Wooley,[1] M. Mareel,[2] M. Huizing,[1] M. Bracke,[2] W. A. Gahl[1]; [1]Medical Genetics Branch, NHGRI, NIH, Bethesda, MD, [2]Laboratory of Experimental Cancerology, Ghent University Hospital, Gent, Belgium

Rabs are ras-like small GTPases that regulate vesicle movement, sorting and secretion. Rab27b is a member of the Rab27 subfamily that shows 72% homology to Rab27a on amino acid level. Rab27b and Rab27a can have the same function in transport and docking of lysosome related organelles in different cell types. Rab27b but not Rab27a has been described as a potential biomarker in breast cancer progression. We prepared stable MCF-7/AZ cells expressing eGFP, eGFP-Rab27a or eGFP-Rab27b and studied the organization of the F-actin cytoskeleton by confocal microscopy and the activation status of Rho GTPases by pull down assay and invasion into Matrigel. We found that cells overexpressing Rab27b, but not Rab27a, show a tremendous change in the organization of the actin cytoskeleton characterized by filopodia-like extensions searching for contact with neighbouring cells. Furthermore, Rab27a and Rab27b localized to vesicular structures; we are now characterizing these vesicles using specific markers. Cells overexpressing Rab27b, but not Rab27a, were invasive into Matrigel. This correlated with a reduction in the activation of the RhoA GTPase, and a stimulation in the activation status of the Ras GTPase as demonstrated with a pull down assay. We did not observe changes in the activation status of the Rac GTPase. Invasion into Matrigel was annihilated by pharmacological inhibitors of PI3K, Akt and MAPK, and by co-transfection of constitutive active mutants of RhoA and dominant negative mutants of Ras and Rac. With these data, we describe for the first time the putative role of a Rab protein (Rab27b) in invasion and actin-reorganization of MCF-7/AZ breast cancer cells. Research on the biological function of up-or down-regulated Rabs in tumor progression could open new perspectives in cancer research.

1832

**Loss of Small Intestinal Villi in Adult Laminin α5 Deficient Mice**

X. Zhen, T. S. Stappenbeck, J. H. Miner; Washington University School of Medicine, St. Louis, MO

The laminin α5 chain is a widely expressed component of both laminin-α5β1γ1 and laminin-α5β2γ1 trimers that are prominent components of basement membranes (BMs) in numerous tissues. *Lama5-/-* mice die perinatally and exhibit multiple developmental defects, such as neural tube closure, digit septation, placentation, lung lobe septation, kidney development, and hair growth. We used a widely expressed laminin α5 transgene (Mr5) to rescue these defects; adult *Lama5-/-*; Mr5 mice appear normal and are viable and fertile. However, Mr5 expression wanes after birth, resulting in greatly reduced levels of laminin α5 in some BMs, including those in the distal small intestine. Normally, the intestinal mucosa that lines the inner surface of the gut tube is organized by repeating units of finger-like villi and adjacent invaginated crypts. In the *Lama5-/-*; Mr5 mice, villi coalesce in the distal small intestine to form cerebroid (like the surface of the brain) or mosaic (individual villi no longer present) patterns. These morphologic patterns strongly resemble villus atrophy observed in human celiac disease and during nematode infection. However, unlike these disease states, there is not inflammatory infiltrate in the small intestines of *Lama5* deficient mice. In the small intestine of wild-type adult mice, epithelial cells proliferate in the base of crypts. Their progeny differentiate into four distinct lineages, three of which, enterocytes, enteroendocrine cells, goblet cells migrate onto and up adjacent villi. The fourth lineage, Paneth cells are retained in the base of the crypt. The epithelium of *Lama5-/-*; Mr5 mice is abnormal and displays alteration in proliferation, Paneth cell differentiation and migration of cells on the villus. Together, these results suggest that laminin α5 and intestinal BMs play crucial roles in organizing crypt-villus architecture, and in regulating the activities of the intestinal epithelial cells.

1833

**Localization of Annexin II and V during Chondrogenesis and Calcification**

T. Minashima,[1] H. Aso,[2] K. Tahara,[3] T. Yamaguchi,[3] S. Takano,[3] S. Ohwada,[1] K. Watanabe,[1] T. Yamaguchi[1]; [1]Cellular Biology Laboratory, Faculty of Agriculture, Tohoku University, Sendai, Japan, [2]Tohoku University, Sendai, Japan, [3]R & D Center, BML Inc., Saitama, Japan

Mesenchymal stem cells have demonstrated the multipotential to differentiate into several cell lineages; osteogenic, chondrogenic or adipogenic lineages. However the exact mechanism of the steps in the pathway leading from an undifferentiated stem cell to a mature chondrocyte are not well understood. A clonal bovine intramuscular preadipocyte (BIP) line has an ability of differentiating to the chondrogenic lineage, because their formed spherical pellets had a chondrogenic morphology and produced typical marker molecules for chondrogenesis, such as cartilage-specific proteoglycans and type II collagen. Under the proteomic approach, one of new spots was identified as annexin II (ANX II) during the chondrogenic differentiation of BIP cells. AXN II as well as AXN V was a marker for terminally differentiated chondrocytes in hyaline cartilage. In the chondrogenic pellet of BIP cells, AXN II increased until 7 days, and disappeared at 28 days, however, AXN V was stained at the periphery until 14 days, and strongly detected also in the center at 28 days. We also investigated expression of AXN II and V in cartilages. In cartilage without calcification, AXN II was detected in chondrocytes and AXN V was detected in chondrocytes or the extracellular matrix surrounding chondrocytes. On the other hand, AXN II and V in cartilage with calcification were strongly stained in the extracellular matrix. ANX II. These results suggest that there is a quite difference in co-expression mechanism of AXN II and V between hyaline cartilage with calcification and the other cartilages, and that the calcification may need the release of AXN II as same as AXN V from cytosole to the extracellular matrix.

1834

**The Self-assembled Network of Type 1 Collagen Revealed by Fibrillogenesis and Topological Studies**

S. Han, W. Losert; Physics, University of Maryland, College Park, MD

Type I collagen is the most abundant protein of connective tissues including tendon, skin and bone .Collagen molecules exhibit the ability to polymerize into fibers (fibrillogenesis), forming the extra cellular matrix. Recent studies of fibrillogenesis of type I normal and mutant collagen (hetero- and homotrimers) revealed a substantial difference in the kinetics of self-assembly, in particular, the absence of lag time in homotrimers. In heterotrimers, a normal S-shaped curve with a typical lag time for nucleating was monitored by turbidity measurements. The origin of this difference and the underlying mechanism of self-assembly are still unknown. We developed a technique for differential fluorescent labeling of collagen which allows us to study self-assembly of collagen and mixture of collagens (e.g. hetero- and homotrimers) using confocal microscopy to visualize collagen fiber formation in 4D(3space,time) while the network self-assembles. We observed that hetero- and homotrimers were co-localized during fibrillogenesis, despite their very different fibrillogenesis kinetics. Turbidity measurements of fibrillogenesis of the mixture of

hetero- and homotrimers showed the S-shaped curve with lag time typical for heterotrimers. The finer and straighter network structure of homotrimers than normal heterotrimers in images of confocal microscopy was observed. We characterized the structural homology of the 3D network through Betti numbers that are robust to variations in scale, primarily describing the connections between different components comprising the geometric structure. The number of Betti numbers equals the dimension of the structure being analyzed.

1835

**Conditional Deletion of Focal Adhesion Kinase (FAK) Perturbs Matrix Organization in the Developing Mouse Eye**

H. Beggs; Ophthalmology and Physiology, University of California, San Francisco (UCSF), San Francisco, CA

Focal adhesion kinase (FAK) is a key mediator of integrin signaling and regulates cell spreading, migration and organization of the extracellular matrix (ECM). However, early lethality of the complete FAK knockout has precluded direct examination of the physiological relevance of FAK signaling in developing systems. Here, FAK has been conditionally deleted from the developing mouse eye using a Nestin-Cre and Six3-Cre mouse line. The Nestin-Cre line results in deletion of FAK protein from the lens and retina, whereas the Six3-Cre line results in deletion of FAK protein from the retina only. Deletion of FAK from the lens and retina results in significant eye abnormalities, including retinal lamination defects, microphthalmia (small eyes), and complete lens degradation. Interestingly, deletion of FAK from the retina alone resulted in similar defects in retinal layering, yet the presence of a normal lens completely rescued defects in eye size. This suggests that faulty lens development is responsible for stunted eye growth in these animals. In order to determine if matrix organization defects were responsible for the phenotype, two prominent BMs were examined: the lens capsule BM organized by lens fiber and epithelial cells and the retinal inner limiting membrane organized on the endfeet of Muller glial cells. Both were strikingly perturbed at developmental stages immediately preceding gross defects. These results indicate that activation of FAK signaling is an important intracellular step in mediating extracellular organization of the ECM into biologically functional BMs. This is a vital role for FAK signaling that is frequently overlooked in cell culture studies. Interestingly, these eye-related abnormalities are often seen in children with congenital muscular dystrophy (also known as muscle-eye-brain disorders), and are thought to result from defects in cell-matrix binding.

1836

**Slit and Robos Coordinate Cardiac Cell Adhesion and Positioning During *Drosophila* Heart Tube Assembly**

S. G. Kramer, E. Santiago-Martinez, N. H. Soplop; Pathology and Laboratory Medicine, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ

Heart tube assembly requires the precise arrangement of precursor cells on either side of the embryo that coordinately migrate to meet their counterparts at the midline. Little is known about the mechanisms that organize cardiac precursors, once specified, into this complex structure. We analyzed the role of Slit, a secreted extracellular matrix protein and its transmembrane receptors Roundabout (Robo) and Roundabout2 (Robo2) during morphogenesis of the *Drosophila* heart tube, a process analogous to early heart formation in vertebrates. During heart tube assembly, two types of progenitor cells align into rows and coordinately migrate to the midline of the embryo where they merge to assemble a linear heart tube. Here we present that cardiac-specific expression of Slit is required to maintain adhesion between cells within each row during dorsal migration. Moreover, differential Robo expression determines the relative distance each row is positioned from the dorsal midline. The innermost cardioblasts express only Robo, whereas the flanking pericardial cells express both receptors. Removal of *robo2* causes pericardial cells to shift towards the midline, whereas ectopic *robo2* in cardioblasts drives them laterally resulting in an unfused heart tube. We propose a model in which migrating cardiac progenitors intrinsically organize their own assembly into a linear heart tube through secretion of Slit and differential expression of Robo receptors. These findings establish Slit and Robo receptors as critical molecules required for the assembly of vascular tissues.

1837

**Modulation of Renal Proximal Tubulogenesis by the Mammalian Target of Rapamycin**

M. L. Taub; Biochemistry Dept, State University of New York at Buffalo, Buffalo, NY

Tubules may arise during branching morphogenesis through several mechanisms including wrapping, budding, cavitation and cord hollowing. In this report we present evidence that is consistent with renal proximal tubule formation through cord hollowing. Primary rabbit renal proximal tubule cell cultures were initiated in matrigel. Cultures containing developing nephrons were incubated in medium containing Lucifer Yellow, a substrate of the p-Aminohippurate transport system (in the renal proximal tubule, Lucifer Yellow is transported intracellularly by a basolateral p-aminohippurate (pAH) transport system, and is subsequently secreted into the lumen of the nephron). Pockets of lumens filled with Lucifer Yellow were observed within developing cords of the rabbit renal proximal tubule cells in matrigel. The observation of Lucifer Yellow accumulation suggests that the developing nephrons were functionally polarized. Consistent with such polarization, Triticum vulgare (a lectin which binds apically in the rabbit renal proximal tubule) was observed to bind to the luminal membranes within pockets of Lucifer yellow filled lumens. Both EGF and HGF caused an increase in the frequency of tubule formation. PD98059 (an inhibitor of MAPK) inhibited the frequency of tubule formation, unlike Wortmannin (an inhibitor of PI3K). Although the frequency of tubule formation was inhibited by PD98059, this drug had no effect on the process of cavitation. In contrast, rapamycin, an inhibitor of mTOR, prevented cavitation, without affecting the frequency of tubule formation. These results suggest the involvement of MAP kinase in the initiation of the process of tubule formation, while mTOR is involved in the formation of functional renal proximal tubules.

1838

**Elastic System Fibers of Rat Molar Periodontal Ligament: Immunohistochemical Study**

T. Sawada,[1] S. Inoue[2]; [1]Ultrastructural Science, Tokyo Dental College, Chiba, Japan, [2]Anatomy and Cell Biology, McGill University, Montreal, PQ, Canada

Among elastic system fibers of the periodontal ligament of the tooth, oxytalan fibers have been well characterized. However, the localization and nature of elastin-containing fibers, that is, elaunin and elastic fibers, remain to be clarified. In this study, the localization of elastin and fibrillin, major proteins of elastin-containing fibers, were immunohistochemically examined in the periodontal ligament of rat molars. With immunoperoxidase staining at the light microscope level, the distribution of elastin was not uniform throughout the ligament. Elastin-positive

structures were often concentrated in close vicinity of blood vessels in the ligament in areas such as, for example, the middle to apical region of the distal half of the distal root. In contrast, fibrillin was more widely distributed throughout the ligament. The pattern of its distribution was comparable to that of the reported distribution of oxytalan fibers. Fibrillin was also seen concentrated in areas of accumulation of small blood vessels. Immunoelectron microscopy showed that approximately 1 µm wide bundles, often localized close to blood vessels, of fibrillin-positive microfibrils contained small amounts of elastin. It clearly indicated that these entities were elaunin fibers. Mature elastic fibers were not found throughout the ligament. Thus, the elastic system fibers of the rat molar periodontal ligament are composed of only oxytalan and elaunin fibers. In addition to the well known role of the elastic system fibers of supporting the tooth, these fibers are also likely to have the role of protecting the vascular system of the ligament from the force of stress/strain caused by mastication and maintaining its integrity.

**Immobilization of Exogenous Ligands in 3D Matrices**

J. A. Hubbell; Integrative Biosciences Institute, Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

Our objective was to develop extracellular matrix analogs that could be engineered to quantitatively incorporate adhesion ligands and growth factors in 3D. We have developed two such model systems, which will be presented. First, we have developed a scheme by which to incorporate exogenous ligands in fibrin matrices during fibrin coagulation. The ligands are either synthesized or expressed as fusions with the sequence NQEQVSP, which incorporates a substrate for the coagulation transglutaminase factor XIIIa. During coagulation, this linker is then covalently grafted within the fibrin matrix. When the 6th Ig-like domain of L1 was thus grafted within fibrin, as a ligand for integrin alpha v beta 3, the angiogenic potential of the fibrin matrix was dramatically increased. When vascular endothelial growth factor (VEGF) was thus grafted within fibrin, it induced potent angiogenesis, however also a more mature angiogenesis than was observed with free VEGF. As a second approach, synthetic analogs of fibrin and collagen were developed, namely gels formed by crosslinking vinyl sulfone-functionalized polyethylene glycol and cysteine-terminated peptides. The peptides were designed as substrates for matrix metalloproteinases (MMPs), permitting degradation of the gel structure under the proteolytic activity of migrating cells. Dermal fibroblasts within such matrices were able to spread in 3D and migrate, and their migration could be enhanced by up-regulators of MMP expression (such as TNF alpha) and inhibited by protease inhibitors. Such synthetic extracellular matrix analogs may thus prove useful for studies of cell migration and invasion.

## Cadherins (1840-1860)

**Differential Expression of *Cdh23* Isoforms in the Cochlea and Retina of Wild Type and *Waltzer* Mice**

A. Lagziel, Z. M. Ahmed, L. M. Peters, T. B. Friedman, R. J. Morell; Laboratory of Molecular Genetics, National Institute on Deafness and Other Communication Disorders National Institutes of Health, Rockville, MD

Mutant alleles of *CDH23* are associated either with deaf-blindness with vestibular dysfunction (Usher syndrome type 1, USH1D), or isolated deafness (DFNB12; Bork et al., 2001). In *waltzer (v)* mice, mutant alleles of *Cdh23*(predicted null alleles and therefore thought to model USH1D) cause deafness and vestibular dysfunction but not blindness. We recently reported the spatiotemporal expression pattern of cadherin 23 during development of the inner ear in wild type and in $v^{6J}$ *waltzer* mice (Lagziel et al., 2005). In addition we reported several short isoforms of *CDH23*/*Cdh23* in the wild type, which are also present in the homozygous $v^{6J}$ mouse mutants and are unaffected by this mutant allele. Here we report an analysis of the relative expression levels of alternative transcripts of *Cdh23* in wild type and $v^{6J}$ mice using semi-quantitative real time PCR assays and RNA from cochleae and retinae from different developmental time points. We found that the *Cdh23* isoforms differ in their temporal and spatial patterns of expression. We also found that certain isoforms were down-regulated in the presence of the $v^{6J}$ allele, while other isoforms were up-regulated. The pattern of up or down-regulation was dependant on the tissue examined (retina or cochlea), and on the developmental stage. The results of this study suggest that a correlation of mutant genotype to phenotype in mice and humans will not depend on a model of a single cadherin 23 isoform, but on the resolution of function for each of the *Cdh23* isoforms.

1841

**Cadherin-11 is Required for Otolith Growth in Zebrafish**

S. G. Babb, J. A. Marrs; Nephrology, Indiana University Medical Center, Indianapolis, IN

Fish otoliths are crystals formed of calcium carbonate and organic matrix and are involved in balance and hearing. Cadherins are transmembrane cell-cell adhesion molecules; In zebrafish, we have found that cadherin-11 (Cdh11, OB-cadherin, VN-cadherin) is localized to otoliths, to puncta within the otic lumen (presumably vesicles), and to the underlying neuroepithelium, suggesting a role for cadherin-11 in otolith growth and biomineralization. To investigate the role of cadherin-11 in otolith formation, we generated cadherin-11 knockdowns using morpholino antisense oligonucleotides. Three independent morpholinos made against cadherin-11 produced the same phenotype. In cadherin-11 knockdowns, little or no Cdh11 protein expression was detected, and significantly, otoliths were small or absent. When present, the correct number of otoliths was found in knockdowns, but their shape was more spherical, rather than the flattened shape of otoliths found in control embryos. Also, otoliths were not tightly tethered to the sensory epithelium. Starmaker, a protein that controls crystal size and lattice formation, was absent in cadherin-11 knockdowns examined. Together, these data show that cadherin-11 is necessary for normal otolith growth in zebrafish. These effects suggest that cadherin-11 may be required to create the proper microenvironment within the otic vesicle for otolith seeding and aggregation. Additionally, cadherin-11 homotypic binding may function in vesicle aggregation during otolith formation and in tethering the otolith to the underlying sensory epithelium.

1842

**A Novel Mechanism for Invasion and Intracerebral Migration of Brain Tumours**

D. Maret, D. R. Colman, R. F. Del Maestro; Neurology and Neurosurgery, Montreal Neurological Institute, McGill University, Montreal, PQ, Canada

Classic cadherins mediate homophilic, calcium-dependent intercellular adhesion. The prodomain of N-cadherin is normally cleaved intracellularly rendering the mature protein competent to mediate adhesion when it is brought to the cell surface. N-cadherin has been shown to promote cell

motility in cancer cells. Our results indicate that uncleaved pro-N-cadherin accumulates at the cell surface in more aggressive glioma and medulloblastoma cells lines compared to less aggressive cell lines, as determined by measuring the surface ratio of pro-N-cadherin to mature N-cadherin. Since total N-cadherin expression has been shown to correlate with increased motility and pro-N-cadherin lacks adhesive function, we hypothesized that loss of adhesion due to aberrant surface expression of the pro-protein may serve as a molecular mechanism for enhanced motility of brain tumour cells. An N-cadherin mutant was engineered where the prodomain could not be cleaved by endogenous proteases but would be cleaved by serum coagulation factor Xa at the cell surface. To test the effect of expression of N-cadherin precursor protein on cellular behaviours, such as migration and invasion, this construct was transfected into the least aggressive glioma and medulloblastoma cell lines. Our results show that pro-N-cadherin surface expression promotes cell migration in wound-healing assays, and increases invasion into a type I collagen matrix, compared to wild-type cells or cells transfected with mock vector. These effects on cell motility can be abrogated upon treatment with factor Xa, presumably via cleavage of the prodomain and activation of the adhesive function of mature N-cadherin. Our work strongly suggests that the abnormal expression of pro-N-cadherin on the surface of certain brain tumour cells plays a pivotal role in augmenting cell migration by compromising adhesive cadherin function of mature N-cadherin.

1843

**Regulation of Neural Crest Migration by Protocadherin-mediated Cell Adhesion**

J. Bononi, R. Bradley; Cell Biology and Neuroscience, Montana State University, Bozeman, MT

Neural crest cells originate along the dorsal neural tube in vertebrate embryos, then delaminate and migrate away from the neural tube to form the majority of the peripheral nervous system (PNS). Cell adhesion molecules are thought to participate in neural crest migration, contributing to both the delamination and subsequent re-aggregation of the neural crest cells to form the various neural crest derivatives. To identify cell adhesion molecules involved in the formation of the PNS we screened an embryonic chicken dorsal root ganglia (DRG) library for members of the protocadherin family, resulting in the isolation of chicken protocadherin-1 (cPcdh1). In the trunk, cPcdh1 is expressed in migrating neural crest cells and in the DRG, sympathetic ganglia (SG) and Schwann cells along the ventral root (VR). Within the DRG, cPcdh1 is first detected as neural crest cells begin to coalesce and is initially restricted to the perimeter, where it colocalizes with undifferentiated and mitotically active cells. This suggests that cPcdh1 may function as a migration arrest signal to localize nascent neural crest cells to the margins of the DRG. To assess the function of cPcdh1, full-length and dominant-negative cPcdh1 constructs were ectopically expressed in neural crest cells by in ovo electroporation. Results indicate that over-expression of cPchd1 alters the distribution of neural crest cells in the PNS, with an increase in the percentage of neural crest cells that migrate to the DRG at the expense of cells that migrate to the SG or VR. Conversely, when cPcdh1 function is inhibited, by ectopic expression of a dominant-negative construct, a greater percentage of neural crest cells are found in the SG and VR. These results suggest that cPcdh1-mediated cell adhesion plays an important role in neural crest cell migration arrest during vertebrate PNS formation.

1844

**Nuclear Localization Signals (NLSs) of E-cadherin Transcriptional Repressor Snail**

H. Ko,[1] K. Kim,[1] H. Kim,[2] X. Li,[3] S. Weiss,[3] J. Yook[2,3]; [1]Department of Biochemistry and Molecular Biology, BK21 Project for Medical Science, College of Medicine Yonsei University, Seoul, Republic of Korea, [2]Department of Oral Pathology, BK21 Projects for Medical Science, College of Dentistry Yonsei University, Seoul, Republic of Korea, [3]Division of Molecular Medicine and Genetics, Department of Internal Medicine, University of Michigan Comprehensive Cancer Center, University of Michigan, Michigan, MI

The E-cadherin transcriptional repressor, Snail, plays a critical role in driving the epithelial-mesenchymal transition programs that mark gastrulation as well as invasion of cancer cells. Recent data suggested that Snail is phosphorylated by glycogen synthase kinase-3β (GSK3-β), resulting in β-Trcp mediated ubiquitination and proteasomal degradation. Accordingly, Wnt signaling inhibits Snail phosphorylation and consequently increases Snail protein levels. In the present study, we have examined the roles of a Snail nuclear localization motif. Typical NLS sequences is located at the N-terminal of Snail overlapping with SNAG domain (residue 8-16) and in front of zinc-fingers (residues 151-152) and are a bipartite NLS motif and a basic cluster NLS motif, respectively. These sequences are highly conserved from xenopus to human. Mutational inactivation of these NLS signals resulted in decreased expression level of nuclear and total Snail protein suggesting NLSs are essential for proper function. NLS mutations resulted in decreased expression of nuclear and cytoplasmic Snail, with corresponding attenuation of Snail repressor activity using a reporter gene assay with an E-cadherin proximal promoter. LiCl treatment increased the expression level of the cytoplasmic fraction of Snail suggesting that cytoplasmic fraction of Snail is rapidly phosphorylated and degraded by GSK3-β. Confocal microscopic examination also showed increased cytoplasmic localization of NLS mutants. These results indicate that the highly conserved N-terminal SNAG domain and the zinc finger domain of Snail function as nuclear localization signals and that Snail expression can be regulated by subcellular localization and phosphrylation by GSK3-β.

1845

**Developing Nanostructured Surfaces to Investigate the Role of Cadherins in Cell Adhesion and Cell Motility**

T. Wolfram,[1,2,3] T. Schoen,[1,3] E. Bock,[2] M. Arnold,[3] T. Lohmueller,[2] P. Girard,[3] J. P. Spatz[1,2,3]; [1]Institute for Molecular Biophysics, The Jackson Laboratory, Bar Harbor, ME, [2]Dept. New Materials and Biosystems, Max-Planck-Institute for Metals Research, Stuttgart, Germany, [3]Dept. Biophysical Chemistry, University of Heidelberg, Heidelberg, Germany

$Ca^{2+}$-dependent cell-cell contacts mediated via homophilic interactions between members of the Cadherin-family are key events in regulating structural integrity of cells and tissue. It becomes more and more obvious that cadherins facilitate not only those specific events, but also control a wide variety of cellular behaviours. They are playing instructive rolls for cell and tissue polarization. They regulate different types of cell movement like cell sorting, cell migration and cell rearrangements. In order to investigate and to mimic positioining of single molecules of N-Cadherin and Cadherin-8 on the cell membrane, we designed a hexagonally close-packed rigid template of gold nano-dots based on Micellar Nanolithography. These gold dots are structured by self-assembly of diblock co-polymers and positioned uniformly or as a gradient over different substrate spacings. The gold dots are biofunctionalised via a Mono-Thiol-NTA group with His-tagged N-Cadherin (Cadherin-2) and Cadherin-8. The glass area between biofunctionalised gold dots is covered with Polyehtyleneglycol (PEG) to circumvent unspecific binding of the cells to the glass surface, giving us the opportunity to exactly control the chemical environment on the cover slips. In the present study, we applied a variety of

different proneural cell lines (B35, PC12, SHSY-5Y, N2a) and primary neuronal cells on these surfaces. Most of the cell lines bind to those substrates and are able to build cellular protrusions. Distances higher than 58nm resulting in less cell adhesion and leading to a higher grade of cell motility. Furthermore we would like to address the questions how the molecular composition of cytoskeleton components like actin, are influenced by different nanometer-patterend surfaces. In general our unique technique enables us to probe proteins involved in cell adhesion, cell signaling, cell survival and cell morphology in a structurally controlled chemical environment.

1846

**Partial Cadherin Unfolding Is a Prerequisite for Adhesive Dimerization**

R. B. Troyanovsky, O. Y. Laur, S. M. Troyanovsky; Dermatology, Washington University Medical School, St. Louis, MO

In this study we compared E-cadherin dimerization on the surface of living cells with how the same process unfolds on agarose beads. In both cases, dimerization was monitored by the same site-specific cross-linking assay. Our work showed that on the bead surface, under native conditions, E-cadherin produced predominantly low affinity (weak) dimers that immediately dissociated after the depletion of calcium ions. However, in either a slightly acidic buffer (pH 5) or in the presence of cadmium ions, E-cadherin produced high affinity (strong) dimers. These dimers were unable to dissociate upon calcium depletion. Both types of dimers apparently had similar structures, and their formations were abolished by the same point mutations (W156A or mutations of the EC1/EC2 calcium-binding sites). Remarkably, only strong dimers were revealed on the cell surface under normal culture conditions. These dimers correspond to the adhesive dimers previously identified in coimmunoprecipitation experiments. The formation of weak dimers was detected on the plasma membrane only when cells had been fragmented by homogenization and E-cadherin was immunoclustered. Taken together, our study uncovers a previously unknown cellular process involving EC1 domain unfolding and leading to the formation of strong cadherin adhesive dimers.

1847

**Regulation of N-Cadherin Adhesion Strength by PIP2 Generated by PIP5KIγ**

T. Y. El Sayegh,[1] P. Arora,[1] C. Laschinger,[1] R. Anderson,[2] P. Janmey,[3] C. McCulloch[1]; [1]CIHR Group in Matrix Dynamics, University of Toronto, Toronto, ON, Canada, [2]Pharmacology, University of Wisconsin, Madison, WI, [3]Institute for Medicine and Engineering, University of Pennsylvania, Philadelphia, PA

Intercellular adhesion is critical for tissue homeostasis but the role of phosphoinositides in regulating the localization and function of actin binding proteins involved in mediating cadherin function has not been examined. We used the donor-acceptor model and a recombinant protein consisting of the extracellular domain of N-cadherin-mouse IgG Fc region, to examine the regulation of N-cadherin junctions by phosphatidylinositol 4,5-biphosphate ($PIP_2$) and gelsolin. $PIP_2$ was generated locally at sites of N-cadherin-mediated intercellular adhesion and was an important regulator of adhesion strength. $PIP_2$-specific antibodies and a GFP-tagged construct of the pleckstrin homology domain of phospholipase Cγ, showed $PIP_2$ enrichment at sites of early N-cadherin ligation. Immunostaining for type I phosphatidylinositol 4-phosphate 5 kinases (PIP5KI) showed that the PIP5KIγ isoform spatially associated with N-cadherin coated beads. Dominant negative PIP5KIγ blocked $PIP_2$ enrichment at sites of N-cadherin ligation and also reduced adhesion strength compared to wt-PIP5KIγ and untransfected controls as determined by shear wash-off assay. Cells incubated with a cell-permeant peptide that competes with the $PIP_2$ binding region of gelsolin showed significantly reduced adhesion strength compared with an irrelevant control peptide ($p<0.05$). This finding underlined the importance of $PIP_2$-induced uncapping of actin filament barbed ends for adhesion. Gelsolin-null fibroblasts transfected with full length gelsolin actin severing mutants (characterized by 80% reduction in severing efficiency but retaining PIP2 binding and barbed end interaction) showed similar adhesion strength as wild-type gelsolin-transfected controls. Collectively these results indicate that transient, localized generation of $PIP_2$ by PIP5KIγ may regulate intercellular adhesion strength in fibroblasts, in part by a mechanism utilizing gelsolin uncapping of actin filaments.

1848

**The Effect of Neurocan on N-cadherin Function is Mediated by Fyn tyrosine kinase**

J. Jiang, J. Lilien, J. Balsamo; Biological Sciences, The University of Iowa, Iowa City, IA

Neurocan is a chondroitin sulfate proteoglycan in the aggrecan, versecan, brevican family, that is highly enriched in the nervous system and thought to act as an axonal guidance cue. Binding of neurocan, or a recombinant N-terminal fusion protein, to its cell surface receptor initiates a signal cascade that results in disruption of the complex of proteins associated with the cytoplasmic domain of N-cadherin, tyrosine phosphorylation of beta-catenin, and consequent loss of N-cadherin function. We now present evidence that the effect of neurocan on N-cadherin function depends on the integrity of lipid rafts and that Fyn, a member of the Src family of tyrosine kinases, plays a major role in neurocan initiated signaling. Disruption of lipid rafts by cholesterol depletion results in loss of response to neurocan. Additionally, inhibition of Fyn catalytic activity by the tyrosine kinase inhibitor PP1 eliminates the effect of neurocan. When the association of Fyn with lipid rafts is prevented by the palmitolation inhibitor 2-bromopalmitate, the amount of Fyn associated with N-cadherin increases, with a concomitant decrease in beta-catenin association with cadherin and loss of N-cadherin function. Loss of beta-catenin from the N-cadherin complex as a result of 2-bromopalmitate can be prevented by inhibiting Fyn activity with PP1, suggesting that the association of Fyn with lipid rafts modulates the ability of Fyn to phosphorylate beta-catenin. Indeed, Fyn specifically phosphorylates beta-catenin on tyrosine residue 654. Phosphorylation of this residue is known to result in a dramatic reduction in the affinity of beta-catenin for cadherin. Consistent with this, introduction of the beta-catenin mutant Y654F into neural retina cells effectively blocks the cells response to neurocan.

1849

**Rhoa Gtpase Regulates M-cadherin Activity and Myoblast Fusion**

S. Charrasse,[1] F. Comunale,[1] Y. Grumbach,[1] A. Blangy,[1] F. Poulat,[2] C. Gauthier-Rouviere[1]; [1]CRBM-CNRS, Montpellier, France, [2]IGH-CNRS, Montpellier, France

The Rho family of GTP-binding proteins plays critical roles during myogenesis induction. To elucidate their role later during myogenesis, we have analyzed RhoA function during myoblast fusion into myotubes. We find that RhoA activity is rapidly and transiently increased when cells are shifted into differentiation medium and then is decreased until myoblast fusion. RhoA activity must be down-regulated to allow fusion, as

expression of a constitutively active form of RhoA (RhoAV14) inhibits this process. RhoAV14 perturbs the expression and localization of M-cadherin, a member of the $Ca^{2+}$-dependent cell-cell adhesion molecule family that has an essential role in skeletal muscle cell differentiation. This mutant does not affect N-cadherin and proteins involved in myoblast fusion, β1-integrin and ADAM12. Active RhoA induces the entry of M-cadherin into a degradative pathway and thus decreases its stability in correlation with the monoubiquitination of M-cadherin. Moreover, p120 catenin association with M-cadherin is decreased in RhoAV14-expressing cells, which is partially reverted by the inhibition of the RhoA effector Rho-associated kinase ROCK. ROCK inhibition also restores M-cadherin accumulation at the cell-cell contact sites. We propose that the sustained activation of the RhoA pathway inhibits myoblast fusion through the regulation of p120 activity, which controls cadherin internalization and degradation.

1850

**a-Actinin Links LPP, but not Zyxin, to Assembly of Cadherin-Based Junctions**

M. D. H. Hansen, M. C. Beckerle; Huntsman Cancer Institute, Salt Lake City, UT

Physiologically relevant cell-cell adhesion requires tethering of cadherin adhesion receptors to actin networks. Cadherin engagement results in dramatic changes in actin dynamics and organization. The cytoplasmic domain of cadherin binds a series of proteins that facilitate actin binding, including α-actinin. Interestingly, the related proteins zyxin and LPP contain functional α-actinin binding sites and bind members of the VASP family of actin regulatory proteins. It has been proposed that zyxin serves as an adaptor to recruit VASP into cadherin complexes in order to drive actin rearrangements. In support of this hypothesis, zyxin colocalizes with VASP at cell-cell junctions. VASP is required for normal cell-cell junction formation, as are the VASP binding motifs of zyxin and LPP. Here we examine whether α-actinin docks zyxin and/or LPP to cadherin complexes. We find that LPP, but not zyxin, requires an α-actinin binding site to drive cell-cell adhesion. Further, dominant negative LPP, but not zyxin, mutants prevent the incorporation of α-actinin into cadherin-actin networks. Thus, α-actinin, through LPP, likely docks VASP family members to cadherin complexes. These results provide a mechanism for linking VASP-mediated regulation of actin dynamics to cell-cell adhesion.

1851

**Zyxin and LPP-VASP Complexes Drive Cell-Cell Adhesion in Response to Rac1**

M. D. H. Hansen, M. C. Beckerle; Huntsman Cancer Institute, Salt Lake City, UT

Cadherins mediate cell-cell adhesion by linking cell junctions to actin networks. Mechanisms of cadherin-actin network assembly remain poorly understood. We examine how zyxin and the related protein LPP contribute to cadherin-actin network formation. Using a quantitative assay for cell-cell adhesion, we demonstrate that zyxin and LPP function to increase the rate of early cell-cell junction assembly. This function is inhibited by the LIM domains and requires intact ActA repeats, which bind VASP family members. Constitutively active zyxin or LPP mutants that lack LIM domains drive increased VASP activity at cell-cell junctions, as measured by increased incorporation of VASP into the actin cytoskeleton and by displacement of capping protein. Recruitment of zyxin/LPP to cell-cell junctions is stimulated by Rac1, suggesting a mechanism by which signaling pathways might control localization and activity of zyxin/LPP-VASP complexes. We propose a model in which zyxin/LPP LIM domains serve as a regulatory switch that exerts local control over VASP activity and thus influences strengthening of cell junctions.

1852

**Immediate-Early Dynamics at E-cadherin Contacts**

T. D. Perez,[1] M. Tamada,[2] S. Yamada,[1] M. P. Sheetz,[2] W. J. Nelson[1]; [1]Molecular and Cellular Physiology, Stanford University, Stanford, CA, [2]Biological Sciences, Columbia University, New York, NY

The Ca++-dependent cell-cell adhesion protein E-cadherin is an early regulator of cell-cell contacts necessary for establishing contacts and allowing epithelial cells to polarize. Though many regulators of E-cadherin adhesion have been found, the mechanisms and dynamics of E-cadherin adhesion are still not well understood during early cell-cell contact formation. To better study the dynamics of proteins at E-cadherin contacts, we utilized small, polystyrene beads coated with the extracellular domain of E-cadherin to initiate cadherin-mediated contacts. Coated beads were placed on cells using a laser trap, and the dynamics of E-cadherin recruitment were determined with respect to Rac, Akt-PH domain, actin, and Arp3 localization at the beads. We find that maximal E-cadherin localization occurs in one of two modes. A fast mode of cadherin accumulation completes within 1 minute and is concurrent with Rac, actin, and PH-domain accumulation. A slow mode of cadherin accumulation occurs over 3 minutes and precedes the initiation of Rac, actin, and PH-domain accumulation by about 2 minutes. E-cadherin fluorescence remained stable after maximal accumulation, but Rac and PH-domain were rapidly lost at contact sites. Additionally, we find no dependence of early cadherin or Rac accumulation on PI3K activity. The results show that early E-cadherin accumulation can be independent of Rac1 and PI3K signaling and allow us to propose new models of how E-cadherin may function as a cell-cell contact receptor.

1853

**E-cadherin Knockdown Disrupts Establishment but not Maintenance of Cell Polarity in MDCK Cells**

C. T. Capaldo,[1] I. G. Macara[2]; [1]Pharmacology, University of Virginia, Charlottesville, VA, [2]University of Virginia, Charlottesville, VA

E-cadherin is a single pass transmembrane glycoprotein that forms calcium dependent, homophilic intercellular adhesions in epithelial cells. These contacts are key regulators of cell adhesion and differentiation, including the assembly of intercellular Tight Junctions (TJs). TJs act as a permeability barrier between cells and maintain cell polarity by preventing diffusion between apical and basal-lateral membrane compartments. TJ formation is stimulated by cell-cell contact, but the mechanisms involved are poorly understood. In the following study, Madin-Darby canine kidney (MDCK) cells were selectively depleted of E-cadherin by RNAi. Surprisingly, this had little effect on the protein levels or localization of several markers of AJs (Adherens Junctions) and TJs. Also, immunofluorescence staining with the apical marker gp135 and the basal-lateral marker Na+ K+ ATPase showed no loss of apical-basal polarity. Fluorescence Recovery After Photobleaching (FRAP) analysis in MDCK cells stably expressing YFP-ZO-1 indicates that E-cadherin knockdown does not alter the apparent stability of tight junction complexes. However, E-cadherin knockdown cells failed to properly establish cell polarity. In response to calcium switch, knockdown cells exhibited severely suppressed trans-epithelial resistance and delayed localization of TJ and AJ markers. These studies indicate that E-cadherin functions in the establishment of cell polarity, but that wild-type levels of E-cadherin are not required for the maintenance of Tight Junctions and cell polarity.

1854

**N-cadherin Adhesion and Cell Signaling Regulates Polarity of Migrating Vascular Smooth Muscle Cells**

P. J. B. Sabatini,[1] M. Zhang,[2] M. P. Bendeck,[1] B. L. Langille[1,2]; [1]Laboratory Medicine and Pathobiology, University of Toronto, Toronto, ON, Canada, [2]University Health Network, Toronto, ON, Canada

Signaling associated with cellular adhesion is a key process for cell migration that promotes cytoskeletal reorganization and couples anterior protrusion and attachment with posterior retraction. Accordingly, anterior activation of integrin-mediated cell-substrate adhesion activates Cdc42 to reorient the microtubule-organizing center (MTOC) towards the direction of migration. N-cadherin polarizes to the posterior-lateral margins of many wound-edge cells and can regulate GTPases; therefore, we hypothesized that N-cadherin also regulates MTOC reorientation in a scrape-wound assay. Treatment with an N-cadherin blocking antibody, or a small peptide that interferes with N-cadherin-mediated cell adhesion, disrupted polarization of the MTOC to the anterior side of the nucleus. Cdc42 was activated by wounding and transfection of a GFP-tagged wild-type Cdc42 plasmid confirmed anterior localization of wound edge cells; however, blocking N-cadherin with antibody had no effect on Cdc42 activity and anterior localization after wounding, thus N-cadherin may exert effects that are independent of Cdc42. The N-cadherin antibody disrupted actin reorganization in wound-edge cells and tracking of microtubules to the anterior of the cell along microfilament bundles was also disrupted. Wounding also rapidly suppressed RhoA activity, a target of N-cadherin signaling, and current experiments are exploring the influences of N-cadherin on RhoA and cytoskeletal reorganization in these cells.

1855

**A Role for N-cadherin in Endothelial Cell Migration via PDGF-R Signaling**

C. Theisen, K. R. Johnson, M. J. Wheelock; Oral Biology, University of Nebraska Medical Center, Omaha, NE

Tumor cells recruit endothelial cells from existing capillaries in order to establish their own vascular system via angiogenesis. Endothelial cells express two classical cadherins, VE-cadherin and N-cadherin. VE-cadherin is localized to the cell-cell junctions in endothelial cells while N-cadherin is not a component of the junctional complex. Using a stable siRNA system we were able to knock-down N-cadherin expression in the immortalized human microvascular endothelial cell line HMEC-1. N-cadherin knock-down cells have impaired ability to form tubes on matrigel in an *in vitro* angiogenesis assay and decreased motility in a transwell motility assay. Using phage display we also discovered a novel binding partner for β-catenin known as NHERF-2. We have mapped regions required for association of both proteins to PDZ II of NHERF-2 and a PDZ binding motif at the very carboxy-terminus of β-catenin. The PDZ I domain of NHERF-2 is known to bind PDGF-Rβ and this interaction leads to enhanced cell spreading and motility. PDGF signaling is also involved in tube formation of microvascular endothelial cells. We show that β-catenin and N-cadherin are in a complex with NHERF-2 and PDGF-Rβ at membrane ruffles using immunoprecipitation and immunofluorescence studies on HT1080 cells expressing NHERF-2 and PDGF-Rβ. HMEC-1 cells are less motile and have impaired tube formation in the presence of a PDGF-R specific inhibitor. These studies implicate N-cadherin and β-catenin in endothelial cell migration and tube formation via PDGF-R mediated signaling through the scaffolding molecule NHERF-2.

1856

**Expression of Inappropriate Cadherins by Epithelial Tumor Cells Promotes Endocytosis and Degradation of E-cadherin via Competition for P120 Catenin**

S. Mandal, M. Maeda, K. R. Johnson, M. J. Wheelock; Oral Biology, University of Nebraska Medical Center, Omaha, NE

Cadherin cell-cell adhesion proteins play an important role in modulating the behavior of tumor cells. E-cadherin serves as a suppressor of tumor cell invasion, and when tumor cells turn on the expression of a non-epithelial cadherin, they often express less E-cadherin, enhancing the tumorigenic phenotype of the cells. Here we show that when A431 cells are forced to express R-cadherin they dramatically down regulate expression of endogenous E-cadherin and P-cadherin. In addition, we show that this down regulation is due to increased turnover of the endogenous cadherins via clathrin dependent endocytosis. p120 catenin binds to the juxtamembrane domain of classical cadherins and has been proposed to regulate cadherin adhesive activity. One way p120 catenin may accomplish this is to serve as a rheostat to regulate the levels of cadherin. Here we show that the degradation of E-cadherin in response to expression of R-cadherin is due to competition for p120 catenin.

1857

**Desmosome Disassembly and Desmoglein Endocytosis are Coordinated Responses to Pemphigus Autoantibodies**

C. C. Calkins,[1] S. V. Setzer,[1] J. M. Jennings,[1] S. Summers,[1] K. Tsunoda,[2] M. Amagai,[2] A. P. Kowalczyk[1]; [1]Dermatology, Emory University School of Medicine, Atlanta, GA, [2]Department of Dermatology, Keio University School of Medicine, Tokyo, Japan

Desmosomes are adhesive intercellular junctions prominent in the skin and heart. Loss of desmosome function is associated with severe congenital and acquired disorders characterized by tissue fragility. Pemphigus vulgaris is an autoimmune disorder in which antibodies are directed against the desmosomal adhesion molecule Dsg3, resulting in severe mucosal erosions and epidermal blistering. To define the mechanisms by which Dsg3 autoantibodies disrupt keratinocyte adhesion, the fate of PV IgG and various desmosomal components was monitored in primary human keratinocytes exposed to PV patient IgG. PV IgG initially bound to keratinocyte cell surfaces and colocalized with desmosomal markers. Within 6 hrs after PV IgG binding to Dsg3, electron microscopy revealed that desmosomes were dramatically disrupted and keratinocyte adhesion was severely compromised. Immunofluorescence analysis indicated that PV IgG and Dsg3 were rapidly internalized from the cell surface in a complex with plakoglobin, but not desmoplakin. Dsg3 internalization was associated with disrupted desmoplakin organization and retraction of keratin filaments from cell-cell borders. The internalized PV IgG-Dsg3 complex colocalized with markers for both early and late endosomes, suggesting that Dsg3 was targeted for degradation. Consistent with this possibility, biotinylation experiments demonstrated that soluble Dsg3 cell surface pools were rapidly depleted, followed by loss of insoluble Dsg3. These findings demonstrate that the loss of keratinocyte adhesion in cells exposed to PV IgG is coupled to Dsg3 endocytosis and degradation.

**Myogenesis Induction is Regulated by Association of N-cadherin with Lipid Rafts**

N. Taulet, F. Comunale, C. Gauthier-Rouvière; Cell Biology, CRBM - CNRS FRE 2593, Montpellier, France

Cell-cell adhesion mediated by cadherins is involved in a wide variety of cellular functions including cell growth, migration and differentiation. These transmembrane glycoproteins act as adhesive receptors when they accumulate at cell-cell contact sites where they promote intracellular signaling pathways. Our study focuses on N-cadherin which plays an important role for myogenesis induction through the positive regulation of RhoA and the negative regulation of Rac1. We have recently shown, in C2C12 myoblasts, that N-cadherin and catenins (α, β, γ and p120) association with membrane microdomains enriched in cholesterol called lipid rafts participates in adhesive complex stabilization (Causeret M./Taulet N. *Mol. Biol. Cell* 2005). Moreover, our results indicate that lipid rafts disruption leads to disorganization of N-cadherin dependent cell-cell contacts and inhibition of myogenesis, suggesting that this association is necessary to promote skeletal muscle differentiation. In the present study, we investigate how the presence of N-cadherin and catenins in lipid rafts might control myogenesis induction through the regulation of Rho GTPases activity, especially RhoA activation. In order to identify the signaling pathways implicated in this process, we try to highlight the dynamic assembly of signaling proteins with N-cadherin in lipid rafts.

**Advanced-glycation End-products Increase Vascular Permeability *In Vitro* through Increased Protease Activity**

D. Navaratna; Cell Biology and Physiology, School of Medicine, University of New Mexico, Albuquerque, NM

Increased vascular permeability is one of the foremost microvascular complications in early non-proliferative diabetic retinopathy. Recently, several studies have implicated advanced glycation end-products (AGEs) and their downstream signaling molecules as significant contributors to increased microvascular permeability and endothelial cell dysfunction in the retina. However, the mechanistic basis of this AGE-induced permeability remains unexplored. The aim of this study was to determine if AGE-BSA alters the cellular distribution of VE-cadherin in endothelial lateral junctions and if this alteration is mediated through increased protease activity. Extracellular proteinases regulate cellular function at various levels and have been shown to play a pivotal role in disrupting the blood-brain barrier. Treatment of bovine retinal microvascular endothelial cells with AGE-BSA, an accepted prototype of advanced glycation end-products led to altered cellular morphology, disruption of lateral junctions and a reduction of VE-cadherin expression on the cell surface. This was accompanied by a 2-fold increase in permeability upon AGE stimulation in an in vitro FITC-dextran permeability assay. Inhibitors of protease activity were able to successfully abolish the action of AGE-BSA on VE-cadherin expression and restore permeability back to near control levels. A separate in vitro experiment showed that MMP-9 is able to cleave VE-cadherin in cell extracts and on the surface of intact cells possibly leading to subsequent internalization. Our findings point out to a novel role for proteases in altering endothelial barrier function that might dictate effective strategies for therapeutic intervention in vivo.

1860

**Prototypical Type-I E-cadherin and Type-II Cadherin-7 Mediate Very Different Distinct Adhesiveness through their Extracellular Domain**

Y. Chu,[1] O. Eder,[1] W. A. Thomas,[2] I. Simcha,[3] A. Ze'ev,[3] F. Pincet,[4] J. Thiery,[1] S. Dufour[1]; [1]Umr144 cnrs, Institut Curie, Paris, France, [2]Natural Sciences, Colby-Sawyer College, New London, NH, [3]Department of Molecular Cell Biology, The Weizmann Institute of Science, Rehovot, Israel, [4]Umr8550 cnrs, ENS, Paris, France

Using a dual pipette assay that measures the force required to separate adherent cell doublets, we have quantitatively compared intercellular adhesiveness mediated by Type-I (E- or N-cadherin) or Type-II (cadherin-7 or -11) cadherins. At similar cadherin expression levels, cells expressing Type-I cadherins adhered much more rapidly and strongly than cells expressing Type-II cadherins. Using chimeric cadherins, we found that the extracellular domain exerts by far the dominant effect on cell adhesivity, that of E-cadherin conferring high adhesivity, that of cadherin-7 conferring low adhesivity. Type-I cadherins were incorporated to a greater extent into detergent-insoluble cytoskeletal complexes, and their cytoplasmic tails were much more effective in disrupting strong adherent junctions, suggesting that Type-II cadherins form less stable complexes with β-catenin. The present study demonstrates compellingly, for the first time, that cadherins are dramatically different in their ability to promote intercellular adhesiveness, a finding that has profound implications for the regulation of tissue morphogenesis.

## Gap Junctions (1861-1884)

1861

**Interplay Between CFTR and Cx45, Cx32 and Cx40, but not Cx50, Channels**

B. A. Kotsias, M. Salim, L. L. Peracchia, C. Peracchia; Pharmacology and Physiology, University of Rochester, Rochester, NY

The cystic fibrosis transmembrane regulator (CFTR) influences the function of other channels via unknown mechanisms. Chanson et al. (1999) have shown that CFTR activation increases the $Cl^-$ current and gap junctional conductance (Gj) of pancreatic cells expressing Cx45. We have confirmed these data in *Xenopus* oocyte pairs coexpressing CFTR and Cx45; in addition, we have reported a decrease in Vj sensitivity, demonstrated by an increase in $G_{j\ steady\ state}/G_{j\ peak}$ at the pulse (Kotsias and Peracchia, 2005). Recently, we have obtained similar results with Cx32 and Cx40, but not Cx50. Application of 20-40 μM forskolin to oocyte pairs clamped at -20 or -40mV and subjected to -40 or -60mV Vj pulses (12s duration) induced a $Cl^-$ current, increased $G_{j\ peak}$ by 30±6% (n=5) and 600±240% (n=6) in Cx32 and Cx40, respectively, and increased $G_{j\ steady\ state}/G_{j\ peak}$ by 28% and 55%, respectively. In oocyte pairs expressing just Cx40 (or Cx45) in one oocyte (#1) and both Cx40 (or Cx45) and CFTR in the other (#2), with negative pulses applied to oocyte #1 forskolin application still increased Gj and decreased Vj sensitivity. $G_{j\ peak}$ increased by 143±25% (n=3) and 61±19% (n=7) in Cx40 and Cx45, respectively, and increased $G_{j\ steady\ state}/G_{j\ peak}$ by 96% and 50%, respectively. This indicates that CFTR activation is effective even when it affects only one of the two hemichannels and that the Gj and Vj changes are not artifacts of decreased membrane resistance in the pulsed oocyte. Preliminary data show that in oocytes coexpressing CFTR and Cx40-TR (Cx40 with COOH-terminus truncated beyond residue 248) forskolin has no effect on Gj and Vj sensitivity. This suggests that the COOH-terminus plays a role in the interplay between CFTR and Cx40 channels. Supported by NIH grant GM20113.

**E-Cadherin Differentially Regulates the Fate of Connexin43 and Connexin32 in A431D Cells**

S. Chakraborty, S. Mitra, R. Govindarajan, K. Knudtson, P. P. Mehta; Biochemistry and Molecular Biology, University of Nebraska Medical

Center, Omaha, NE
It is as yet unknown how cadherin-mediated cell-cell adhesion facilitates the assembly of connexin(Cx)s into gap junction(GJ)s. Because the C-terminal tail of Cxs varies significantly in amino acid identity, we hypothesized that assembly of Cxs into GJs is regulated by C-terminal tail of Cxs and their interaction with the cadherins, or both. We used cadherin-null, human epidermoid carcinoma-derived A431D cells, and an alpha-type (Cx43) and a beta-type (Cx32) Cx that have divergent C-terminal tails, to test our hypothesis. Immunocytochemical analysis following transient expression of these Cxs revealed that both Cxs failed to assemble into GJs and accumulated intracellularly in the Golgi and early endosomal compartment. Transient expression of both Cxs along with E-cadherin in A431D cells induced the assembly of Cx43, but not Cx32, into GJs. Significant colocalization of Cx43 and E-cadherin was observed not only at the cell-cell contact areas but also in the sub-cellular compartments. These observations were substantiated by transiently expressing Cx43 and Cx32 in A431DE cells that were engineered to express E-cadherin stably. To investigate if the C-terminal tail of Cxs regulates their subcellular fate in the presence of E-cadherin, we transiently expressed A431DE cells with C-terminal tail deleted mutants of Cx43 and Cx32. We found that the mutant Cxs accumulated intracellularly and did not assemble into GJs. These data suggest that the C-terminal tail of Cx43 harbors motif(s) that allows it to interact with E-cadherin, either directly or indirectly, and assemble into GJs. These findings suggest that the trafficking and assembly of Cxs are regulated by domains in the Cxs that are Cx subtype dependent and by the interaction among Cxs and cadherins, or both.(Supported by NIH CA113901)

**Cell Adhesion Proteins and Gap Junction Formation**

M. A. Matrone,[1] D. M. Abel,[1] S. Braconnot,[2] M. M. Falk[1]; [1]Biological Sciences, Lehigh University, Bethlehem, PA, [2]Macromolecular Systems & Human Physiology, CNRS-bioMérieux, ENS de Lyon, Lyon, France

In the plasma membrane, gap junction channels typically cluster to provide direct cell-cell communication between adjacent cells. Previous studies suggest that “helper” proteins, such as cadherins and claudins found in adherens and tights junctions, respectively, are necessary for connexons to dock into double-membrane-spanning gap junction channels, perhaps by reducing the natural distance of adjacent plasma membranes to within a certain threshold. To identify where the first connexons dock, high-resolution immunofluorescence microscopy in T51B cells, which endogenously express Cx43, demonstrated that the first gap junction plaques were formed at adherens junction-mediated cell-cell adhesion sites, where the distance between the adjacent cell membranes is reduced. Abolishing adherens junction formation at the plasma membrane by calcium-depletion revealed the reversible abolition of gap junction formation. Return of calcium to the growth media allowed for the reformation of adherens junctions, followed quickly by the reformation of gap junctions. Similarly, use of a dominant negative N-cadherin mutant, which lacks the N-terminal calcium-binding domains, dramatically reduces adherens junction formation by depleting the available catenin pool, and, thus, reduces gap junction formation. Provided that the loss of adherens junctions observed in these experiments results in markedly reduced or abolished gap junction formation, it remains uncertain whether the membrane proximity conferred by cell adhesion proteins affects connexon docking/clustering and/or connexin expression/localization. To investigate this, genetically manipulated cadherin proteins were engineered and characterized in regard to their effect on gap junction formation.

1864

**Intracellular Site of Gap Junction Protein Oligomerization**

L. Musil, J. VanSlyke; Oregon Health and Science U., Portland, OR

Oligomerization of connexin molecules into hexameric connexons (hemichannels) is a key step in gap junction assembly. Using five mechanistically distinct blockers of specific steps in intracellular transport including brefeldin A (BFA), Musil and Goodenough (1993) demonstrated that endogenously expressed, $^{35}$S-methionine metabolically labeled Cx43 assembles into connexons in a post-endoplasmic reticulum (ER), pre-plasma membrane compartment likely to be the trans Golgi network (TGN). It is not known whether this unusual site of assembly is a general property of connexins, or (as has recently been proposed) is restricted to Cx43 and other alpha group members. To address this issue, we used our previously established chemical cross-linking techniques to examine the assembly of Cx32 in two cell types that naturally express this beta-type connexin. In both cases, oligomerization of newly synthesized $^{35}$S-met-Cx32 into connexons was abolished when transport out of the ER was blocked by brefeldin A (BFA). In contrast, PC12 and HeLa cells stably transfected with plasmids encoding WT Cx32 driven by viral promoters oligomerized $^{35}$Smet-Cx32 into connexons even in the presence of BFA. Similar results were obtained with Cx43 in C6 cells: although assembly of endogenous Cx43 into connexons occurred exclusively after ER exit (e.g., was BFA-sensitive), BFA did not block connexon formation in transfectants expressing high levels of exogenous Cx43. Moreover, a cell line that simultaneously synthesizes both endogenous Cx43 and exogenous Cx32 oligomerized only the latter into hemichannels under conditions that prevented ER exit. We conclude that natively expressed Cx32, like Cx43, is assembled into connexons only after its transport out of the ER. High-level overexpression of either connexin can induce premature oligomerization within the ER, which may indicate that connexon formation is largely a self-assembly process driven by the local abundance of connexin monomers.

1865

**Gap Junction Degradation in Clathrin and Dab2 Depleted Cells**

A. Gumpert, M. Falk; Biological Sciences, Lehigh University, Bethlehem, PA

Gap Junction channels consist of two single-membrane spanning half-channels, which provide direct cell-to-cell communication between adjoining cells. Once connected the two half-channels cannot be separated under physiological conditions. It has been shown that the half-life of Gap Junction proteins is only a few hours and that the double-membrane channel clusters are degraded via internalization of the cluster into one of the two coupled cells. The internalization of gap junction cluster or its portion is believed to lead to the formation of a double-membrane vesicle termed “annular junction” Experiments indicate that the internalization of gap junction employs proteins like clathrin, AP-2 and Dab2 which are know to participate in receptor mediated endocytosis. To show the proteins’ involvement in gap junction degradation we investigate the internalization of gap junction clusters after down-regulation of proteins known to be essential in endocytosis and by site directed mutagenesis. The internalization process is studied in clathrin, AP-2 and Dab2 depleted cells. Down-regulation of protein expression, achieved by transient transfections with short interfering RNAs, and gap junction protein internalization are demonstrated by Western blotting and by

immunoflourescence staining respectively.

1866

**Double-Membrane Gap Junction Vesicles Generated by a Clathrin-Mediated Endocytosis-Like Mechanism**

M. Piehl,[1] C. Lehmann,[1] D. Segretain,[2] M. Falk[1]; [1]Biological Sciences, Lehigh University, Bethlehem, PA, [2]INSERM U670, Universite de Paris 5, Paris, France

To provide direct cell-to-cell communication, gap junction (GJ) channels connect the cytoplasm of two adjacent cells by traversing the apposing plasma membranes. These GJ channels (one half-channel from each cell) cluster into large GJ plaques (up to several square µms in diameter), and cannot be split under physiological conditions. Although gating can regulate GJ channels, biochemical analyses have shown that GJ proteins are turned over quite rapidly (half-life = 2-3 hours). This suggests that cells need to degrade GJ plaques efficiently. The degradation process may occur via the unusual invagination of double-membrane GJ plaques into one of the two coupled cells, consequently forming double-membrane vesicles termed annular gap junctions (AGJs). These AGJs have been previously described by ultra-structural analysis of differentiating tissues and cells in culture. Here we report that entire GJ plaques, or large portions of plaques, are internalized to form double-membrane AGJs (one membrane from each cell). These AGJs are then fragmented into smaller vesicles that are degraded preferentially by phago-lysosomal pathways. Surprisingly, functional analysis of components involved in GJ plaque internalization revealed an endocytosis-like mechanism. This mechanism involves the coat protein clathrin, the alternative adaptor protein Dab2, dynamin, myosin-VI, and actin filaments. Our results indicate that these components are responsible for the internalization, inward movement, and degradation of GJ plaques. To our knowledge, this is the first time receptor-mediated endocytosis components were shown to be involved in the generation of double-membrane vesicles.

1867

**Connexin 43 Degradation is Associated with its Aberrant Localization in Lung Tumor Cells**

S. C. Pfister,[1] R. V. Santelli,[2] G. M. M. Santelli[1]; [1]Biologia Celular e do Desenvolvimento, University of São Paulo, São Paulo, Brazil, [2]Biochemistry, University of São Paulo, São Paulo, Brazil

Gap Junction Channels (GJCs), structures present in plasma membrane of contacting cells, have been associated with tumor suppression. Gap Junctions (GJs) are composed by connexons, GJC precursors, require hexameric proteins named connexins. Even though the connexin family consists of around 20 members, only few isoforms are detected on distinct cells. Abnormal GJC may be consequence of failures in assembling or connexin degradation. So, the goal of this study was to identify if the degradation routes of connexin 43 has influenced the GJC maintenance. First, we compared some GJC features between normal hepatocyte cells (BRL3A) and hepatocarcinomas (HTC), both derived from *Rattus norvegicus.* Immunofluorescence reactions and Lucifer Yellow assays showed significant formation of functional channels in BRL3A while HTC cells presented not-functional GJC and connexin 43 was modestly detected on intracellular compartments. In a second step, HTC cells transfected with connexin 43 fused to Green Fluorescent Protein (Cx43-GFP) have restored GJC formation. Furthermore, HTC expressing Cx43-GFP reduced significantly cell growth when compared to HTC cells. Analysis by immunoblotting permitted us to identify that Epidemical Growth Factor Receptor (EGFR) was also decreased in HTC expressing Cx43-GFP. To identify if failures on cell trafficking is responsible to abnormal characteristics of GJCs, we used some inhibitors of both lysosomes and proteasoma pathways, besides a treatment with a drug that disrupts the Golgi transport, Brefeldin A. The present data suggest that abnormalities in degradation of connexin 43 are associated with GJC of lung tumor cells.

1868

**3D Microscopic Localization of Connexin43 Phospho-specific Isotypes**

G. M. Hand,[1] G. M. Gaietta,[1] B. N. Giepmans,[1] J. L. Solan,[2] P. D. Lampe,[2] G. E. Sosinsky[1]; [1]National Center for Microscopy and Imaging Research, Dept. of Neurosciences, University of California, San Diego, La Jolla, CA, [2]Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA

Cell-cell communication via gap junctions is dependent on the assembly, transport and formation of cell-to-cell channels formed by connexin (Cx) proteins. Multiple phosphorylation sites are present in the abundant and best-studied connexin isoform, Cx43. Phosphorylation is involved in proper protein trafficking, assembly, degradation and regulation of channel gating. Our goal is to determine the sub-cellular localization of Cx43 specific phospho-forms. We use a combination of immunolabeling, tyramide signal amplification (TSA), fluorescence photooxidation and electron microscopic tomography (EMT) to study the distribution of different Cx43 phospho-types. Cell lysates from non-stimulated NRK cells contain multiple Cx43 isoforms, including a non-phosphorylated form (P0 or NP form, although additional analysis indicates phosphorylated and non-phosphorylated Cx43 species can co-migrate) and two phosphorylated forms (P1 and P2). P1 and P2 are phosphorylated on multiple, unidentified serine sites and are the main form in native gap junction plaques. In immunostainings performed with Zymed monoclonal antibody 13-8300, we found strong intracellular, perinuclear fluorescence and far less gap junctional staining. This antibody labels only the P0 form of Cx43 (Nagy et al. (1997) Exp. Cell Res. 236:127-136). Subsequently, we used a different monoclonal antibody (CT antibody) that preferentially stains the P0 form as well as an antibody that stains primarily gap junction plaques (IF antibody). CT and IF antibodies were both made against the same peptide, located between amino acids 360-382 in the Cx43 sequence. Current studies are testing the hypothesis that the CT antibody most likely includes S372 as part of its binding site and when S372 is phosphorylated the CT antibody no longer binds. Initial EMT results indicate that the P0 form of Cx43 is primarily localized in the lumen of Golgi tubules. Analysis of tomograms provides a 3D representation of this labeling and its relationship to other Golgi components.

1869

**Truncation of the Gap Junction Protein Cx43 Changes the Molecular Composition of the Intercalated Disc**

K. Maass,[1] J. Shibayama,[1] S. E. Chase,[1] S. F. Noujaim,[1] K. Willecke,[2] M. Delmar[1]; [1]Pharmacology, SUNY Upstate Medical University, Syracuse, NY, [2]Institut fuer Genetik, Universitaet Bonn, Bonn, Germany

OBJECTIVE: To analyze the effect of the Cx43K258stop mutation on intercalated disc organization and on cardiac function in mice. INTRODUCTION: Recent studies indicate that the carboxy terminal (CT) region of connexin43 (Cx43) acts as a regulatory domain in the gating of

gap junction channels and is also involved in the direct interaction with other proteins. To analyze the function of the Cx43CT *in vivo*, mice expressing a mutant isoform lacking most of the Cx43CT (Cx43K258stop) in place of Cx43 were recently generated. Homozygous Cx43K258stop mice died postnatally due to a defective epidermal barrier; however, most mice harbouring only one *Cx43K258stop* and one *cx43 knockout* allele (Cx43K258stop/Cx43KO) survived to adulthood. Hence, hearts of Cx43K258stop/Cx43KO animals were used for the experiments described below. RESULTS: Immunolocalization studies on wild type adult cardiac ventricles showed that, consistent with previous studies, the position of Cx43 signals at the intercalated disc alternated with that of adherens junction proteins such as N-cadherin, p120-, alpha- and beta-catenin. In contrast, the Cx43K258stop protein segregated from adherens junctions, forming enlarged plaques at the lateral boundaries of the intercalated disc. Similar changes in co-localization were detected for the proteins ZO-1 and gamma-catenin. Separate studies are in progress to determine whether the Cx43K258stop mutation has an effect on cardiac function, particularly regarding the electrophysiological properties under normal and ischemic conditions. CONCLUSION: In the adult murine heart, lack of the Cx43CT is associated with larger gap junction plaques and segregation of Cx43 from other junctional proteins at the intercalated disc. The functional consequences of this molecular rearrangement remain to be determined.

1870

**Production of a 20kD Fragment by Intramembrane Proteolysis of Connexin43**

R. Joshi-Mukherjee,[1] C. Burrer,[2] L. Gao,[1] W. Coombs,[1] M. Delmar,[1] S. Taffet[2]; [1]Pharmacology, SUNY Upstate Medical Univeristy, Syracuse, NY, [2]Microbiology and Immunology, SUNY Upstate Medical Univeristy, Syracuse, NY

In vertebrates, gap junctions are formed by oligomerization of a protein subunit called connexin. One of the most prevalent connexin isotypes is connexin43 (Cx43). This protein is immunodetected as a 43kD band. In addition, in some cell lines, Cx43 antibodies directed to the carboxyl terminal domain allow for the detection of a ~20kD band. Previous studies suggested that the ~20kD fragment may result from protein degradation during sample handling. However, here we show that protection of the sample using a commercial protease inhibitor (Roche Complete®) along with various levels of PMSF (1-5 mM) did not prevent the production of this ~20kD fragment. This indicates that the fragment is not the result of degradation during sample preparation but the result of processing within the cell. Given the fragment size (and assuming that the fragment extends to the very C-end of the Cx43 sequence) we estimated that the point of proteolysis would be localized within the 4$^{th}$ transmembrane domain. Interestingly, the sequence of this domain presents a consensus site for intramembrane proteolysis by signal peptidase. Hence, the potential cleavage site L228-F229 was replaced with K228-K229. The construct was transfected into N2a cells. Consequent to the mutation, Cx43-CT antibodies failed to detect the 20kD fragment. As a separate approach to assess *in vivo* Cx43 processing, we induced the fragment in a cell line where it would be normally undetectable. CHO cells were used for this purpose. Exposure to TPA (a treatment known to activate intramembrane proteolysis) led to the production of the ~20kD fragment. Overall, our data strongly support the notion that the ~20kD fragment is a result of intramembrane proteolysis due to the constitutive expression of an intramembrane protease or, alternatively, by a mechanism that is induced by TPA treatment.

1871

**Aminosulfonate Inhibition of Cx26-containing Channels Involves the C-terminal Domain**

l. Tao, A. L. Harris; Pharmacology/physiology, UMDNJ, Newark, NJ

The protonated form of taurine and other aminosulfonates directly inhibited heteromeric connexin 26/connexin32 (Cx26/Cx32) hemichannels purified from rodent liver and reconstituted into liposomes (JBC 274:3711& 279:38544). The mechanism of the inhibition was examined in reconstituted hemichannels and HeLa junctional channels composed Cx26, Cx32 or both, with and without a cleavable C-terminal tag (T) consisting of an hemagglutinin-6x(HN) epitope (Biochem J. 383:111). Hemichannel inhibition was assessed by transport-specific fractionation of liposomes (TSF). In contrast to Cx26/Cx32 channels, Cx26T/Cx32 and Cx26T hemichannels were not inhibited by aminosulnate. On the other hand, Cx26/Cx32T hemichannels were sensitive. This suggested that Cx26 tag blocked the aminosulnate sensitivity. To explore this possibility, effects of tag cleavage were examined. Inhibition was restored when the tag was cleaved from Cx26T/Cx32 channels (Cx26Tc/Cx32). Cx26/Cx32Tc hemichannels remained sensitive, but, surprisingly, Cx26Tc hemichannels remained insensitive. These results confirmed that the Cx26 C-terminal tag interferes with aminosulfonate sensitivity, and suggest that the sensitivity requires Cx32 in the same channels. Hemichannel results were corroborated by studies of junctional channels, for which inhibition was assessed by the “parachute” dye-coupling assay (Bio. Tech. 18:490). Extracellular taurine causes cytoplasmic taurine levels to increase, due to the endogenous taurine transport in HeLa cells. Taurine substantially reduced dye coupling of junctional channels composed of Cx26/Cx32T, but not Cx26T, Cx26T/Cx32 or Cx32T. Taurine-induced inhibition was blocked by presence of HEPES in the medium, which blocks the taurine transport and is not membrane-permeable. Thus the junctional channel results corresponding reconstituted hemichannels. These data show that aminosulfunote inhibition is blocked by a Cx26 C-terminal-tag, that Cx32 is required and that junctional channels have the sensitivity of the corresponding reconstituted hemichannels. (Supported by NIH GM36044 and GM61406)

1872

**Identification of Residues of the Third Transmembrane Helix of Connexin 43 (Cx43) that Line the Gap-Junctional Hemichannel (GJH) Pore**

S. Lee, L. Reuss, G. A. Altenberg; Neuroscience and Cell Biology, University of Texas Medical Branch, Galveston, TX

The gap-junctional channels that mediate intercellular communication are formed by head-to-head docking of two connexons or gap-junctional hemichannels (GJH) from adjacent cells. GJH are connexin (Cx) hexamers and each Cx has four transmembrane domains (M1-M4). A definitive identification of the transmembrane helices that line the gap-junctional pore is not available. Here, we used a sensitive technique (the uptake of carboxyfluorescein, CF, elicited by lowering extracellular [$Ca^{2+}$] by GJH in frog oocytes) to identify residues in M3 that face the pore of Cx43 GJH. Cx43 is expressed in several tissues and organs, including brain, myocardium, kidney and capillary endothelial cells. We have previously demonstrated that the uptake of CF in oocytes injected with Cx43 cRNA is *via* GJH and that Cys-less version of Cx43 forms functional GJH. We substituted individually each M3 native residue with Cys, and then determine where reaction with the cell-membrane impermeable thiol-selective biotinylation reagent MBB ($M_r$ 537) affected CF uptake. All mutants showed CF uptake upon lowering [$Ca^{2+}$], but this CF uptake was sensitive to the inhibition by MBB only in the mutants I156C, F161C, V164C and V167C (-74 ± 5 %, mean ± SEM, $P < 0.001$). Prior reaction with the small

hydrophilic thiol reagent iodoacetic acid ($M_r$ 186) prevented the block by MBB in F161C, V164C and V167C. These results indicate that none of the native M3 residues is essential for GJH assembly and function, and suggest a face of the M3 helix lining the Cx43 pore that is consistent with a recent structure model of gap-junctional channels.

1873

**Functional Comparison of Connexin 26 Wild Type and Deafness Causing Mutant Channels**

G. Mese,[1] V. Valiunas,[2] P. R. Brink,[2] T. W. White[2,1]; [1]Graduate Program in Genetics, SUNY at Stony Brook, Stony Brook, NY, [2]Department of Physiology and Biophysics, SUNY at Stony Brook, Stony Brook, NY

There are at least four connexins (Cxs) in the cochlea and mutations in Cx26, Cx30 and Cx31 are leading causes of hereditary deafness. Differential selectivity of connexins to different molecules and second messengers is one basis of their uniqueness, therefore compensation for the absence of even a single connexin is challenging in the inner ear. Contrasting the permeability of human Cx26 deafness associated mutations with wild type Cx26 may provide insight for characterizing the molecules that need to be shared between cells for normal cochlear function. For this study, two human Cx26 mutations which retained some level of activity, Thr8Met (T8M) and Asn206Ser (N206S), were investigated. In order to assess the differences in the single channel properties and permselectivity, wild type and mutant Cx26 constructs were transfected into connexin deficient mouse neuroblastoma cell lines (N2A). Individual cell pairs were analyzed by dual whole-cell voltage clamp and intercellular fluorescent dye transfer. The average unitary conductance of wild type channels was 107±17pS using a pipette solution with 120mM K-aspartate which facilitated the examination of channel permeability to potassium ions. Similarly, N206S and T8M mutants had unitary conductances of 105±20pS and 106±19pS, respectively. These observations indicated that N206S and T8M mutant channels were as permeable to potassium ions as wild type Cx26 junctions. The permeability of mutant and wild-type channels to Lucifer yellow (LY) were also analyzed in individual cell pairs. The initial observations suggest that LY transfer through the mutant channels was also comparable to that of wild-type channels. Further investigation of Cx26 wild type and mutant channels may identify a difference in their permselectivity, providing a basic understanding about the etiology of the hereditary deafness in molecular level.

**Connexin 43 Hemichannels: Oxidative Stress Increases Open Probability**

M. V. L. Bennett,[1] M. A. Retamal,[2] C. Cortés,[2] L. Reuss,[3] J. C. Saez[2]; [1]Department of Neuroscience, Albert Einstein College of Medicine, Bronx, NY, [2]Departamento de Ciencias Fisiológicas, Pontificia Universidad Católica de Chile, Santiago, Chile, [3]Sealy Center for Structural Biology and Department of Neuroscience and Cell Biology, University of Texas Medical Branch, Galveston, TX

Cx43 hemichannels are formed in intracellular membranes and transported in vesicles that are inserted into the surface membrane. They diffuse in the surface to dock with hemichannels in an apposed membrane to form the full cell-cell channels. The surface but nonjunctional hemichannels open rarely, but opening is increased by metabolic inhibition (MI) with iodoacetate and antimycin A ("chemical ischemia"). Opening is detected by electrophysiological measurement of single channel conductances about twice that of the cell-cell channels and by dye uptake that is prevented by gap junction blockers and restricted to molecules that permeate gap junctions. Dephosphorylation and/or oxidation of Cx43 were proposed as potential mechanisms of hemichannel opening, since MI leads to dephosphorylation of total Cx43 and reducing agents can prevent dye uptake. Here using rat cortical astrocytes in primary culture, we isolated surface proteins by biotinylation followed by Western blotting. MI about doubled the amount of Cx43 on the cell surface in 15 min with a small further increase by 50 min. Dephosphorylation began at about 15 min MI and was nearly complete by 50 min. S-nitrosylation of Cx43 was detected by 30-40 min. DTT, a membrane permeant reducing agent, did not affect dephosphorylation but almost completely blocked hemichannel opening and S-nitrosylation. Hemichannel opening was also blocked by glutathione ethyl ester, which is membrane permeant, but not by glutathione, which is membrane impermeant. Moreover, GSNO, a membrane permeant nitric oxide donor, induced dye uptake and Cx43 nitrosylation, but did not affect the levels of Cx43 in the surface or its phosphorylation state. We propose that S-nitrosylation of intracellular Cx43 cysteine residues is a critical factor in the opening of Cx43 hemichannels induced by MI, a chemical treatment mimicking ischemia.

**Connexin47 (Cx47) and Cx32 in Adult Rodent CNS: A Major Role for Oligodendrocyte Gap junctions in "Dynamic Potassium Siphoning"**

T. Yasumura,[1] N. Kamasawa,[1] K. G. V. Davidson,[1] A. Sik,[2] J. I. Nagy,[3] J. E. Rash[1]; [1]Biomedical Sciences, Colorado State University, Fort Collins, CO, [2]Centre de Recherche, University Laval Robert-Giffard, Quebec, PQ, Canada, [3]Physiology, University of Manitoba, Winnipeg, MB, Canada

Cx47/Cx32 double-knockout mice have severe seizures, the innermost layer of their myelin sheaths is grossly swollen, and all mice die by 10 weeks of age (Odermatt et al., 2003). We analyzed the subcellular distributions of Cx47 and Cx32 in normal adult rodent CNS. By confocal microscopy, Cx47 was co-localized with astrocytic Cx43 on oligodendrocyte somata, and along myelinated fibers, whereas Cx32 without Cx47 was co-localized with contactin-associated protein (caspr) in paranodes. By freeze-fracture replica immunogold labeling, large gap junctions between oligodendrocyte somata and astrocyte processes contained much more Cx47 than Cx32. Along surfaces of internodal myelin, Cx47 was several times as abundant as Cx32 and often occurred without Cx32. In contrast, Cx32 was localized without Cx47 in autologous gap junctions in Schmidt-Lanterman incisures and between paranodal loops bordering nodes of Ranvier. Thus, Cx47 is the most abundant connexin in heterologous oligodendrocyte-to-astrocyte gap junctions, whereas Cx32 is the predominant if not sole connexin in autologous ("reflexive") oligodendrocyte gap junctions. Autologous gap junctions between myelin layers and heterologous gap junctions linking oligodendrocytes to the astrocyte syncytium are proposed to act in electrical series to facilitate long-distance intercellular "dynamic $K^+$ siphoning". $K^+$ at high concentration in the depolarized (+40 mV) innermost layer of myelin is proposed to flow down its electrochemical gradient, through paranodal and Schmidt-Lanterman gap junctions, to the outermost layer of myelin (−70mv), thence through oligodendrocyte/astrocyte gap junctions to the astrocyte endfeet (−85 mV) that form the glia limitans (total 125mV potential difference). Elimination of all oligodendrocyte gap junction pathways for $K^+$ siphoning in Cx32+Cx47 double-knockout mice would account for $K^+$ accumulation and extensive swelling of myelin in these animals. **Transient Opening of Connexin 32 Hemichannels in Liver Releases ATP and Functions as an Early Signal for the Onset of Regeneration after Partial Hepatectomy in Rats**

S. Crumm, J. B. Hoek; Pathology, Anatomy and Cell Biology, Thomas Jefferson University, Philladelphia, PA

Liver regeneration after partial hepatectomy (PHx) is orchestrated by a variety of signals from cytokines and growth factors. However, the onset of regeneration remains poorly understood. Here, we report a marked (30%) and rapid (30sec) decrease in ATP, total adenine nucleotides (TAN) and $NAD^+$ levels in the remnant liver following PHx, resulting in a change in ATP/AMP ratio. These changes were followed by activation of AMP-activated protein kinase (AMPK) with phosphorylation of both α1 and α2 isoforms of AMPK. Changes in TAN were not due to increased energy demand and pretreatment with L-NAME (NOS inhibitor) or phentolamine (α1-adrenergic receptor antagonist), which have been previously reported to inhibit liver regeneration, prevented the loss of TAN and $NAD^+$ and inhibited AMPK activation, suggesting a role for an early stress response in the liver. The loss of TAN and $NAD^+$ was also prevented by treatment with 18-α-glycerrhetinic acid, an inhibitor of gap junctions, or with peptide inhibitors against connexin 32 (32-GAP26 and 32-GAP27), which block connexin 32 hemichannels by binding the extracellular connexin 32 interaction domain. The connexin 32 inhibitors also prevented phosphorylation of AMPK α subunits in the remnant liver. By contrast, peptide inhibitors against connexin 43 were only partially effective. These findings indicate that PHX causes a stress response in the remnant liver that induces a transient opening of connexin 32 hemichannels in hepatocytes resulting in a rapid release of ATP and $NAD^+$ and activation of AMPK. We suggest that these effects constitute an early signal for the onset of liver regeneration after PHx.

**Shear Stress Alters Connexin Expression and Gap Junction Communication in Endothelial Cells**

T. L. Johnson, R. M. Nerem; Institute for Bioengineering and Bioscience, Georgia Institute of Technology, Atlanta, GA

Vascular gap junctions maintain vessel function by allowing the passage of vasoactive molecules and second messengers within the endothelium and underlying smooth muscle cells. Altered expression of endothelial gap junction proteins (Connexins 37, 40 and 43) has been linked to atherosclerosis and hypertension; however their response to mechanical forces remains unclear. The goal of this study is to examine the influence of shear stress on endothelial connexin gene expression, protein expression and localization, and gap junction communication. Human aortic endothelial cells were cultured in monolayer on collagen I-coated glass slides and exposed to static or laminar shear stress (15 dynes/cm2) using a parallel plate flow chamber. Real time RT-PCR was used to quantify gene expression and flow cytometry was used to quantify protein expression. Immunohistochemistry was used to localize protein expression and transfer of biocytin after scrape loading was used to measure gap junction communication within the endothelial monolayer. Results show a differential effect of shear stress on connexin gene expression with a decrease in Cx37, increase in Cx40 and no change in Cx43. There is no significant difference in Cx37, Cx40 or Cx43 protein expression in shear and static samples however image analysis identifies connexin proteins at the cell membrane and in the cytoplasm. Dye transfer results show a significant reduction in gap junction communication following shear exposure with a dye coupling index of one recipient cell per donor cell in shear samples and five recipients per donor in static samples. We conclude that shear stress influences endothelial cell connexin expression and gap junction communication which has implications in vascular health and disease.

**Role of ILK and Akt in the Transcriptional Regulation of Connexin32 in Rat Hepatocytes**

I. Plante, M. Charbonneau, D. G. Cyr; INRS-Institut Armand-Frappier, Université du Québec, Pointe-Claire, PQ, Canada

Gap junctions mediate intercellular communication through channels composed of proteins, termed connexins (Cxs). We have shown that Cx32, the principal hepatic Cx, is down-regulated in the liver of female rats exposed to hexachlorobenzene (HCB), an epigenetic environmental carcinogen. This is concomitant to an activation of the Integrin-linked kinase (ILK) pathway, leading to the activation and nuclear translocation of Akt and the inactivation of GSK3β. Using an *in vitro* model, the aim of this study was to demonstrate the role of the ILK in Cx32 down-regulation pathway by assessing down-stream phosphorylation targets of ILK. In order to mimic the activation of ILK pathway, a rat hepatocyte cell line, $MH_1C_1$, was transiently transfected with an expression vector for ILK (ILK+ cells). These ILK-overexpressing cells showed a significantly lower Cx32 mRNA levels. In ILK+ cells, Akt was also activated and translocated into the nucleus. Using an constitutively-active Akt expression vector, we then observed that Akt+ cells showed a decrease in Cx32 mRNA levels. $MH_1C_1$ exposed to two specific inhibitors of GSK3β demonstrated that Cx32 is not regulated by GSK3β. Overall, these experiments demonstrate that Cx32 is down-regulated by the ILK pathway activation in rat hepatocytes. Moreover, data suggest an important mechanistic function of the nuclear translocation of Akt in the down-regulation Cx32. In the HCB-treated rat model, modulation of transcription factor of promoter regions of Cx32 were observed concomitantly with the nuclear translocation of Akt. was present into the nucleus. Thus, future experiments will looked at transcription factors in Akt overexpressing cells.

1879

**Rat Mast Cells Communicate with Fibroblasts via Gap Junction Communications Both in Vivo and in Vitro**

S. R. Au,[1] K. Au,[2] G. C. Saggers,[2] H. P. Ehrlich[2]; [1]University of California Davis, Davis, CA, [2]Department of Plastic Surgery, Hershey Medical Center, Hershey, PA

Mast Cells (MC) are suggested to promote fibrotic conditions such as hypertrophic scarring and keloid formation. Do gap junction intercellular communications (GJIC) between MCs and fibroblasts play a role in advancing fibrosis? GJIC between fibroblasts and MCs was demonstrated by the passage of fluorescent dye from preloaded rat MCs into fibroblasts both in vivo and in vitro. MCs were harvested from the peritoneal cavity of adult male rats and isolated with a density gradient. The MCs were treated with two dyes, the plasma membranes were stained red with DiI and the cytoplasms labeled green with Calcein-AM. These pretreated MCs were injected into 1. subcutaneous implanted polyvinyl alcohol (PVA) sponges in rats, 2. human fibroblasts in monolayer culture, and 3. added into co-cultured rat MC-fibroblast populated collagen lattices (FPCL) a model of wound contraction. Two weeks after implantation of the PVA sponges, pretreated rat MCs were injected into PVA sponge implants. Sponges were harvested 4 hrs later, frozen and cryosectioned. Fluorescent microscopy revealed red (DiI) and green (Calcein-AM) fluorescent stained MCs associated with fluorescent green fibroblasts, which were devoid of fluorescent red staining. *In vitro* the dye preloaded MCs passed Calcein-AM into human fibroblasts in monolayer culture. Green fluorescent fibroblasts were found in co-cultured rat MC-FPCLs. Co-cultured rat MC-FPCLs

showed a 35% enhancement of lattice contraction compared to FPCLs without added MC. It is clear that freshly isolated rat MCs form GJIC with fibroblasts in granulation tissue and tissue culture. FPCL contraction is an *in vitro* model of scar contracture, a common feature of hypertrophic scar. The inclusion of MCs in the casting of FPCLs enhanced FPCL contraction. These findings support the notion that MCs interactions with fibroblasts through GJIC escalate the severity of fibrosis.

1880

**Aldosterone Protection of MDCK Cells from Inhibition of Cell-to-Cell Communication by Ouabain**

R. M. Genga, M. L. S. Ledbetter; Biology, College of the Holy Cross, Worcester, MA

Cultured animal cells can exchange small molecules through gap junctions in their adjoining membranes. If the $Na^+$, $K^+$-ATPase of the cells is inhibited by the cardiac glycoside ouabain, cells lose $K^+$ and gain $Na^+$ at a rate determined by the corresponding channels and the chemiosmotic potential. This in turn leads to diminished junction-mediated cell communication, as assessed by transfer of Lucifer Yellow (457D) but not Texas Red-conjugated dextran (10kD ) from donor cells to neighboring recipients, estimated by quantitative image analysis. For many types of cells communication reaches a minimum after several hours, but is readily reversible. We are eager to understand the mechanism of this process. Using cultured Madin-Darby canine kidney (MDCK; ATCC CCL34) cells, we conducted careful measurements that confirmed the inhibition of communication by ouabain. Immunofluorescence of connexin43, the primary connexin in MDCK cells, also decreased at the cell surface, accumulating temporarily in a cytoplasmic compartment before disappearing altogether. Addition of amiloride, a blocker of the $Na^+$ channel, protected the cells from inhibition, implying that the pathway requires $Na^+$ elevation as a consequence of ouabain treatment. Addition of the mineralocorticoid hormone aldosterone also protects the cells from inhibition. The mechanism of this protection is not clear, but it seems to require the involvement of the aldosterone receptor (AR), since spironolactone and eplerenone, both AR antagonists, prevent rescue of communication by aldosterone. Whether the protection by activation of the AR involves direct stimulation of gap junction metabolism, or more likely, involves modulation of the ion homeostasis of the cells is not yet clear. We wish to thank the National Science Foundation (DUE-0308559) for support of this work, the Fortin Foundation for a Summer Research Fellowship to RMG, and Pfizer Pharmaceuticals for a sample of eplerenone.

**Cell-Cell Cooperation Between Epithelial Cells: The Role of Hormone Ouabain**

I. Larre, A. Ponce, L. Shoshani, R. G. Contreras, A. Lázaro, M. Cereijido; Department of Physiology, Biophysics and Neurosciences, CINVESTAV, México, Mexico

We have previously found that ouabain-resistant MDCK cells (R-MDCK) can rescue sensitive ones in co-cultures, in the apparent absence of communicating junctions (Cereijido et al., 1985; Bolivar et al., 1987). On the basis that at that time ouabain was considered to be a toxin of vegetal origin, the problem was taken as a sort of pharmacological artifact and its elucidation was not pursued. Yet, since now ouabain is regarded as a hormone, whose function awaits to be elucidated, in the present work we reinvestigate the R/W cooperation. While studies with Lucifer Yellow fully confirm our previous data, Neurobiotin, a probe of smaller size and opposite electric charge (+ instead of -) that was not available in 1985-1987, shows that cells maintain sufficient communication to explain rescuing. Interestingly, the degree of communication is significantly enhanced ($p < 0.001$) by ouabain. However, an exchange of ions between R and W cells may not account for the observations reported below. Thus, in previous work we have found that ouabain triggers a P→A mechanism (from ***p***ump/***a***ttachment) that starts with a cascade of phosphorylations, retrieves junction-associated molecules from the plasma membrane, and ends up detaching the cell (Contreras et al., 1999, 2004). We now assay the P→A through occludin, β-catenin and β-subunit of $Na^+$,$K^+$-ATPase, and find (i) that upon treatment with ouabain, W cells retrieve these molecules from the plasma membrane; (ii) R cells do not express such phenomenon; and (iii) when W cells are in contact with R ones, they cannot express the P→A mechanism.

1882

**Expression of Connexin (Cx) 37 in Sheep Corpora Lutea during the Estrous Cycle and Prostaglandin $F_2\alpha$ (PGF)-Induced Luteal Regression**

E. Borowczyk, M. Johnson, L. P. Reynolds, D. A. Redmer, J. J. Bilski, A. T. Grazul-Bilska; Animal and Range Sci., North Dakota State Univeristy, Fargo, ND

Corpora lutea (CL) exhibit periodic growth, differentiation and regression during each estrous cycle. Gap junctions seem to play an important role in the regulation of luteal function. Ovine Cx37 was cloned and characterized (Accession # AY45977) to design species-specific probes and primers. CL collected on days 5, 10 and 15 of the estrous cycle and at 0, 4, 8, 12 and 24 h after induction of luteal regression were snap-frozen for isolation of total cellular RNA (tcRNA), and also were fixed for Cx37 immunostaining and image analysis. Luteal regression was induced by one injection of Estrumate (analog of PGF, 250 mg/injection) on day 10 of the estrous cycle. Cx37 mRNA expression was quantified and normalized to expression of the 18s ribosomal housekeeping gene by real time RT-PCR (ABI Prism 7000; Applied Biosystems, Foster City, CA). Staining of Cx37 was punctate and localized on the luteal cell borders. Cx37 mRNA and protein expression were the highest ($p<0.05$) on day 5, lower on day 10 and least on day 15 of the estrous cycle. PGF-treatment decreased ($p<0.001$) Cx37 protein but not mRNA expression at 4, 8, 12 and 24 h by 25-67% compared with 0 h (100%). However, the pattern of decrease of Cx37 mRNA and protein expression after PGF-treatment was similar. This study demonstrates that expression of Cx37 depends on the stage of luteal development, differentiation and regression and suggests a role of Cx37 in luteal function. Knowledge of the pattern of connexin expression, coupled with studies of the functional consequences of connexin expression, may lead to improved methods of estrous cycle regulation and ways to influence fertility in humans and domestic livestock. *Supported by USDA NRICGP 2002-35203-11643 grant to ATGB.*

**Anti-Proliferation Activity of the Transfected Cx26 in Breast Cancer Cells**

H. J. Lee, S. K. Rhee; Biochemistry, Yeungnam University, Kyongsan, Republic of Korea

Connexin (Cx) genes are reported to be tumor suppressors in various cancer cells. Recent studies have shown that the tumor-suppressing activity acquired by Cx gene transfection is not mainly due to the recovery of the gap junction-mediated intercellular communication (GJIC). In order to

elucidate the mechanism of the Cx-induced tumor-suppressing activity, we transfected Cx26 cDNA into a rodent breast tumor cell-line (BICR-M1Rk) in which Cx43 is normally expressed and a typical pattern of GJIC had been observed. Under observation with an immuno-fluorescent microscope, the exogenous Cx26 was mainly localized in the nuclear region, whereas most of the endogenous Cx43 resided at the plasma membrane of the BICR-M1Rk cells. Consistent with the localization of the exogenous Cx26, GJIC was not increased upon transfection of Cx26 when assessed by a scrape-loading dye transfer technique. A conventional [3H]-thymidine incorporation study showed that the growth rate of the Cx26-transfected cells was significantly decreased (35%), compared to that of the control BICR-M1Rk. Taken together, our results demonstrate that the transfected Cx26 in the BICR-M1Rk cancer cell-line exerts an anti-proliferate activity in a GJIC-independent manner.

1884

### Connexin-integrated Liposomes: A Novel Tool for Drug Delivery into Mammalian Cells

M. Kaneda,[1,2] S. M. Nomura,[2,3] K. Nakahama,[1] K. Akiyoshi,[2,3] I. Morita[1,2]; [1]Department of Cellular Physiological Chemistry, Tokyo Medical and Dental University, Tokyo, Japan, [2]21st Century COE, Tokyo Medical and Dental University, Tokyo, Japan, [3]Department of Organic Materials, Institute of Biomaterials and Bioengineering, Tokyo, Japan

Intercellular communication through gap junction (GJ) plays important roles in development, proliferation, and homeostasis. GJ allows small molecules (up to 1.5kD) to pass directly from cell to cell. Here, we developed a new drug delivery system using giant liposomes with hemichannel composed of connexin43 (Cx43), a component protein of GJ. Cx43 was expressed in giant liposomes by cell-free protein synthesis. Western blot analysis showed that synthesized Cx43 was integrated into liposomal membrane, whereas enhanced green fluorescent protein, water-soluble protein, was detected in supernatants. The function of liposomes expressing Cx43 (Cx43-liposome) was examined by bidirectional dye-transfer assay. First, Cx43-transfected U2OS cells, human osteosarcoma cell line, were preincubated with calcein-AM, after that, Cx43-liposomes were plated onto the cells. 2h after, calcein was transferred from the cells to Cx43-liposomes. Second, to elucidate dye-transfer from Cx43-liposomes to cells, calcein was entrapped in Cx43-liposomes and the liposomes were applied to the Cx43-transfected cells. Calcein in the Cx43-liposomes was transferred to the cells, whereas liposomes lacking Cx43 didn't transfer. Furthermore, we examined whether a bioactive substance entrapped in Cx43-liposome can affect cellular function in Cx43-expressing cells. Treatment of oligo-peptide (TALDWSWLQTE, MW 1.3kD, IKK inhibitor) entrapped in Cx43-liposomes suppressed IL-1β-induced NF-κB activation and cyclooxygenase-2 expression, and in this system the addition of an inhibitor of GJ intercellular communication abolished this suppressive effect. The results indicate the peptide acts on the cells through GJ between cells and liposomes. In conclusion, liposome with GJ hemichannel provides a novel drug delivery carrier for transfer of water-soluble drugs to cells directly, and this is a beneficial tool for regulation of cell functions.

## Structure & Function of Membrane Proteins I (1885-1905)

### A Role for Serine-373 in Regulation of the Sodium-Dependent Choline Transporter

S. A. G. Black,[1,2] R. J. Rylett[1,2]; [1]Cell Biology, Robarts Research Institute, London, ON, Canada, [2]Physiology and Pharmacology, University of Western Ontario, London, ON, Canada

Choline uptake into cholinergic neurons by the sodium-dependent choline transporter (CHT) is an important rate-limiting and regulatory step in acetylcholine synthesis. CHT cycles rapidly between the cell surface and intracellular vesicles, suggesting that trafficking of CHT is an important mechanism determining the number of transporters at the surface for uptake of choline. CHT is phosphorylated, and treatments to alter phosphorylation events change the number of functional CHT proteins at the surface, although the mechanism(s) involved remain undefined. We are examining the role of phosphorylation by protein kinase-C (PK-C) in regulation of CHT activity and subcellular localization. Using transiently-transfected HEK293 cells, we evaluated protein phosphorylation, choline uptake, and cell-surface expression of a FLAG-tagged rat CHT protein (WT-FLAG-CHT) and also that of PK-C phospho-site mutant proteins S373A-, S367A-, and T558A-FLAG-CHT. Phosphorylation, measured by [$^{32}$P]-phosphate incorporation, was enhanced for S373A-FLAG-CHT compared to WT; phosphorylation of S367A- and T558A-FLAG-CHT was not different from WT. Choline uptake of S373A-FLAG-CHT was reduced to ~50% of WT-FLAG-CHT uptake, whereas uptake of the other mutants did not differ from WT. Treatment with phorbol ester to activate PK-C reduced choline uptake of WT-, S367A-, and T558A-FLAG-CHT, but did not alter S373A-FLAG-CHT uptake. To evaluate cell-surface levels of CHT proteins, cell-surface biotinylation was used, revealing a dramatic decrease in the amount of S373A-FLAG-CHT present at the plasma membrane compared to WT. These findings indicate that mutation of serine-373 to alanine to prevent phosphorylation at this residue enhances CHT phosphorylation overall while decreasing its solute transport activity and cell-surface localization, highlighting a role for serine-373 in maintenance of normal CHT function and relative subcellular distribution, as well as its response to phorbol ester. ### Characterization and Regulation of the Membrane Sector of the Vacuolar ATPase

A. R. Flannery,[1] L. A. Graham,[1] T. H. Stevens[2]; [1]Institute of Molecular Biology, University of Oregon, Eugene, OR, [2]Department of Chemistry, University of Oregon, Eugene, OR

The vacuolar ATPase (V-ATPase) is responsible for the acidification of intracellular organelles in eukaryotes. In the yeast *Saccharomyces cerevisiae*, the V-ATPase's primary function is to acidify the vacuole. It is composed of 14 subunits that are divided into two distinct domains, $V_1$ and $V_0$. The peripheral $V_1$ domain hydrolyzes ATP and couples this activity to proton transport. The $V_0$ domain contains the proton pore and is composed of six unique subunits (a, d, e, c, c', and c"). The c, c', and c" subunits are integral membrane proteins thought to form a ring ($c_{4\text{-}5}$, c', c") that rotates as ATP is hydrolyzed by $V_1$ to translocate protons across the lipid bilayer into the lumen of the vacuole. The stoichiometry of the c subunit ring has not been defined. Previous studies have shown that there is one copy each of c' and c" subunit per complex, and multiple copies of the c subunit. The number of c subunits per complex still remains to be determined. In yeast, it is thought that there are 4 to 5 copies of the c subunit per complex. To address this question, we have constructed genetic fusions of the c, c', and c" subunits. We have found that genetic fusions of c" and c subunits, c' and c subunits, as well as c" and c' subunits, are expressed as intact dimer proteins and each results in a fully assembled and functional V-ATPase complex. Our studies also reveal that genetic fusions of two c subunits also result in intact dimer proteins and a functional

complex. From these data we conclude that the V-ATPase can function with an even number of c subunits, supporting the model that there are 4 c subunits per complex.

1887

**The Cytosolic Domain of Bcl-2 Protein Forms Pores of Various Sizes in a Model Mitochondrial Outer Membrane After Acidic Ph-induced Conformation Change, Homo-association and Membrane Insertion**

J. Peng,[1] C. Tan,[1] G. Roberts,[2] S. Lapolla,[1] D. Andrews,[2] J. Lin[1]; [1]Biochemistry & Molecular Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK, [2]Biochemistry, McMaster University, Hamilton, ON, Canada

Bcl-2 family proteins regulate apoptosis by regulating the permeability of mitochondrial outer membrane. The pro-apoptotic Bcl-2 family member Bax can release Cyt c from purified mitochondria, and form large pores in the liposomal membrane that can release 2 MDa dextran molecules. Though previous studies demonstrated that the anti-apoptotic Bcl-2 family members Bcl-2 can form pores in liposomal membranes, the size of the pores and the mechanism of the pore formation remain elusive. By using spectroscopic approach, we found that the radius of Bcl-2 pores in liposomal membrane is less than 22 Å, much smaller than that of Bax pore. We also found that Bcl-2 forms pores possibly through homo-association. We demonstrated that homo-association of Bcl-2 in solution facilitates Bcl-2-membrane interaction and pore formation by showing that a preformed Bcl-2 oligomer has a faster pore-forming kinetics than a Bcl-2 monomer, that a mutant Bcl-2 having a higher affinity for homo-association than the wild type Bcl-2 also has a faster pore-forming kinetics, and that a Bax BH3 peptide which inhibits Bcl-2 homo-association also inhibits Bcl-2-membrane interaction and pore formation. In contrast to a previous report, we found that the low pH that is required for Bcl-2 to form pores in the liposome system did not promote Bcl-2 homo-association. Instead the low pH induced a conformation change in Bcl-2 that exposes the hydrophobic core of Bcl-2 to solvent, promoting Bcl-2-membrane interaction. Interestingly the Bcl-2 mutant with fast pore-forming kinetics in vitro shows a better activity in Rat-1 cells against etoposide-induced apoptosis. Based on these data, we proposed a model mechanism for Bcl-2 pore-formation that may be used by Bcl-2 to regulate the permeability of membrane during apoptosis.

1888

**High-Level Heterologous Expression and Purification of Functional Human Vitamin K 2,3-Epoxide Reductase (hVKORC1): The N-terminus is Inaccessible to in situ Labeling in Membranes**

C. Reinhart,[1] W. Haase,[2] S. Rost,[3] A. Fregin,[3] M. Huenerberg,[3] C. R. Mueller,[3] C. G. Bevans,[2] J. Oldenburg[3,4,5]; [1]Molecular Membrane Biology Department, Max Planck Institute of Biophysics, Frankfurt/Main, Germany, [2]Structural Biology Department, Max Planck Institute of Biophysics, Frankfurt/Main, Germany, [3]Institute of Human Genetics, Biocenter - University of Wuerzburg, Wuerzburg, Germany, [4]Institute of Transfusion Medicine and Immunohematology, DRK Blood Donor Service Baden-Wuerttemberg-Hessen, Frankfurt/Main, Germany, [5]Institute of Experimental Hematology and Transfusion Medicine, University Clinic Bonn, Bonn, Germany

The trace nutrient vitamin K is rapidly converted to its 2,3-epoxide (VK>O) in animal cells during the initial enzymatic step leading to post-translational ?-carboxylation of various intracellular proteins. Recycling of VK>O to vitamin K is achieved by a putative vitamin K epoxide reductase (VKOR) enzyme complex (*Arch. Biochem. Biophys.* 141:473). The recently identified human *VKORC1* gene (*Nature* 427:53*7, Nature* 427:541) encodes hVKORC1 (18.2 KDa, 163 amino acids), an ER intrinsic membrane protein. In order to obtain sufficient quantities of functional hVKORC1 for structural studies, we produced up to 3.47 mg/L affinity-tagged hVKORC1 in *Pichia pastoris*. VKOR activity of membranes from cells with multi-copy constructs pPIC9K(αF-flag-his$_{10}$-VKORC1-biotag) was measured using a standard assay (*J Clin Invest* 76(5):1879) and was several hundred-fold greater than that of cells with an empty vector. In order to enhance target purity in membranes prior to solubilization, we determined the subcellular localization of hVKORC1. Attempts to visualize hVKORC1 subcellular localization by electron microscopic examination of immunostained thin section and freeze-fracture specimens of construct-expressing cells revealed no significant immunostaining, suggesting no construct expression or construct proteolysis. However, Western blots of SDS-solubilized membranes from the same cells indicated high levels of construct. To further investigate these paradoxical results, we performed preparative sedimentation of cell extracts, under isotonic conditions, to obtain ER/plasma membranes and membrane-bound organelles. Surprisingly, only 20% of hVKORC1 construct was found by Western blot in the ER/plasma membrane fraction, while most of the remaining construct was found in the mitochondrium/peroxisome/vacuole fraction. Taken together, these results suggest that the aqueous-soluble N-terminal domain of hVKORC1 is folded *in vivo* into an adjacent protein domain or might participate in binding interaction with other proteins. 1889

**Topological Analysis of the Human ABC Transporter ABCG2**

N. K. Diop; Chemistry, Purdue University, West Lafayette, IN

The human ATP Binding Cassette (ABC) transporter ABCG2 is a 655 amino acid glycoprotein that can confer multidrug resistance to cancer cells by functioning as an energy dependent efflux pump. We have previously shown that ABCG2 is N-linked glycosylated at asparagine (Asn) 596 and that the lack of glycosylation does not affect function or cell surface localization. These data provided the first direct evidence for the localization of the loop containing Asn 596 to the extracellular space, previously only predicted from hydropathy analysis. In our present work, we used an epitope insertion approach to further test the topology model of ABCG2. Using the glycosylation deficient mutant ABCG2 (N596Q) as a template, we introduced fourteen N-linked glycosylation consensus sites into the predicted intracellular and extracellular loops of ABCG2. Flow cytometric analyses show that the majority of our mutants are expressed at the cell surface and are capable of transporting rhodamine 123. Among the engineered glycosylation mutants, three (G577N, F586S, and A606T) are glycosylated and treatment with peptide N-glycosidase F reduces the apparent molecular mass by SDS-PAGE. These data indicate that these residues are localized in the extracellular space. In addition, we introduced FLAG epitope tags at either the amino or carboxyl terminus of ABCG2 and found that these sequences were localized to the cytoplasm. Together, these data support a topological model of ABCG2 containing six transmembrane segments, three extracellular loops, and both the amino and carboxyl termini localized in the cytoplasm.

**Multi-site Occupancy of the Cytochrome P450 Catalytic Cavity by Substrates and Inhibitors**

A. Banerjee, H. Liu; Department of Pharmaceutical Sciences, Wayne State University, Detroit, MI

The cytochrome P450 monooxygenases form a large and omnipresent superfamily of enzymes. While each individual P450 exhibits unique and specific substrate and catalytic activity profiles, overall, P450s perform a wide range of oxidation reactions on a diverse spectrum of substrates. The mammalian microsomal P450s degrade most xenobiotics encountered by man and animals. P450s are important targets for drug design. In our laboratory, structure-based ligand design has been used to find putative inhibitors of selected CYPs. Virtual screening of large libraries can be performed speedily *in silico*, and the best results can then be tested for biological activity in experimental assay systems. In the current work, the paradigm of structure-based ligand design was followed in which the aim was to design chemical inhibitors. We have screened ~450,000 molecules of ACD 3D database (MDL, Inc.) using LUDI software (Accelrys, Inc.). The radius and center of search depended on the CYP target pockets. We fixed a radius of 12Å from the heme iron for different targets. By our studies we have found the existence of a second compound binding site at the proximal side of heme; this we refer to as the "2nd site" where as the catalytic site is the "1st site". We have also performed enzyme inhibition assays with the compounds. We have used Gentest CYP-2E1, -2C9 and -3A4 high throughput inhibition assay kits to measure the potential inhibition or induction of the CYP2E1, -2C9 and -3A4 catalytic activity. The results will be presented. For CYP2C9 we find that selected compounds can actually increase its catalytic activity. Crystallographic determination of their binding properties and changes they induce in these CYPs will be very illuminating for the study of CYP structure and function relationships. (Supported by NIH grant GM-59467.)

1891

**Identification of the Domains of Heavy Chain Subunits of Heterodimeric Amino Acid Transporters in the Recognition of their Light Chains**

N. Ahmed, P. Kongsuphol, Y. Kanai; Dept. of Pharmacology and Toxicology, Kyorin University, Mitaka, Japan

The heterodimeric amino acid transporters are comprised of a 12-membrane-spanning light chain subunit of SLC7 family and a single-membrane-spanning type II membrane glycoprotein of SLC3 family as a heavy chain subunit. The heterodimerization of two subunits are proposed to be required for the functional expression of the transporters in the plasma membrane. 4F2hc (4F2 heavy chain) subserves various amino acid transport systems by dimerization with six different light chains, whereas one light chain is associated with other heavy chain subunit rBAT (related to $b^{0,+}$ amino acid transporter). In order to determine the mechanisms of recognition of the light chain subunits by the heavy chains, we have generated chimeras of human 4F2hc and human rBAT and examined whether they are associated with LAT1 a partner of 4F2hc or $b^{0,+}$AT/BAT1 a partner of rBAT. The chimeras were functionally expressed in *Xenopus oocytes* or COS-7 cells and analyzed by measuring the ability to induce amino acid transport activity. The results indicated that the transmembrane and cytoplasmic juxta-transmembrane region of 4F2hc and rBAT are essential for the recognition of LAT1 and $b^{0,+}$AT/BAT1, respectively. The importance of this region was further confirmed by the series of complementary chimeras (rBAT/4F2hc chimeras). It is, thus, suggested that the recognition of light chains by heavy chains is accomplished by the interaction of amino acid residues of heavy chains in transmembrane and intracellular small region close to the transmembrane domains with those of the transmembrane and intracellular domains of light chains.

1892

**Novel Glucose Transport Activation Process Regulated by Glucose in C2C12 Myotubes**

T. Nedachi, M. Kanzaki; Tohoku University Biomedical Engineering Research Organization, Miyagi, Japan

It is well established that insulin stimulates glucose uptake in skeletal muscle by causing translocation of the insulin responsive glucose transporter GLUT4 from intracellular storage sites to the plasma membrane. However, the established skeletal muscle cell lines, such as L6 and C2C12, usually show very low insulin-dependent glucose uptake/GLUT4 translocation compared to skeletal muscle *in vivo*. In this study we attempted to characterize glucose transport system in C2C12 myotubes. **[Methods]** Glucose transport activity was measured by 2-deoxyglucose (2DG) uptake, and GLUT4 translocation was assessed by the exofacial-myc-GLUT4-ECFP translocation evaluated by anti-Myc Ab uptake assay. **[Results]** Even in the basal condition, C2C12 myotubes displayed considerably high 2DG uptake without any detectable GLUT4 protein at the plasma membrane. After insulin stimulation, about 3-fold increase in GLUT4 translocation was induced, whereas only a little (~1.2-fold) of insulin-stimulated 2DG uptake was observed, indicating that there is obvious discrepancy between GLUT4 translocation and glucose uptake. Interestingly, the basal 2DG uptake, which is not mediated through GLUT4, was rapidly decreased by the 5-min-pretreatment of the myotubes with 22.5 mM glucose (pre-HG), while it was increased by glucose deprivation. The attenuation of 2DG transport activity by the pre-HG was not due to a competitive inhibition by glucose, but required enzymatic activites, since the inhibitory effect of pre-HG was not observed at 4C. Importantly, a PI 3-kinase inhibitor wortmannin also suppressed the basal 2DG uptake to a similar extent to the pre-HG. **[Conclusion]** Based upon these data, we here propose that in C2C12 myotubes there is unidentified regulatory mechanism for glucose transport activity, which is dependent on glucose metabolism and is also sensitive to wortmannin. This glucose transport activation process modulated by glucose perhaps obscures the insulin-induced glucose uptake via GLUT4 translocation in cultured myotubes.

1893

**Structural Changes of Band 3 in Miltenberger Blood Group-expressed Erythrocytes**

K. Hsu, Y. Chen, Z. Chen, M. Lin; Transfusion Medicine Laboratory, Mackay Memorial Hospital, Tamsui, Taiwan Republic of China

Various Taiwanese aboriginal tribes exhibit significantly higher frequencies of the rare Miltenberger (MNS) blood group expressions. The MNS molecular entities, originated from specific gene recombination of glycophorin A and glycophorin B, are distinct glycophorin hybrids that could elicit hemolytic reactions during incompatible blood transfusion. As there are a plethora of Miltenberger phenotypes (11 variations serologically identified up to date), we attempt to purify these unique glycophorin complexes and dissect their compositions using proteomic approaches. Glycophorin-band 3 macrocomplexes were antibody-purified from red blood cell ghost. Their individual components were identified by 1D SDS-PAGE and Western blots. Further separation of the glycophorin macrocomplexes using 2D gel electrophoresis shows no apparent difference between Miltenberger type III (Mi.III) and normal samples when visualized by conventional silver stain. Nonetheless, Miltenberger band 3, once 2D gel electrophoresed, is no longer recognizable on Western blot, whereas normal band 3 still is. As this phenomenon is not apparent in SDS-

solubilized protein extracts, we hypothesize that the 3D structure of Mi.III band 3 probably differs from that of normal band 3 due to its physical interaction with the glycophorin hybrid of Mi.III. We are currently actively pursuing the structural and functional consequences resulted from these glycophorin hybrids characteristic of Miltenberger.

1894

**Characterization of a Thyroid Sodium/Iodide Symporter (NIS) Mutant (V59E) That Causes Congenital Iodide Transport Defect (ITD)**

M. D. Reed, C. S. Ginter, N. Carrasco; Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, NY

Iodide (I-) is an essential component of the thyroid hormones T3 and T4, which are required for proper development of the central nervous system and for intermediary metabolism in virtually all tissues. Most of the ingested I- is actively transported into thyroid epithelial cells via NIS, a specialized intrinsic plasma membrane glycoprotein that couples the "downhill" inward translocation of sodium to the "uphill" inward translocation of I-. The cDNA that encodes NIS was first identified in our laboratory, where an extensive structure/function characterization of NIS is being carried out. Several NIS mutants have been identified as causes of congenital ITD, including a mutant that contains glutamic acid instead of valine at position 59 (V59E). ITD is characterized by low thyroid I- uptake, hypothyroidism, goiter, and a low saliva/plasma I- ratio. The patient's V59E substitution yields a non-functional NIS protein; the aim of this project was to characterize its effects and structural/functional implications. I have transfected COS-7 cells with various NIS constructs coding for different amino acids (A, D, E, I, K, L, M, N, Q, R, T) at position 59, and have characterized the effects of each substitution on protein expression, processing, targeting to the plasma membrane, and I- transport activity. Transfection of all mutant NIS constructs resulted in proper expression, processing, and targeting of NIS. Kinetic analysis of A, I, L, M, N, Q, and T showed a decrease in iodide uptake due to a Vmax effect, not a change in the affinity of NIS for Na or I-. Constructs encoding a charged amino acid or proline at position 59 showed no I- transport activity. In conclusion, the structural requirement for NIS at this position is a neutral, helix-promoting, branched amino acid.

1895

**Molecular Dissection of the Syntaxin4/Munc18c Interaction: Implications for the Regulation of Membrane Trafficking**

J. A. Lopez,[1] C. F. Latham,[2] D. H. Blair,[1] C. L. Gee,[2] S. Hu,[2] E. Westbury,[2] N. J. Bryant,[1] J. L. Martin,[2] D. E. James[1]; [1]Diabetes and Obesity, Garvan Institute of Medical Research, Sydney, Australia, [2]Institute for Molecular Bioscience, University of Queensland, Brisbane, Australia

SNARE proteins play a fundamental role in docking and fusion of membranes at every compartment throughout the cell. Regulation of SNARE complex assembly is a critical control point in intracellular membrane trafficking. A key player in this regulation is the Sec1p/Munc18 (SM) family of proteins. There is considerable debate, however, concerning the precise role of different SM isoforms in the SNARE assembly process. One model based on secretory neuronal SNAREs, suggests that the SM protein stabilises the entire cytoplasmic domain of syntaxin in a closed form, preventing SNARE assembly and fusion. An apparently contradictory model, based on intracellular SNAREs, suggests that the SM protein can bind both monomeric syntaxin and SNARE ternary complexes. The aim of this study was to define the interaction of the plasma membrane t-SNARE, Syntaxin4, and its cognate SM protein, Munc18c. Consistent with the latter model we found deletion of Syntaxin4's first 29 amino acids resulted in almost complete loss of Munc18c binding. In addition, mutation of the highly conserved leucine 8 in Syntaxin4 resulted in a 70% reduction in Munc18c binding. We also found that Munc18c interacts with preformed SNARE complexes *in vitro*. Interestingly, however, Munc18c/Syntaxin4 dimeric complex formation prevented subsequent binding of Syntaxin4 with its SNARE partners SNAP23 and VAMP2. Taken together these results suggest that the Munc18c/Syntaxin4 interaction occurs via sequential binding initiated through Syntaxin4's $NH_2$-terminus. This may chaperone Syntaxin4 through the *cis* to *trans* SNARE complex transition. Supporting a chaperone-type role, we found RNAi knockdown of Munc18c resulted in a coincident reduction in Syntaxin4 levels. These data are consistent with a model whereby Munc18c regulates the assembly of the functional SNARE complex through both negative regulation of Syntaxin4 prior to fusion and by ensuring the fidelity of SNARE assembly/disassembly.

1896

**The Putative Membrane Occupation Repeat Nexus (MORN) Region of Arabidopsis PtdInsP Kinase 1 Affects Enzyme Activity as Well as Subcellular Distribution**

Y. Im, A. J. Davis, E. Johannes, N. S. Allen, W. F. Boss; Plant Biology, North Carolina State Univ, Raleigh, NC

The type I B family of phosphatidylinositol phosphate kinases (PIPKs) from Arabidopsis is characterized by a region of N-terminal putative MORN repeats. In theory, this MORN region should bind to membranes and affect the subcellular distribution of the enzyme. We have used in vitro and in vivo studies to characterize the function of the putative MORN region of *At*PIPK1(At1g21980). Constructs encoding both truncated and full length proteins were expressed in *E. coli* and the recombinant proteins were characterized for enzyme activity. Deletion of the N-terminal putative MORN region (amino acid #1-252) increased the activity of the remaining truncated C-terminal catalytic domain (#253-752) >4 fold. When the recombinant MORN region was added back to the truncated C-terminal catalytic domain, it enhanced the Vmax of the truncated C-terminal enzyme but it had no effect on activity of the full-length enzyme suggesting that the MORN region facilitated substrate delivery only when the active site was available. The MORN region affects the expression and localization of *At*PIPK1 and expressing the GFP-MORN region increases the PtdInsP kinase activity of the plasma membrane. Our working hypothesis is that the putative MORN region of *At*PIPK1 regulates enzyme activity as well as subcellular distribution. Lipid binding studies indicate that the MORN region binds to both the substrate, PtdIns(4)P, and the product, PtdIns(4,5)$P_2$, of the lipid kinase reaction. Our current model is that the MORN region protects the active site of the lipid kinase until the enzyme (particularly the MORN region) associates with a lipid bilayer; then the catalytic domain opens up and the MORN delivers PtdIns(4)P and removes PtdIns(4,5)$P_2$. This work was supported in part by a grant from the National Science Foundation.

1897

**Role of the C-Terminus in the Membrane Trafficking of hSERT**

B. Jeffus, F. Kilic; Department of Biochemistry and Molecular Biology, University of Arkansas for Medical Sciences, Little Rock, AR

The human serotonin transporter (hSERT) is the primary means of attenuating serotonergic signaling in the central nervous system of humans. hSERT exists as an oligomeric protein that spans the plasma membrane 12 times and where both termini are cytosolic. Included in the same protein

family as hSERT, are other $Na^+$ and $Cl^-$ dependent monoamine transporters, namely the human dopamine transporter (hDAT) and the human norepinephrine transporter (hNET). In addition to belonging to the same family, hSERT, hNET, and hDAT share 60% sequence homology and have many overlapping characteristics. Previous research has indicated the importance of the C-terminus of hNET and hDAT in the regulation of their transport function. Considering this, and the shared sequence homology to hSERT, we have investigated the role of the C-terminus in the function of hSERT proteins. Through the use of genetic, immunofluorescent, and functional assays we have identified amino acid residues in the C-terminus that are vitally important to the transport function of hSERT proteins. In addition to this, we believe the alteration in transport activity is due to an inability of cellular machinery to properly traffic the proteins to the plasma membrane, not due to an altered functional state of the protein.

1898

**Functional Characterization of a Palmitoylation-Deficient CD81 Mutant**

C. Delandre, T. R. Penabaz, A. L. Passarelli, R. J. Clem, S. K. Chapes; Division of Biology, Kansas State University, Manhattan, KS

Functional characterization of a palmitoylation-deficient CD81 mutant The transmembrane protein CD81 is a member of the tetraspanin superfamily that regulates the assembly of the B-cell coreceptor (CD19/21/81) and serves as a receptor/ coreceptor for hepatitis C virus and *Plasmodium falciparum*. CD81 may function as an adaptor molecule which regulates how proteins such as integrins, antigen receptors, and other tetraspanins associate in the plasma membrane microdomains. Recently, several groups showed that tetraspanin palmitoylation linkage of long-chain fatty acids to cysteine residues may have an important role in the formation of these microdomains. In addition, we hypothesized that palmitoylation is involved in the participation of CD81 in microdomain assembly. To test this hypothesis, we generated a palmitoylation-deficient CD81 mutant (CD81plm) by altering all available cysteines in the cytoplasmic and transmembrane domains. We found that CD81plm could be expressed in mammalian cells while maintaining antigenicity as determined by a conformation specific CD81 antibody. The migration of CD81plm in SDS-PAGE was consistent with the lack of palmitic acid modification. We tested the palmitoylation state of this mutant using radiolabelled palmitic acid, and as expected, no detectable palmitic acid was incorporated in CD81plm. CD81plm was transported to the plasma membrane as indicated by flow cytometry data. Finally, we found that there is an association between CD81plm and the tetraspanin CD9, a major CD81 binding partner. In conclusion, we have generated an important tool that will bring new insights into the regulation of CD81 by palmitoylation. This project was funded by NIH grants AI0552206, AI55052, RR16475, and NASA grants NAG2-1274 and NAGW-1197 and the Kansas Agriculture Experiment Station.

1899

**Localization of PAT Family Proteins in Cholesterol-Loaded Macrophages and Adipocytes**

O. Hofnagel,[1] I. Buers,[1] M. J. Robenek,[2] D. Troyer,[1] N. J. Severs,[3] H. Robenek[1]; [1]Department of Cell Biology and Ultrastructure Research, Leibniz-Institute for Arteriosclerosis Research, University of Münster, Germany, [2]Department of Medicine, Division of Cardiology, Pulmonary Disases and Angiology, University of Düsseldorf, Germany, [3]National Heart and Lung Institute, Imperial College of London, United Kingdom

The PAT family proteins, named after perilipin, adopophilin and TIP47, are implicated in intracellular lipid metabolism. Current information on the localization of PAT family proteins is inconsistent. The general consensus is that these proteins occur exclusively in the surface monolayer of lipid droplets and not in any other subcellular compartment. We studied the distribution of the PAT family proteins in cholesterol-loaded THP-1 cell derived macrophages and 3T3-L1 adipocytes using freeze-fracture immunolabeling and other techniques. We now demonstrate that in macrophages and adipocytes PAT family proteins are: 1) distributed not only in the surface but also throughout the lipid droplet core; 2) localized in endoplasmic reticulum (ER) and outer nuclear membranes, and 3) integral components of the plasma membrane. The localization of PAT family proteins apart from lipid droplets to the plasma membrane and membranes of organelles such as ER and nucleus raises intriguing questions as to its roles at these sites. Under normal culture conditions, PAT family proteins are dispersed in the cytoplasmic leaflet of the plasma membrane. Stimulation of lipid droplet formation by cholesterol-loading of the cells leads to clustering of the PAT family proteins in specialized plasma membrane domains. The aggregation of the PAT family proteins into such assemblies may facilitate carrier-mediated lipid influx from the extracellular environment into the lipid droplet. They further raise the possibility that transit of PAT family proteins with their fatty acid cargo into lipid droplets functions as part of this influx mechanism. Whether the pools of PAT family proteins in ER and nuclear membranes are regulated by alternative mechanisms to those of the plasma membranes and whether they provide a pathway by which PAT family proteins transit to the lipid droplet remains to be determined. Supported by the Deutsche Forschungsgemeinschaft, SFB 492.

**Role of the Membrane Lipid Structure in Signaling Through G Protein-coupled Receptors**

J. Casas,[1] J. Martínez,[1] O. Vögler,[1] Q. Yang,[2] R. Alemany,[1] G. Borchert,[1] T. Nagy,[1] S. M. Lanier,[3] P. V. Escribá[1]; [1]Biology, University of the Balearic Islands, Palma de Mallorca, Spain, [2]Medicine, Medical University of South Carolina, Charleston, SC, [3]Health Science Center, Lousiana State University, New Orleans, LA

Heterotrimeric G proteins are peripheral membrane proteins that propagate signals from membrane receptors to regulatory proteins localized in distinct cellular compartments. The aim of our study was to determine the role of the membrane lipid structure in the interaction and activity of G proteins and related proteins. For this purpose, we used two systems: model membranes (liposomes) and membranes from 3T3 cells overexpressing the $\alpha_{2A/D}$-adrenoceptor. We found that nonlamellar lipid phases favor the binding of pre-active Gαβγ proteins, driven by the Gβγ dimer. Activated Gα subunits dissociate from Gβγ dimers. Gα subunits have higher affinity for lamellar-prone regions, such as lipid rafts, where they interact with signaling effectors (e.g., adenylyl cyclase). Gβγ dimers remain in $H_{II}$-prone regions nearby the receptor and recruit GRK, which inactivates the receptor protein. Thus, membrane structure is involved in recruitment of G proteins to the receptor vicinity and also participates in the active sorting of G protein subunits upon activation by agonists. In addition, the membrane lipid structure also regulates the function of G proteins and related signaling proteins. In this context, the oleic acid (OA) changed the membrane structure and regulated G protein activity in 3T3 cell membranes. OA also induced marked changes in $\alpha_{2A/D}$-adrenoceptor and adenylyl cyclase activities. In contrast, the OA analogs elaidic and stearic acids did not change the activity of the above-mentioned proteins. In contrast, elaidic and stearic acids did not significantly change membrane lipid organization or function of G proteins, receptors and effectors. These fatty acids are chemical but not structural OA analogs, supporting the

structural basis of the modulation of membrane lipid organization and subsequent regulation of G protein-coupled receptor signaling. The present results demonstrate the active participation of membrane lipid structure in cellular signaling.

### Lipid Therapy: Manipulation of the Membrane Structure for Treatment of Human Pathologies

P. V. Escribá,[1] J. Martínez,[1] A. Gutierrez,[2] V. Lladó,[1] F. Barceló,[1] J. Prades,[1] J. Casas,[1] J. Besalduch,[2] R. Alemany,[1] O. Vögler[1]; [1]Biology, University of the Balearic Islands, Palma de Mallorca, Spain, [2]Hematology, Hospital Son Dureta, Palma de Mallorca, Spain

Most marketed drugs are targeted to proteins. Some novel approaches aim other cellular structures. We have developed a new therapeutic approach based on the modulation of the membrane lipid structure: **Lipid Therapy**. The goal of this work was to study the molecular bases underlying the control of cell functions upon manipulation of membrane structure and subsequent clinical applications. We have designed a fatty acid, 2-hydroxy-9-cis-octadecenoic acid (Minerval), and studied its effects on the structure of lipid membranes by X-ray scattering. We have also investigated its activity on cancer cell proliferation in cultured cells and animal models of cancer. Finally, we have investigated protein expression alterations produced by Minerval treatments on cancer cells by immunoblotting and RT-PCR. We found that Minerval increased the nonlamellar-phase propensity of membranes and subsequent recruitment of protein kinase C (PKC) to the plasma membrane. The moderate activation of this enzyme was associated with overexpression of $p21^{CIP1}$, which in turn inactivated cyclin-cdk complexes. As a consequence, the retinoblastoma protein (pRb) was hypophosphorylated, favoring formation of pRb/E2F-1 complexes. Impairment of active E2F-1 release resulted in lack of activation of several genes involved in cell proliferation: E2F-1, cyclins, cdks and dihydrofolate reductase (DHFR). Indeed, DHFR appeared to be a pivotal protein in the effects mediated by Minerval, since addition of the enzyme product (THF) to the incubation medium reversed the antiproliferative effects of the drug. In addition to its high antitumor activity, Minerval showed a lack of toxicity and side-effects. In summary, we have used the manipulation of the plasma membrane structure to trigger a series of molecular events that resulted in antitumor activity through a novel pharmacological mechanism. This therapeutic strategy can be used for treatment of other pathologies, such as hypertension and obesity.

1902

### Molecular Basis of Oxidative Stress Protection by *Bacillus anthracis Dlp-1* and *Dlp-2*

X. Liu,[1] E. C. Theil[2,3]; [1]Center for BioIron, Children's Hospital and Research Center at Oakland, Oakland, CA, [2]Dept. of Nutritional Biochemistry and Toxicoly, University of California, Berkeley, Oakland, CA, [3]BioIron, Children's Hospital and Research Center at Oakland, Oakland, CA

Cells use ferritin for protection during stress by converting iron and oxidants to solid mineral. Bacterial pathogens resist host macrophage release of oxidants during infection. The conserved cage-like *Dps* proteins are bacterial mini-ferritins. Many bacteria overexpress *Dps* under stress conditions. Understanding cellular roles of *Dps* proteins in bacterial stress response, physiology, and pathogenesis requires study of molecular mechanisms. Objective: Biochemical characterization of *Bacillus anthracis Dlp-1* and *Dlp-2*, two isoforms of *Dps*. Results *Iron uptake/mineralization*: *Dlp-1* and *Dlp-2* catalyze $Fe^{2+}$ oxidation with $O_2$ and store up to 500 $Fe^{3+}$. Rates of $Fe^{2+}$ /$O_2$ reaction are comparable for *Dlp-1* and *Dlp-2* and are 100-fold slower than maxi-ferritins. *Dlp-2* but not *Dlp-1*, also catalyzes $Fe^{2+}/H_2O_2$ reaction 3-fold faster than with $Fe^{2+}/O_2$ reaction, illustrating its role in $H_2O_2$ detoxification. *Iron Release*: Both *Dlp-1* and *Dlp-2* control Fe efflux from dissolved mineral with reductant/chelator. Thermostability study with *CD* detected flexible subdomains, possibly iron pores, transition around 37°C. Rates of iron release correlate well with iron pore dynamics, suggesting pore gating to regulate Fe efflux. *DNA binding and protection*: *Dlp-1* bond DNA but did not protect it from hydroxyl radical damage; *Dlp-2* did not bind DNA but protected it against oxidative cleavage; *Dlp-1* and *Dlp-2* together altered the properties of DNA/protein complexes. Results reflected different roles of *Dlp-1* and *Dlp-2* interacting with DNA, and presence of both *Dlp-1* and *Dlp-2* offers comprehensive protection to bacterial genome from damage. Conclusions: The multiple biochemical functions associated with *Dlp-1* and *Dlp-2* suggest complementary roles of the two proteins in iron and oxygen homeostasis, peroxide detoxification, and DNA protection that contribute to the ability of *B. anthracis* to survive iron depletion and the "oxidative burst" of macrophages and neutrophils. Support: NIH-DK20251, Cooley's Anemia Foundation, CHORI Foundation.

1903

### Functional Relevance of Overexpression of LAT1 and 4F2hc in SHR Immortalized Renal Proximal Tubular Epithelial Cells

M. Pinho,[1] P. A. Jose,[2] P. Soares-da-Silva[1]; [1]Inst. Pharmacol. Ther., Faculty of Medicine, Porto, Portugal, [2]Department of Pediatrics, Georgetown University Medical Center, Washington, DC

The present work examined the expression of LAT1 and its associated glycoprotein 4F2hc in renal cortical membranes and immortalized renal proximal tubular cells from spontaneously hypertensive (SHR) and normotensive (WKY) rats. The study also examined the inward and outward transport of [$^{14}$C] L-leucine, the preferred substrate of LAT1. The [$^{14}$C] L-leucine uptake in WKY cells was largely promoted through a $Na^+$-insensitive transporter, though in SHR cells a significant component (~50%) of [$^{14}$C] L-leucine influx was found to require extracellular $Na^+$. [$^{14}$C] L-leucine uptake that was insensitive to system A inhibitor N-(methylamino)-isobutyric acid (MeAIB), but sensitive to inhibition by 2-aminobicyclo(2,2,1)-heptane-2-carboxylic acid (BCH), a system L inhibitor. L- isomers of neutral amino acids and D-leucine markedly reduced the [$^{14}$C] L-leucine accumulation. In SHR cells [$^{14}$C] L-leucine uptake in the presence of extracellular $Na^+$ was sensitive to inhibition by basic amino acids. Accumulation [$^{14}$C] L-leucine in SHR and WKY cells was insensitive to pH variations. Unlabeled L-leucine increased [$^{14}$C] L-leucine efflux in a time- and concentration-dependent manner. The abundance of LAT1 and 4F2hc were also found to be greater in SHR than in WKY, both in renal cortex and immortalized renal proximal tubular cells. In conclusion, it is likely that system $B^{0,+}$ might be responsible for the $Na^+$-dependent uptake of L-leucine in SHR cells, whereas the $Na^+$-independent uptake of L-Leucine in both cells lines may include system LAT1, which functions as an exchanger and whose activation results in *trans*-stimulation of L-leucine outward transfer.

1904

### The Stem-Cell Marker Bcrp1/Abcg2: a Role in Mature Sperm?

C. Scharenberg,[1] P. Repges,[1] T. Jähn,[1] T. Saharge,[1] R. W. Robey,[2] G. Wennemuth[1]; [1]Department of Anatomy and Cell Biology, Philipps-University of Marburg, Marburg, Germany, [2]Center of Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, MD

An increasingly exploited strategy for the isolation of stem cells from a variety of species and tissues is based on the increased efflux-capacity for

the lipophilic dye Hoechst 33342. This efflux activity is mostly mediated by Abcg2, an ATP-binding-cassette transporter, which is highly expressed in various stem cells. However, ablation of Abcg2 does not lead to a stem cell defect. In addition to its expression on stem cells, Abcg2 is also expressed by some mature cells in blood, liver, kidney, gut, and brain. While studying the expression pattern using RT-PCR from FACS-isolated germ cell populations of different developmental stages, we noted that Abcg2 is upregulated at later stages of spermatogenesis, particularly spermatocytes I and II. Western blot analysis using a polyclonal Abcg2-antibody corroborated expression of a 72 kDa band in mature sperm of murine, bull and human origin. Immunocytochemistry studies with the same antibody revealed an acrosomal staining pattern of Abcg2 in spermatozoa. Experiments using known Abcg2 substrates and the Abcg2-specific inhibitor Fumitremorgin C demonstrated efflux activity of Abcg2 in mature sperm, suggesting its function in the outer plasma membrane. Among the substrates of Abcg2 are genotoxic agents, steroids and other lipophilic molecules, some of which play important roles in capacitation of spermatozoa. Besides its putative function in prevention of genotoxic stress, we investigated whether Abcg2 mediates changes in membrane composition that go along with maturation of spermatozoa. Based on the evolutionary conservation of this ABC-Transporter in mature sperm, we conclude that Abcg2 is an important regulator of post-testicular maturation of spermatozoa.

1905

### Effects of Growth Support on Multi-Drug Resistance and Cellular Differentiation

S. D. Sheridan, A. A. Arena; Millipore Corporation, Danvers, MA

Effects of Growth Support on Multi-Drug Resistance and Cellular Differentiation Steven D. Sheridan, Ph.D. and Andrew A. Arena Multiple drug resistance due to efflux is a major cause for failure of many therapeutic regiments. For example, augmentation of transporter expression can protect cancer cells from chemotherapeutic agents. Over-expression of ATP-binding cassette (ABC) drug transporters, including MDR-1 (P-glycoprotein) and the MRP proteins, have been shown to be involved in drug resistance by preventing the uptake of oral drugs, causing the efflux of drugs from target tissues, or both. This study investigates the impact of tissue culture conditions on optimal ABC transporter expression, activity and multi-drug resistance. This study utilizes cell lines with various levels of efflux activity including Caco-2, MDCK and MDCK cells transfected with the human MDR-1 gene. Cell growth was compared on microporous filters against solid plastic plate growth supports. Monolayer integrity in the filter plates was evaluated by Trans-epithelial Electrical Resistance (TEER) and Lucifer yellow rejection. MDR-1 protein activity and expression was characterized by calcein-AM uptake, immunocytochemistry, and drug resistance measured by $LD_{50}$ determination. Transfected MDCK cells showed high MDR-1 activity that was augmented after culture on filters when compared to solid bottom plates. Both non-transfected MDCK cells and non-fully differentiated Caco-2 cells (10 days of culture or less) had minimal activity when grown on both filter and solid bottom plates. Alterations of MDR-1 activity and expression in the Caco-2 cells were dependent on growth support upon differentiation. This data suggests that microporous filter supports contribute to greater monolayer differentiation and therefore higher expression of MDR1. Filter based cell culture plates are ideal platforms for culturing differentiated cell monolayers and also provide an optimal environment for investigating the drug resistance activity of ABC transporters.

## Golgi to Cell Surface Transport (1906-1924)

1906

### The Role of Ypt/Rab GTPase Interactions in Coupling Vesicular Transport Steps

N. Segev, Z. Lipatova; Biological Sciences, University of Illinois, Chicago, IL

Ypt/Rab GTPases are master regulators of protein trafficking in eukaryotic cells. When in the GTP-bound state, they interact with multiple effectors that mediate all the known aspects of vesicular transport, from vesicle formation and motility, to their targeting and fusion. An attractive idea is that Ypt/Rabs and their accessory factors not only regulate individual vesicular transport steps, but also coordinate them. In yeast, the Ypt31/32 GTPase pair regulates the formation of trans-Golgi vesicles, while Sec4 GTPase controls their subsequent targeting and fusion. Here, we show that these GTPases interact directly in a nucleotide-specific manner, and that this interaction is physiologically relevant. Nucleotide-specific interaction of Ypt31 and Sec4 was shown by two-hybrid analysis and co-precipitation of purified proteins. The physiological relevance was shown by co-localization of these GTPases, co-precipitation from yeast lysates, and genetic interactions of nucleotide-restricted Ypt31 and Sec4 mutations. Finally, we show that, like Sec4, Ypt31/32 localize to trans-Golgi vesicles, and that Ypt31 is required for intracellular localization of Sec4. These results suggest that direct interaction of Ypt31/32 with Sec4 on trans-Golgi vesicles is important for the recruitment of Sec4 to these vesicles, which in turn is required for their polarized targeting and fusion. Therefore, direct GTPase interactions serves to couple Ypt31/32-mediated trans-Golgi vesicle formation with Sec4-mediated targeting and fusion of these vesicles. We propose direct GTPase-GTPase interactions as a novel mechanism by which the highly conserved Ypt/Rab GTPases coordinate separate vesicular transport steps.

### Roles of ARFRP1 (ADP-Ribosylation Factor-Related Protein 1) in Post-Golgi Membrane Trafficking

H. Shin,[1] H. Kobayashi,[2] M. Kitamura,[1] K. Nakayama[1]; [1]Graduate School of Pharmaceutical Sciences, Kyoto University, Kyoto, Japan, [2]Faculty of Pharmaceutical Sciences, Kanazawa University, Kanazawa, Japan

ADP-ribosylation factors (ARFs) constitute a family of small GTPases belonging to the Ras superfamily and play essential roles in intracellular membrane trafficking. In addition to ARFs, there exists a subfamily of small GTPases with sequence similarity to ARFs, referred to as the Arl (ARF-like) subfamily. Little is known about the function of the Arl proteins, yet Arl1 has been relatively well characterized among them. Arl1 is localized to the Golgi complex and recruits a subset of golgins onto Golgi membranes through binding directly to the GRIP domain at their C-termini. Mammalian ARFRP1 (ADP-ribosylation factor (ARF)-related protein 1), previously designated ARP is a membrane-associated 25 kDa GTPase with 33% of amino acids identical to those of ARF1. Arl3p, a yeast counterpart, shares 43% of amino acids with mammalian ARFRP1. Studies in yeast have shown that Arl3p is required for recruitment of Arl1p and the GRIP domain-containing protein, Imh1p/Sys3p, onto the Golgi. The functional importance of ARFRP1 is underscored by the finding that targeted disruption of the *Arfrp1* gene in mice resulted in embryonic lethality at gastrulation stage and apoptosis of ectodermal cells. However, the function of mammalian ARFRP1 has not been explored at the molecular level. Here, we demonstrate that ARFRP1 is associated mainly with the *trans*-Golgi compartment and the *trans*-Golgi network (TGN)

and is an essential regulatory factor for targeting of Arl1 and GRIP domain-containing proteins, golgin-97 and golgin-245, onto Golgi membranes. Furthermore, we show that ARFRP1 is involved in the anterograde transport from the Golgi to the plasma membrane as well as in the retrograde transport from endosomes to the Golgi.

1908

**The UBX Containing Protein UBXD4 Regulates Cell Surface Number and Subunit Stability of Alpha3-containing Nicotinic Acethylcholine Receptors**

K. Rezvani,[1] Y. Teng,[1] Y. Pan,[1] J. Cotton,[1] J. M. Lindstrom,[2] J. Dani,[1] M. De Biasi[1]; [1]Neuroscience, Baylor College of Medicine, Houston, TX, [2]Neuroscience, University of Pennsylvania Medical School, Philadelphia, PA

Neuronal nicotinic acetylcholine receptors (nAChRs) are ligand-gated ion channels expressed in many regions of the central and peripheral nervous systems. nAChRs are necessary for proper synaptic transmission in ganglia and the number of functional nAChRs in neuronal membranes is a crucial factor for the efficacy of neurotransmission. By using the large cytoplasmic domain of α3 as a bait in the yeast two-hybrid system, we isolated a novel UBX-containing protein as the first cytosolic protein known to interact directly with the α3 nAChR subunit. The isolated clone was identified as protein UBXD4 (Accession number# NM_145441) which according to its role on nAChRs, we re-named "Nicotinic Receptor Partner Protein" or NRPP. Transient expression of tagged NRPP in HEK cells stably expressing α3* nAChRs facilitated cell surface expression of α3* receptors. The same effect was observed when NRPP was stably expressed in PC12 cells. Further experiments indicated that NRPP is located in the Golgi lumen, and that upon ubiquitination it is targeted by the 26S proteasome for degradation. Taken together our data suggests that NRPP may modulate the number of cell surface α3* nAChRs by controlling the stability of α3 and its distribution between specialized intracellular compartments and the plasma membrane. Key words: nicotinic acetylcholine receptor, α3 subunit, ubiquitin, proteasome, UBX domain, trafficking This work was supported by NIDA grants DA12661 and DA 017173 and a Philip Morris grant to MDB.

1909

**Function of the Phosphatidylinositol 4-Kinase Pik1p in a Golgi-to-Endosome Pathway Involving Gga2p**

L. Demmel,[1] M. Gravert,[1] E. Ercan,[1] M. Peter,[2] C. Walch-Solimena[1]; [1]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, [2]Institute of Biochemistry, Swiss Federal Institute of Technology Zurich, Zurich, Switzerland

In *Saccharomyces cerevisiae*, experiments with temperature-sensitive mutants of the Phosphatidylinositol 4-kinase Pik1p revealed that the PI4P pool generated by this enzyme is essential for Golgi morphology, transport of cargo for exocytosis (invertase) as well as for vacuolar delivery (Carboxypeptidase Y, CPY). Moreover, several lines of evidence indicate that the PI4P pool at the Golgi represents a regulatory signal on its own. However, it remains elusive which proteins bind to PI4P and mediate its effects on Golgi function. In a screen for synthetic genetic interactions between a library of knockout of genes and a conditional-lethal *pik1* mutant allele, Gga2p has been isolated. As a role of Pik1p in control of vesicle formation at the Golgi has been suggested by previous work, we further investigated a possible common role of Pik1p and Gga2p. Gga proteins (Gga1p and Gga2p) are monomeric clathrin adaptors regulating Golgi-to-endosome transport. We provide data indicating that Pik1p, similar to Gga proteins, is involved in exit from the Golgi. Genetic and biochemical results were obtained suggesting that PI4P generated by Pik1p is required for normal Gga2p localization to the Golgi and for transport of cargo from the Golgi to the late endosomes as well as for a Golgi-to-surface pathway transiting an endosomal compartment. This proposed pathway is parallel to AP-1 mediated trafficking between Golgi and early endosomes. Thus, Gga2p might be a target of PI4P signaling at the Golgi and we further provide evidence for the existence of biosynthetic transport to endosomes in a specialized route for exocytosis.

1910

**Lipid Phosphatases Establish Spatially and Functionally Distinct Regions within the Golgi**

F. Cheong, B. Brankatschk, P. Mayinger; Department of Medicine, Division of Nephrology and Hypertension, Oregon Health and Science University, Portland, OR

Objective: To study the regulation of phosphoinositides at Golgi membranes by lipid phosphatases SAC1 and OCRL1. Methods: Vector-based RNA interference (RNAi) was used to deplete cellular levels of SAC1 and OCRL1. Confocal immunofluorescence microscopy was used to localize proteins in tissue culture cells. Bulk anterograde trafficking was monitored by pulse-labeled cells with 35S-Methionine. High performance liquid chromatography (HPLC) was employed to analyze phosphoinositides levels after in vivo labeling wih 3H-myo-inositol. Results: Phosphoinositides (PI) are important in regulating Golgi trafficking and structure. Phosphatidylinositol-4-phosphate (PtdIns(4)P) is required for anterograde carrier formation while phosphatidylinositol-4,5-bisphosphate (PtdIns(4,5)P2) is responsible for maintaining the structural integrity of the Golgi. These phospholipids are tightly regulated by distinct phosphoinositides kinases and phosphatases. SAC1 is the main PtdIns 4-phosphatase at Golgi membranes while OCRL1 is a PtdIns(4,5)P2-specific 5-phosphatase. We found that SAC1 establishes low PtdIns(4)P regions in the Golgi. Golgi resident enzymes such as mannosidase II are concentrated in theses regions while cargo proteins are largely excluded. Depletion of SAC1 abrogated Golgi retention of mannosidase II and led to surface localization of this enzyme. In addition, Golgi morphology is dramatically affected in SAC1 depleted cells. In contrast, OCRL1 co-localizes with cargo proteins and knock down of this phosphatase caused defects in bulk anterograde trafficking. Conclusions: SAC1 and OCRL1 establish distinct phosphoinositide-specific regions within the Golgi that are instrumental for segregating anterograde trafficking from the recycling of resident Golgi enzymes.

1911

**Effect of a Chronic Deficiency of a $PIP_2$ 5-phosphatase on Cell Signaling**

S. F. Suchy, J. Cronin, R. L. Nussbaum; NHGRI/GDRB, NIH, Bethesda, MD

The importance of PI kinases and phospholipase C in regulation of $PIP_2$ levels in cell signaling is well established. However, the role of $PIP_2$ phosphatases in cell signaling has received little attention. This study was done to determine whether chronic deficiency of a $PIP_2$ 5-phosphatase, ocrl1, plays a role in calcium signaling. Ocrl1 is a ubiquitiously expressed, TGN/endosome localized enzyme and its deficiency in humans causes Lowe syndrome, characterized by bilateral congenital cataracts, renal Fanconi syndrome and mental retardation. Lowe patient fibroblasts were previously shown to have increased $PIP_2$ levels. In this study cell permeant AM esters of the $Ca^{2+}$ indicator dyes Fluo-4 and Fura red were used to

monitor changes in intracellular [$Ca^{2+}$] after agonist stimulation in patient and control fibroblasts. Several agonists were studied, including bradykinin, histamine and PDGF. Only the response to bradykinin differed consistently between Lowe and control fibroblasts. In 7 pairs of cell lines tested, Lowe cells had a peak [$Ca^{2+}$] after stimulation that was 25% higher than controls and reached their peak [$Ca^{2+}$] 20% faster than did controls. 2-Aminoethoxy-diphenylborate, an inhibitor of $IP_3$ induced calcium release, reduced the number of cells that responded to bradykinin in a dose dependent manner. There was no difference in total calcium stores, monitored by treatment with the ionophore A23187. Although the total bradykinin receptor concentration, measured by western analysis, did not differ between Lowe and control fibroblasts, Lowe cells had approximately two-fold more bradykinin receptors at the cell surface than controls, as measured in radioactive binding assays. This implies a decrease in receptor desensitization in Lowe cells. These findings indicate that although ocrl1 is concentrated at the TGN/endosome it plays a role in various functions at the plasma membrane including cell signaling and receptor desensitization.

1912

**Drs2p-Dependent Translocation of Phosphatidylserine and Phosphatidylinositol Fluorescent Analogs Across the Yeast Late Golgi Membrane**

P. Natarajan, T. R. Graham; Biological Sciences, Vanderbilt University, Nashville, TN

Phospholipid translocases (PLTs) are capable of flipping fluorescent or spin-labeled derivatives of phospholipids from the external leaflet of a membrane bilayer to the cytosolic leaflet and are thought to establish phospholipid asymmetry in biological membranes. The best candidates for PLTs are the Drs2p/ATPase II (ATP8A1) subfamily of P-type ATPases. Drs2p from budding yeast localizes to the *trans*-Golgi network (TGN) and is required for a flippase activity in this membrane. Using a Drs2 temperature-sensitive mutant, we have shown that ATP hydrolysis by Drs2p catalyzes the translocation of 7-nitro-2-1,3-benzoxadiazol-4-yl (NBD) phosphatidylserine (PS) from the luminal leaflet to the cytosolic leaflet of this membrane. No Drs2p-dependent translocation of NBD-phosphatidylethanolamine or NBD-phosphatidylcholine was detected indicating headgroup specificity for the translocase. The specificity of Drs2p for NBD-PS suggested that translocation of PS would be required for the function of Drs2p in protein transport from the TGN. However, this is not the case, the PS-deficient *cho1* mutant does not phenocopy *drs2* but instead transports proteins normally through the secretory pathway. Moreover, a *drs2 cho1* double mutant retains *drs2* transport defects. Therefore, endogenous PS is not an essential substrate *in vivo* for the role Drs2p plays in protein transport. A search for additional substrates for Drs2p led to the surprising finding that Drs2p is required for the ATP-dependent translocation of bodipy-phosphatidylinositol (PI) and NBD-PI across the TGN membrane. These data suggest that Drs2p is a PS/PI translocase and further work is required to determine if PI translocation by Drs2p is needed to bud vesicles from the TGN.

1913

**Isolation of Extragenic Suppressors of the drs2 Cold-Sensitive Growth Defect in Saccharomyces cerevisiae**

B. Muthusamy, T. R. Graham; Biological Sciences, Vanderbilt University, Nashville, TN

Drs2p is an integral membrane P-type ATPase required for a phospholipid translocase activity in the *trans*-Golgi network (TGN) of *Saccharomyces cerevisiae.* The ATPase activity of Drs2p, and presumably its ability to flip phospholipid from the luminal leaflet to the cytosolic leaflet of the TGN, is required along with clathrin for formation of one of the two classes of post-Golgi, exocytic vesicles found in yeast. Disruption of *DRS2* yields a viable strain that grows well at 30C but fails to grow at 20C or below. Growth of *drs2Δ* at 30C requires the presence of three closely related P-type ATPases (Dnf1p, Dnf2p and Dnf3p) that show some functional redundancy with Drs2p. However, Drs2p provides an essential function at low temperatures that cannot be replaced by the Dnf ATPases. To better understand this essential function of Drs2p at low temperatures, we have screened for spontaneous bypass suppressors of the *drs2Δ* cold-sensitive growth defect. *drs2Δ* strains of opposite mating types were spread on rich medium at 17°C or 20°C and 19 spontaneous mutants were isolated that suppress the cold sensitive (cs) growth phenotype of *drs2Δ.* Genetic analyses of 19 cold-resistant *drs2Δ* strains indicated that 3 dominant and 15 recessive suppressors were caused by single gene mutations, and one recessive mutant was caused by multiple mutations. The 15 recessive mutants fell into two complementation groups called *sdk1* (12 alleles) and *sdk2* (3 alleles) for **s**uppressor of ***d****rs2* **k**nockout. We are in the process of cloning *SDK1* and *SDK2* by transforming the recessive suppressor strains with a genomic library and screening for complementation of the cold-resistant growth phenotype.

1914

**The Role of Sphingomyelin Synthase-Derived Diacylglycerol on Vesicular Transport**

Y. Ueda,[1] S. Yamaoka,[2] T. Okazaki,[2] T. Kobayashi[1]; [1]Discovery Research Institute, RIKEN, Wako, Japan, [2]Pathophysiological and Therapeutic Science, Tottori University Faculty of Medicine, Yonago, Japan

Sphingomyelin is a major cell surface sphingolipid. Sphingomyelin synthase is proposed to locate in the Golgi apparatus. During the lipid synthesis, phosphocholine moiety of phosphatidylcholine is transferred to ceramide. Therefore, sphingomyelin systhesis is accompanied by the formation of diacylglycerol. The role of this diacylglycerol has long been discussed. Fumonisin B1 inhibits ceramide synthesis and thus prevents sphingomyelin synthase-derived diacylglycerol production. Using fumonisin B1, it has been suggested that the diacylglycerol formed during sphingomyelin synthesis is involved in vesicular traffic from the Golgi apparatus. In addition to the inhibition of diacylglycerol synthesis, fumonisin B1 accumulates sphingoid bases that are growth inhibitory and pro-apoptotic for many types of cells. In order to directly assess the effect of the sphingomyelin synthesis dependent diacylglycerol on membrane traffic, we employed recently isolated sphingomyelin synthase defective mouse lymphoid cell mutants. Whereas the mutants contain less diacylglycerol than sphingomyelin-positive revertant cells, the release of glucosaminoglycan was not significantly altered between two cell types. Addition of fumonisin B1 decreased the release of glucosaminoglycan in both mutants and revertants. These results suggest that sphingomyelin synthase-derived diacylglycerol is not involved in the secretion of glucosaminoglycan and fumonisin B1 inhibits vesicular traffic via sphingomelin-independent mechanism.

1915

**Discrete Domains within Naked2 Cooperate in the Transport of TGF-α-containing Exocytic Vesicles to the Basolateral Surface of Polarized Epithelial Cells**

C. Li, M. Hao, Z. Cao, W. Ding, R. Graves-Deal, J. Hu, D. W. Piston, H. A. Brown, R. J. Coffey; Departments of Medicine, Pathology, and Cell

and Developmental Biology, Vanderbilt University Medical Center and Dept of Veterans Affairs Medical Center, Nashville, TN

Mechanisms underlying basolateral transport of exocytic vesicles to the plasma membrane are largely unresolved. We previously reported that Naked2 associates with exocytic vesicles containing a Golgi-processed form of TGFα and escorts TGFα to the basolateral surface of polarized MDCK cells in a Naked2 myristoylation-dependent manner (PNAS 101: 5571-5576, 2004). Here we show that residues 51-173 of human Naked2 provide basolateral directionality in that fusion of these residues to a $Na^+/H^+$ exchanger regulatory factor 1 (NHERF1)-DsRed2 fusion construct completely redirects fluorescence from the apical cytoplasm to the basolateral plasma membrane of MDCK cells. Residues 1-36 bind PIPn broadly, and, in the absence of N-myristate, confer general post-Golgi vesicle recognition. Myristoylation of Naked2 is required for docking and fusion of Naked2 vesicles, but not for vesicle recognition or trafficking of these vesicles in the basolateral cytoplasm. In μ-1B deficient polarized LLC-$PK_1$ cells, both Naked2 and TGFα traffic normally to the basolateral membrane. These data demonstrate that Naked2 is an adaptor-like protein that contains distinct functional domains that orchestrate the delivery and fusion of exocytic vesicles at the basolateral plasma membrane of polarized epithelial cells in a μ-1B-independent manner.

1916

### Purification and Characterization of Naked2-Associated Exocytic Vesicles

Z. Cao,[1] C. Li,[1] R. Graves-Deal,[1] A. L. Ham,[2] J. N. Higginbotham,[3] J. L. Franklin,[1] R. J. Coffey[1]; [1]Departments of Medicine, Cell and Developmental Biology, Vanderbilt University, Nashville, TN, [2]Mass Spectrometry Research Center, Vanderbilt University, Nashville, TN, [3]Departments of Pediatric Infectious Diseases, Vanderbilt University, Nashville, TN

Genetic studies in *Drosophila* have established that activation of canonical Wnt signaling results in upregulation of Naked Cuticle that then binds and inactivates Dishevelled, a positive regulator of Wnt signaling. Two mammalian Naked homologs, Naked 1 and 2, have been found. We recently reported that Naked2, but not Naked1, interacts with the cytoplasmic tail of pro-TGFα, and escorts post-Golgi TGFα-containing exocytic vesicles to the basolateral surface of polarized epithelial cells, where these vesicles dock and fuse in a Naked2 myristoylation-dependent manner. In GFP-tagged, myristoylation-deficient Naked2-expressing polarized MDCK cells (G2A Naked2-GFP), Naked2-associated vesicles are trapped at the basolateral corner and TGFα is unable to reach the basolateral membrane (PNAS 101:5571-5576, 2004). We have successfully isolated G2A Naked2-GFP-containing vesicles using a combination of iodixanol density gradient separation and dual color labeling flow sorting (DiD:1,1'-dioctadecyl-3,3,3',3'-tetramethylindodi-carbocyanine perchlorate and GFP) by using BD FACSAria flow cytometry. Sufficient amounts of these flow cytometric-enriched vesicles have been isolated to perform proteomic analysis by LC MS/MS. The identification of proteins that comprise the machinery and additional cargo of this specialized subset of exocytic vesicles will be presented.

1917

### Identification of Signals in ATP7B Mediating Its Cu-dependent Trafficking in Polarized Hepatic Cells

Y. Guo, L. K. Nyasae, L. T. Braiterman, A. L. Hubbard; Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD

Copper (Cu) is an essential cofactor of cellular proteins but is toxic in its free state. The hepatic Cu-ATPase, ATP7B, has two functions in Cu homeostasis: it loads $Cu^+$ onto newly-synthesized apo-ceruloplasmin in the secretory pathway thereby activating the plasma protein; and it participates in the excretion of excess $Cu^+$ into the bile. To carry out these two functions, the membrane protein responds to changes in intracellular Cu levels by cycling between the Golgi and apical region. Using polarized hepatic WIF-B cells and confocal microscopy, we found that both endogenous and exogenous ATP7B resided in the Golgi region in Cu-depleted cells, while in Cu-loaded cells, the protein relocated to unique vesicles near to the apical plasma membrane as well as the membrane itself. To determine the roles of ATP7B's cytoplasmic N- and C-termini in regulating its trafficking, we generated 9 mutation/deletions and analyzed their behaviors in WIF-B cells. Truncation of the ATP7B N-terminus up to the fifth copper binding domain yielded an active ATPase that was insensitive to cellular Cu levels and constitutively trafficked to the opposite (basolateral) plasma membrane domain. Fusion of the N-terminal 63aa of ATP7B to the truncated protein restored both its Cu-responsiveness and correct intracellular targeting, indicating that important targeting information is contained in this sequence. We also identified two signals, tri-L (L1454-1456) and di-E (E1461-1462), in the C-terminus of ATP7B. In Cu-loaded WIF-B cells, the tri-L mutant traffics to apical vesicles and the apical membrane, while the di-E protein traffics to the vesicles only. When Cu levels are decreased, neither mutant protein returns to the TGN region, suggesting that the two motifs contain retrieval signals. We are currently searching for binding partners.

1918

### Adenosine Receptor-dependent Modulation of Bladder Umbrella Cell Surface Area

W. Yu, G. L. Apodaca; Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA

Adenosine receptors are expressed in all tissues and play important roles in regulating cellular functions such as neurotransmission, cell polarization, and exocytosis. Bladder umbrella cells undergo cycles of exocytosis/endocytosis as the bladder fills and empties. Previous data showed that modulation of umbrella cell surface area occurs through a P2X purinergic receptor-, cAMP- and PKA- dependant mechanism. To test the hypothesis that adenosine receptors are also involved in this process, isolated uroepithelium was mounted in modified Ussing chambers and changes in membrane capacitance (where 1uF=1cm2 surface area) were measured in the presence of adenosine or different adenosine receptor agonists. Administration of adenosine to the serosal or mucosal surface of uroepithelium led to increased membrane capacitance of ~30% or ~24%, respectively, after 5 hours, and the administration of deaminase abolished adenosine-induced capacitance increases. While A1, A2a and A3 agonists (CCPA, CGS21680, IB-MECA, respectively) all increased the membrane capacitance gradually after being administrated serosally (~22%, ~33%, ~26%), only A1 agonist increased the membrane capacitance significantly after being administrated mucosally (~39%). Adenosine receptor antagonists, as well as deaminase, had no effect on pressure-induced capacitance increases. 2-APB or calcium-free Krebs solution inhibited adenosine- or agonists- induced capacitance increases. Western blot analysis confirmed the expression of all 4 receptors in uroepithelium, and immunofluorescence staining also showed that A1, A2a, A2b and A3 receptors were expressed in the uroepithelium/submucosa. Upon stretch, adenosine was released significantly to both mucosal and serosal chamber measured by HPLC. These results indicate that adenosine receptor signaling may contribute to the modulation of bladder umbrella cell exocytosis through a calcium dependent pathway.

1919

**Crn7 is Crucial for the Golgi Complex Architecture and Function**

V. Rybakin,[1] N. Gounko,[2] R. Müller,[1] A. A. Noegel[1]; [1]Biochemistry I, University of Cologne, Cologne, Germany, [2]Cell Biology, University of Groningen, Groningen, The Netherlands

Crn7 is a novel mammalian WD-repeat protein. Using biochemical methods and microscopy, we established that Crn7 is present at the cytosolic side of early Golgi membranes, and in the cytosol. Golgi localization of Crn7 was further shown to depend on the integrity of the ER-to-Golgi transport and on tyrosine phosphorylation of Crn7. The protein is still present on ER-Golgi chimaeric membranes formed upon the BFA treatment, suggesting that the COPI system or preservation of the Golgi membrane identity is not important for its localization. Using Crn7 siRNA, we established that the protein is indeed important for the Golgi structure and function. The structure of the Golgi matrix is significantly altered in RNAi cells. GRASP65 displays scattered staining pattern in dot-like structures. The bulk of GM130, a protein depending on GRASP65 in its matrix localization, is displaced to the cytosol, and only a minor amount remains in the matrix remnants. These data suggest that GRASP65 alone is not sufficient to drive the matrix localization of GM130. The trans-Golgi network is disassembled into smaller flat cisternae in Crn7 RNAi cells, as shown by TGN38 staining. This is apparently not a direct effect of the Golgi matrix disassembly, as the matrix is predominantly present in the cis-zone of the Golgi complex, as shown by previous studies. Thus, Crn7 knockdown results in profound defects in the Golgi architecture. These defects correlate with functional abnormalities. TGN38 protein, known to cycle between the TGN and cell surface, redistributes from scattered trans-Golgi remnants to cytoplasmic vesicles, implying that proteins destined to downstream locations are gradually depleting from the Golgi, while there is no import of new cargo. This is further confirmed by the fact that lysosomal LAMP1 staining is depleted in cells stably expressing Crn7 siRNA.

1920

**A Peripheral Membrane Multi-protein Complex that Binds to Chitin Synthase III is Important for its Transport from the Trans-Golgi Network to the Cell Surface**

S. Sanchatjate, R. Schekman; University of California, Berkeley, Berkeley, CA

In *Saccharomyces cerevisiae*, the plasma membrane protein chitin synthase III (Chs3p) synthesizes chitin to strengthen the yeast cell wall. Unlike most plasma membrane proteins whose transport to the cell surface is tightly linked to gene expression and protein synthesis, Chs3p follows a unique itinerary. In steady state, Chs3p resides in internal punctate structures of trans-Golgi network (TGN) and early endosome. During the cell cycle or upon heat shock, Chs3p is rapidly mobilized to the cell surface and subject to rounds of internalization and re-export. Chs5p and Chs6p are two peripheral membrane proteins necessary for the transport of Chs3p from the TGN to the plasma membrane. We have found that Chs5p forms large stable complexes with Chs6p and three Chs6 paralogs: Ymr237w, Ykr027w, and Bud7p. These Chs5p/Chs6p complexes transiently interact with its cargo, Chs3p, and the presence of Chs3p in the complexes is dependent on every subunit. Chs5p and Chs6p have unique and crucial roles in Chs3p transport because either *chs5Δ* or *chs6Δ* mutant drastically reduces the level of Chs3p bound to the remaining subunits of the complex. Ymr237w and Bud7p appear to have redundant function in Chs3p transport because double deletion of both is necessary to displace Chs3p from the complex. Our results suggest that these Chs5p/Chs6p complexes may function as adaptor and possibly coat protein complexes which selectively transport certain cargos from the TGN to the plasma membrane in response to regulatory cues (see poster by R. Barfield).

1921

**Chs5p, Bud7p, and YMR237w Localize Fus1p to the Plasma Membrane in *Saccharomyces Cerevisiae***

R. M. Barfield, R. Schekman; Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

During *Saccharomyces cerevisiae* mating, the single-pass transmembrane protein Fus1p is transported to the plasma membrane by a mechanism requiring the peripheral membrane protein chitin synthase 5 (Chs5p) (1,2). In the absence of Chs5p, Fus1p no longer localizes to the plasma membrane but instead localizes to intracellular punctate structures, probably representing a late golgi compartment (2). We know that Chs5p functions with Chs6p to transport the cargo molecule Chs3p to the plasma membrane (3). We also know that Chs5p forms a complex *in vivo* with Chs3p, Chs6p, and three Chs6p-related proteins, YKR027w, Bud7, and YMR237w (see poster by S. Sanchatjate). Therefore, we hypothesize that Fus1p forms a complex with Chs5p and a Chs6p-like protein(s) and that transport of Fus1p to the plasma membrane requires a Chs6-like protein(s). We have found that Fus1p co-purifies with Chs5p *in vivo* and that the intracellular domain of Fus1p interacts with purified Chs5p *in vitro*. We have also found that the intracellular domain of Fus1p interacts with YMR237w and YKR027w in a yeast two-hybrid assay. Using fluorescence microscopy and a protease protection assay, we have analyzed Fus1p plasma membrane localization in cells mutant for one or more *CHS6*-related gene. Whereas single mutants have a wild-type Fus1p localization pattern, *bud7 YMR237w* double mutants are defective in Fus1p plasma membrane localization. Based on our biochemical and genetic data, we propose a model where Chs5p and Bud7p/YMR237w recruit Fus1p into a complex to transport Fus1p to the plasma membrane. 1. Trueheart *et al*. **Clathrin Participates in the Exit of a Subset of Cargo Proteins from the TGN**

S. Deborde, E. Perret, D. Gravotta, E. Rodriguez-Boulan; Ophthalmology, Weill Medical College of Cornell University, New York, NY

Clathrin coated vesicles are present not only at the plasma membrane but also at the trans Golgi network (TGN), considered a major segregation site for apical and basolateral proteins in polarized cells. Whereas the function of clathrin in the endocytic process has been extensively studied, its function at the TGN remains to be demonstrated. We disrupted the function of clathrin using MDCK cells stably transfected with FKBP-light chain a, which can be reversibly cross-linked with a permeable bifunctional reagent (Moskowitz et al., Mol Biol Cell, 2003). We first showed that the maturation of the lysosomal hydrolase cathepsin D was impaired upon addition of the cross-linker. We then investigated the role of clathrin on the exit from the Golgi complex of GFP-tagged basolateral membrane proteins NCAM and VSVG and apical membrane protein p75-NTR. MDCK cells were microinjected in the nucleus with cDNAs encoding the membrane proteins, which were accumulated in the TGN using a 20°C temperature block. We then measured the exit of the GFP-tagged protein from the Golgi at 32°C in presence or absence of the cross-linker. The cross-linker did not modify the exit of p75-GFP or VSVG-GFP, whereas it delayed the exit of NCAM. The half time of TGN emptying was

increased from 40 to 100 min. These experiments clearly demonstrate a role of clathrin at the TGN level and this effect is protein-specific.

1923

### GGA Function is Required for Membrane Remodeling and Substrate Processing in Maturing Neuroendocrine Secretory Granules

O. Kakhlon,[1] P. Sakya,[2] B. Larijani,[2] S. A. Tooze[1]; [1]Secretory Pathways Laboratory, Cancer Research UK, London, United Kingdom, [2]Cell Biophysics Laboratory, Cancer Research UK, London, United Kingdom

The recently described clathrin adaptor GGA (Golgi associated, γ-ear containing, ARF (ADP-ribosylation factor) binding protein) has been implicated in sorting of Mannose-6-Phosphate receptors (MPRs) from the trans-Golgi network (TGN) to endosomes. As secretory granule (SG) maturation has been proposed to involve formation of clathrin-coated vesicles (CCVs) from immature SGs (ISGs), we test here the effect of repression of GGA function on maturation of SGs in neuroendocrine cells. Overexpression of a truncated GFP tagged GGA, VHS-GAT-GFP, containing only the cargo (VHS) and ARF (GAT) interacting domains, led to retention of the SNAREs VAMP 4 and syntaxin 6 in mature SGs (MSGs). This suggested that membrane remodelling by ISG-derived CCV budding is down-regulated by the SG-localizing VHS-GAT-GFP. Furthermore, our flow cytometry data demonstrate that in VHS-GAT-GFP-expressing cells, Secretogranin II (SgII) processing in SGs is inhibited, and the positive correlation between the levels of the prohormone convertase 2 (PC2) and the SgII processing product p18 is abrogated. All these effects were not observed if full-length GGA1-GFP was overexpressed. Neither GGA1-GFP, nor VHS-GAT-GFP perturbed SG protein sorting in, or budding from the TGN. A new fluorescence-based ISG homotypic fusion assay demonstrates that repression of GGA function also does not affect homotypic fusion of ISGs. Lastly, reducing GGA3 levels by short interfering (si) RNA also down-regulated SgII processing by PC2. Our results suggest that when GGA activity is repressed SgII processing is compromised due to a specific inhibition of ISG-derived CCV budding. We propose that formation of CCVs from maturing SGs is required for the maintenance of SG function.

1924

### Dynamic Actin has Roles in Trans-Golgi Network Tubulation and Post-Golgi Carrier Budding

L. A. Hammond, J. L. Stow; Institute for Molecular Bioscience, University of Queensland, St Lucia, QLD, Australia

Post-Golgi carriers (PGC) bud from the trans-Golgi network (TGN) by a process of membrane tubulation. Proteins of the GRIP-domain golgin family selectively associate with these membrane tubules during this process and their GFP-tagged GRIP-domains serve as markers to study such events. Microtubules and a dynamic population of short actin microfilaments have been observed to associate with the TGN and with budding PGCs. Here we have examined the role of actin filaments and drug effects in membrane tubulation using real time epifluoresence and 4-dimensional confocal imaging. Cytochalasin D, latrunculin A and jasplakinolide all resulted in significant perturbation of membrane tubulation and PGC budding. The effect of actin targeting agents does not alter the velocities of tubule extension, which instead was shown to be a microtubule dependent event. In accordance with these findings, a close association between microtubules and short, dynamic actin microfilaments has been demonstrated. It is proposed that dynamic actin plays a role in the preliminary stages of PGC bud formation. However, once an initial bud has formed the emerging tubule becomes microtubule dependent to be drawn out and eventually detach.

## Endocytic Machinery: Structure, Function & Regulation (1925-1949)

1925

### Regulation of the Ubiquitin Ligase Itch by the Epidermal Growth Factor Receptor (EGFR)

B. A. Azakir, A. Angers; Biological Sciences, University of Montreal, Montreal, PQ, Canada

Endophilin is an endocytic protein first identified because of it Src homology 3 (SH3) domain and its interaction with dynamin and synaptojanin. Endophilin A1 promotes the epidermal growth factor receptor (EGFR) internalisation in a tripartite complex with cbl and CIN-85. Recently, we showed that endophilin A1 is a substrate for Itch, a HECT domain ubiquitin ligase. Upon activation of EGFR by EGF, Endophilin is translocated to endosomes where it colocalizes with Itch. Here, we show that like Endophilin, Itch itself is ubiquitinated upon stimulation with EGF. EGF-induced ubiquitination of both proteins is transient, but does not lead to proteasomal degradation as the proteasome inhibitor Lactacystin has no effect. Recently, it has been reported by others that the activated stress kinase JNK can phosphorylate Itch and increase its ubiquitin ligase activity. JNK can also be activated by EGF treatment. Endophilin is also involved in another JNK activation pathway through its binding to the Map 4 kinase GLK. We thus examined the effect of GLK and Endophilin overexpression on Itch autoubiquitination. We found that GLK activity led to increased Itch ubiquitination, and that Endophilin A1 could regulate the effect. Together, these data suggest that Itch activity can be regulated by endocytic processes involving Endophilin, tyrosine kinase receptors, and the JNK pathway.

1926

### The Ubiquitin Ligase Itch Binds and Is Regulated by the Ubiquitin Protease FAM

R. Moutchantaf,[1] B. Azakir,[1] P. S. McPherson,[2] S. A. Wood,[3] A. Angers[1]; [1]Biological Sciences, Montreal University, Montreal, PQ, Canada, [2]Neurology and Neurosurgery, Montreal Neurological Institute, Montreal, PQ, Canada, [3]Child Health Research Institute, North Adelaide, Australia

Itch is an ubiquitin ligase closely related to Nedd4, a HECT domain ligase implicated in the regulation of epithelial sodium channels by endocytosis. We have identified Itch as a binding partner of the endocytic accessory protein endophilin, and found it to be localized to endosomes and the trans-Golgi network (TGN) in mammalian cells. Using a GST-Itch affinity column and tandem mass spectrometry, we identified the ubiquitin-protease FAM as an Itch-binding partner. FAM (also known as Usp9x) is the mammalian homologue of *faf* in *Drosophila*, known to regulate the expression of the *Drosophila* epsin homologue and to thereby play a regulatory role in endocytosis. FAM also localizes to endosomes and the TGN where it overlaps significantly with Itch. We mapped the FAM-binding domain on Itch to the WW domains, small protein interaction modules usually involved in substrate recognition. However, upon co-expression of both proteins with ubiquitin in HEK-293T cells, we found that FAM is not ubiquitinated by Itch. Rather, Itch is readily auto-ubiquitinated, and this ubiquitination is fully reversed by the activity of FAM. We thus conclude that Itch is a substrate for the de-ubiquitinating activity of FAM. This observation suggests that FAM activity could stabilize the level of Itch protein in cells. Accordingly, we found that overexpression of FAM led to the accumulation of Itch in transfected cells. Likewise, expression levels of the proteins parallel each other in a variety of cell lines. We suggest that Itch is a functional substrate of FAM, and that this

interaction is important to regulate Itch and processes in which Itch has been identified as the ligase.

1927

**UIM-dependent Regulation of the Yeast Hrs Homologue, Vps27**

W. W. Lin, R. Dunn, R. Hostetler, L. Hicke; Biochemistry Molecular Biology & Cell Biology, Northwestern University, Evanston, IL

Endocytosis is a cellular process that regulates proteins involved in communication between the cell and its environment. Ubiquitin is a short polypeptide that can be covalently conjugated onto substrates to modify protein conformation, localization, and/or function. Ubiquitin plays a key role in multiple steps of endocytosis. It regulates receptor internalization at the plasma membrane and sorting at multivesicular endosomes (MVE) by acting as a cargo localization signal and regulating activity of endocytic machinery. These ubiquitin signals are recognized by ubiquitin-binding domains (UBD) that have been identified in many proteins along the endocytic pathway. In addition to recognizing the ubiquitin moiety in *trans*, ubiquitin-binding also promotes monoubiquitination in *cis*. The relationship between ubiquitin-binding by and ubiquitination of endocytic proteins has yet to be understood. In this study, we analyze this relationship by investigating how Vps27 ubiquitination is regulated and how monoubiquitination affects Vps27 function. Vps27 is an ubiquitin-binding vacuolar protein sorting (VPS) protein that is essential for cargo sorting at the MVE. Vps27 binds ubiquitin via two ubiquitin-interacting motifs (UIM). Vps27 is monoubiquitinated by the ubiquitin ligase Rsp5 in an uncharacteristic manner that is independent of Rsp5 C2 and WW domains. Ubiquitination of Vps27 is dependent on its UIMs and probably occurs on a series of lysines immediately N-terminal to the UIMs. Another UBD, the UBA domain, does not efficiently mediate ubiquitination of Vps27, but does replace ubiquitin-binding and rescues growth phenotypes of *vps27*-UIM mutants. Vps27 is also phosphorylated, and this modification does not require the UIMs. These findings suggest that while ubiquitination is dependent on the UIMs, the role of the UIMs in Vps27 function is predominantly in binding ubiquitin. Further characterization of the Vps27 UIMs and the lysine mutants will define the role of Vps27 ubiquitin-binding and how ubiquitin-binding is regulated.

1928

**Role of Hrs UIM-mediated Ubiquitin Signaling in the Coordination of Multiple Steps in Endosomal Trafficking**

J. W. Pridgeon, J. A. Olzmann, E. A. Kirk, L. Chin, L. Li; Department of Pharmacology, Emory University School of Medicine, Atlanta, GA

Ubiquitination plays a crucial role in the control of diverse cellular processes, and its defective regulation has been implicated in the pathogenesis of a variety of human diseases. However, the molecular mechanisms by which cells recognize and transmit ubiquitin signals remain poorly understood. The ubiquitin-interacting motif (UIM) is a conserved ubiquitin binding module found in many proteins, including hepatocyte growth factor regulated tyrosine kinase substrate (Hrs), a key component of the endosomal sorting machinery. Here we show that the Hrs UIM domain preferentially binds K48- and K63-linked polyubiquitin chains over monoubiquitin. By using an in vitro expression cloning (IVEC) screening approach, we have identified 47 ubiquitinated proteins that are specifically recognized by the UIM domain of Hrs. The validity and specificity of the IVEC screen have been confirmed by subsequent characterization of two identified proteins, Munc18-1 and Hsc70. Surprisingly, only a small fraction of the identified Hrs UIM-interacting ubiquitinated proteins are membrane cargo proteins. Major classes of the identified proteins include components of the vesicular trafficking machinery, cell signaling molecules, membrane protein-associated adaptor proteins, components of cytoskeleton and cytoskeleton-dependent transport, and enzymes involved in ubiquitination, lipid metabolism, and other metabolic processes. Furthermore, we have identified 6 novel proteins. Our results reveal the involvement of Hrs UIM-mediated ubiquitin signaling in the coordination of multiple steps in endosomal trafficking as well as in the regulation of cell signaling, cytoskeleton and membrane dynamics, and other cellular processes. Supported by NIH Grant NS047575

1929

**Ubiquitination of Hrs by a Novel UBE4B (E3) Ligase Involved in EGFR Degradation**

Q. Yan, W. Sun, Y. Lotfi, A. J. Bean; Neurobiology and Anatomy, University of Texas Health Science Center at Houston, Houston, TX

Altering the number of surface receptors can rapidly modulate cellular responses to extracellular signals. Some receptors, like the EGF receptor, are internalized after ligand binding and are transported to late endosomes/multivesicular bodies, where they either remain on the limiting membrane from where they may be recycled, or are sorted into luminal vesicles resulting in lysosomal degradation. This critical step in the sorting of internalized proteins on the limiting membrane of a multivesicular body is hypothesized to involve attachment and removal of ubiquitin sorting signals recognized by sorting complexes. We have observed a direct interaction between hrs, a protein that recruits both of the hypothesized sorting complexes to endosomal membranes, and an E3 ubiquitin ligase, UBE4B. Hrs recruits UBE4B to endosomal membranes where it binds saturably. UBE4B monoubiquitinates hrs both *in vitro* and *in situ* and a UBE4B mutant lacking the catalytic U-box acted in a dominant negative manner, inhibiting basal ubiquitination of hrs. Overexpression of UBE4B had no effect on the level of hrs protein compared to normal HeLa cells, nor were there alterations in the levels of other proteins that interact with either hrs or UBE4B such as actinin-4, Eps15, VCP, or Syntaxin13. These data suggest that the ubiquitination of hrs by UBE4B does not alter its stability. Overexpression of UBE4B or blocking the interaction of hrs and UBE4B by expressing a small fragment of hrs required for their binding affected EGFR degradation suggesting that the ubiquitination of hrs may affect the sorting machinery. Depletion of UBE4B also affected EGFR trafficking.

1930

**Hrs Interacts with the E3 Ubiquitin Ligase UBE4B**

Y. Lotfi, W. Sun, Q. Yan, A. J. Bean; Neurobiology and Anatomy, University of Texas Health Science Center at Houston, Houston, TX

The endocytic pathway can be separated into numerous stages based on the movement of cargo. Following transport from early to late endosomes, proteins to be degraded in the lysosome are internalized into the lumen of the late endosome via a process of membrane invagination and vesicle fission resulting in the formation of an organelle with a limiting membrane, (from which recycling occurs,) and intralumenal vesicles (that are degraded in lysosomes), called a multivesicular body (MVB). The sorting step at the limiting membrane of the MVB has been shown to involve ubiquitination. Hrs is an endosome-associated protein that functions to recruit proteins to the endosomal membrane that affect endosomal sorting/trafficking. Hrs interacts with a number of proteins including eps15, tsg101, SNAP-25 and STAM, all previously implicated in membrane sorting/trafficking. We have detected an additional interaction of hrs with the E3 ubiquitin ligase UBE4B. We identified the hrs-UBE4B interaction

using a two-hybrid screen and confirmed this interaction using immunoprecipitation and in vitro binding assays. UBE4B bound to hrs in the region between the FYVE domain and the coiled-coil region. We observed that when expressed alone, UBE4B is cytosolic and it is recruited to endosomal membranes when coexpressed with hrs, suggesting that hrs may recruit UBE4B to endosomes. In this regard, recombinant UBE4B bound saturably to endosomal membranes and this binding was blocked by addition of the fragment of hrs required for UBE4B binding. UBE4B is a member of the U-box protein family that mediates ubiquitination of various target proteins. We examined whether UBE4B might function to ubiquitinate hrs using in vivo and in vitro assays. We observed that UBE4B does ubiquitinate hrs. The effect of this ubiquitination on the function of hrs is under investigation.

1931

**HIM, a Novel Hrs-Interacting Molecule Implicated in Endosomal Trafficking**

E. A. Kirk, L. Chin, L. Li; Department of Pharmacology, Emory University School of Medicine, Atlanta, GA

Endocytic trafficking is crucial for cell development, immune response, and signal transduction. Internalized cell surface receptors are rapidly and efficiently sorted between recycling and degradative pathways. Despite recent progress in the identification of proteins involved in endocytic trafficking, the precise molecular mechanisms that govern sorting and transport of proteins to the lysosome remain poorly understood. Hepatocyte growth factor regulated tyrosine kinase substrate (Hrs) has recently been implicated as a key player in the regulation of endosomal cargo sorting and multivesicular body formation. In an effort to further understand the mechanism of action and regulation of Hrs, we performed a yeast two-hybrid screen to search for proteins that interact with Hrs. Here, we report the identification of a novel 105 kDa Hrs-interacting molecule named HIM. Unlike the ubiquitously expressed Hrs, HIM is detectable only in brain, heart, kidney, and testis, suggesting that HIM may be involved in tissue-specific regulation of Hrs function. We have confirmed the Hrs-HIM interaction by co-immunoprecipitation and mapped the binding domains of Hrs and HIM that mediate their association. Subcellular fractionation studies reveal the presence of HIM in membrane-associated pools and immunofluorescence confocal microscopic analyses demonstrate that HIM is partially co-localized with Hrs on early endosomes. Furthermore, overexpression of HIM inhibits ligand-induced degradation of the epidermal growth factor receptor (EGFR) without affecting either constitutive or ligand-induced receptor-mediated endocytosis. These results suggest that HIM is a functional partner of Hrs in the regulation of endosome-to-lysosome trafficking. This work is supported by NIH grant NS047575.

1932

**MTMR2 Interacts with hVPS34/p150 to Regulate Late Endosomal PI3P Formation**

C. Cao; Dept of Pathology, University of New Mexico Health Science Center, Albuquerque, NM

Phosphatidylinositol 3-phosphate (PI3P) plays a regulatory role in vesicular trafficking and cargo sorting by serving as a binding site for effector proteins containing phosphoinositide-binding domains. PI3P formation on late endosomes is initiated by active Rab7, which in turn regulates the activity of the hVPS34/p150 PI 3-kinase. The recruitment of myotubularin lipid phosphatases in response to localized PI3P synthesis serves to control endosomal PI3P levels. For proper late endosome function, the synthesis and degradation of PI3P must be tightly coordinated. Our data suggest a novel mechanism whereby the myotubularin lipid phosphatase related protein 2 (MTMR2) regulates late endosomal PI3P formation. Immunofluorescence staining shows that MTMR2 colocalizes with hVPS34 and Rab7. In vivo coimmunoprecipitation between MTMR2, hVPS34/p150 and rab7 demonstrate that both MTMR2 and Rab7 interact with p150 while they do not interact with each other. Furthermore, in vitro studies identify that an overlapping binding site consisting of the HEAT and WD40 domains of p150 mediates a competitive binding of MTMR2, or rab7, to p150. Our study suggests that MTMR2 regulates late endosomal PI3P formation through a competitive binding mechanism where Rab7 must be released from p150 to allow binding of MTMR2. Work supported by NSF MCB9982161 and UNMSOM.

1933

**PI3K-C2a Modulation of Clathrin Coated Membrane Dynamics**

Y. Zhao, J. H. Keen; Dept. of Biochemistry and Molecular Biology, Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, PA

Clathrin mediated membrane trafficking requires coordination of protein-protein and protein-lipid interactions in a precise spatial and temporal order. The Class II PI3K-C2α has recently been identified as a component of clathrin coated pits (CCPs) in cells, and its exogenous expression can both inhibit clathrin mediated membrane trafficking at the plasma membrane and trans-Golgi network, and induce the proliferation of novel, cytoplasmic clathrin coated structures (CCSs) (Gaidarov et al., *Molecular Cell*, 2001). Here we examine the interrelationship of PI3K-C2α expression and localization with the dynamics of clathrin coated membranes. siRNA-mediated knockdown of PI3K-C2α levels results in inhibition of endocytosis, confirming its involvement in the uptake pathway. At relatively low levels of exogenous expression, PI3K-C2α is enriched in forming CCPs in a stage-specific manner, and escorts endocytic cargos through endosomal compartments. At higher levels, PI3K-C2α is constitutively associated with clathrin, leading to stationary CCPs on the plasma membrane and highly motile, intracellular CCSs in the cytoplasm. The average speed of these CCSs is >10 times faster than that of canonical clathrin coated vesicles and endosomal buds. However, their rapid movement appears restricted to relatively short range, suggesting that they are novel, clathrin decorated structures. The PI3K-C2α-induced movement of intracellular CCSs is primarily microtubule-based, and assays reveal the existence of a complex between PI3K-C2α and dynactin subunits. These findings suggest that PI3K-C2α plays key roles in the coordination required for endocytic trafficking. By providing a structural link between clathrin coated membranes and the microtubule motor machinery, it is part of the molecular mechanism responsible for movement of plasma membrane and endosomal CCSs, and its lipid kinase activity is also likely to be functionally involved in modifying the local membrane environment of CCSs.

1934

**Characterization of Rab7 Interactions with Lipid Kinases and Phosphatases**

M. Tessema,[1] C. Cao,[1] M. Stein,[2] P. C. Simons,[1] L. A. Sklar,[1] A. Wandinger-Ness[1]; [1]Pathology, University of New Mexico, Albuquerque, NM, [2]Section of Microbial Pathogenesis, Yale University, New Haven, CT

Rab7 plays a pivotal role in endocytic transport, in part by regulating late endosomal phosphoinositide signaling and metabolism. GTP-bound Rab7 interacts with the human phosphatidyl inositol (PI) 3 kinase (hVPS34) and its adaptor protein (p150) and regulates the activity and function of the

hVPS34 kinase on late endosomes. The downstream lipid kinase, PIKfyve, also localizes on late endosomes and utilizes the hVPS34 product PI3P to produces PI3,5P. Late endosomal PI3P and PI3,5P are pivotal in recruiting trafficking cofactors and regulatory lipid phosphatases such as the myotublarins (MTMs). Like Rab7, MTM1 and MTMR2 interact with the WD40 domain of p150 and possibly compete for binding to the same domain. In order to further understand the kinetics of these interactions and obtain information about reaction equilibria and order of assembly of the multicomponent systems, we have developed a novel bead-based flow cytometry assay. We have tested the utility of this assay for monitoring protein-protein interactions using a GST-GFP fusion protein and glutathione loaded flow cytometry suitable sized beads (GSH-beads). The results indicate high-density GSH-beads stably bind GST-GFP only with a very slow off rates that resist several washing steps. Using flow cytometry, we were also able to accurately measure the binding and dissociation constants of GST-GFP to the GSH-beads. Therefore, application of this novel technology to quantitatively monitor the above mentioned interactions between Rab7 and its effector proteins will provide a new mechanistic insights into late endosomal regulation. This technology could also serve as key methodological advance for other protein-protein interaction assays.

1935

**Mapping and Functional Characterization of Phosphorylation Sites on the Endocytic Adaptor Protein Numb**

C. A. Smith,[1] S. Dho,[1] G. Brothers,[2] Y. She,[2] J. McGlade[1]; [1]Labatt Brain Tumor Research Center, Hospital for Sick Children, Toronto, ON, Canada, [2]Advanced Protein Technology Center, Hospital for Sick Children, Toronto, ON, Canada

Regulation of signaling from cell surface receptors is maintained, in part, by tight control over receptor protein levels at the plasma membrane. Receptors can be internalized by constitutive or receptor activation-dependent pathways. Following internalization, receptors are incorporated into intracellular vesicles that results in their removal from the plasma membrane and subsequent down-regulation. The vesicles are then sorted to the lysozome for degradation or recycled back to the cell surface. Attachment of ubiquitin or phosphoryl groups to the activated receptor or associated endocytic proteins often facilitates this sorting process. The adaptor protein Numb plays a role in cell fate determination during development primarily through antagonism of the Notch signaling pathway, and has recently been implicated in both clathrin-dependent and -independent trafficking pathways. The Numb protein contains multiple protein-protein interaction regions including a phosphotyrosine binding (PTB) domain, and precisely conserved endocytic motifs within the carboxy terminus. In *Drosophila*, Numb associates with the serine/threonine kinase NAK (Numb-associated kinase), an enzyme closely related to the adaptor-associated kinase (AAK), a regulator of clathrin mediated endocytosis. This suggests that Numb is a substrate for phosphorylation, and in support of this we observed a mobility shift in the Numb protein following agonist stimulation or with the addition of phosphatase inhibitors, indicating that Numb phosphorylation/dephosphorylation is dynamically regulated. To confirm that Numb is phosphorylated, *in vivo* labeling and phosphopeptide mapping experiments identified five tryptic phosphopeptide fragments in resting cells and two additional fragments following agonist stimulation. Furthermore, mass spectrometry has identified seven individual sites of phosphorylation. Using site-directed mutatagenesis, these residues have been mutated to alanine or glutamic acid to mimic phosphorylation and we are investigating the functional consequences of Numb phosphorylation on stability, localization and receptor trafficking.

1936

**Phosphatases and Kinases Regulate AP2 Binding and Release from Plasma Membrane**

Y. Yim, S. Scarselletta, E. Eisenberg, L. E. Greene; NHLBI, NIH, Bethesda, MD

Three different mechanisms have been described for inducing the dissociation of the clathrin adaptor AP-2 from clathrin-coated pits: phosphorylation of a mu chain tyrosine, dephosphorylation of multiple beta chain serines, and hydrolysis of $PI(4,5)P_2$ on the plasma membrane. To investigate the specific role of each of these mechanisms, we used a cell-free system to which addition of cytosol causes AP2 release and rebinding. While dephosphorylation of AP2 by protein phosphatase 2A (PP2A), which is thought to act on the mu chain, and phosphorylation of the AP2 by casein kinase II which is thought to act on the beta chain, both dissociated AP-2, removal or inhibition of cytosolic PP2A had no effect on AP-2 release. On the other hand, AP2 was dissociated when it was phosphorylated by a cytosolic kinase presumably acting on the beta chain and treatment of the cytosol with ATPgammaS prevented its rebinding suggesting that phosphorylation and dephosporylation is responsible for the AP-2 exchange caused by cytosol. In contrast, in the presence of $Ca^{2+}$ cytosol irreversibly dissociated AP-2. Inhibition of the cytosolic $Ca^{2+}$-activated phosphatase calcineurin prevented this effect and addition of pure calcineurin reproduced it. Calcineruin activates the $PI(4,5)P_2$ phosphatase synaptojanin, which then hydrolyzes $PI(4,5)P_2$. Thus, once $PI(4,5)P_2$ is hydrolyzed, cytosol is no longer able to induce rebinding of AP-2 to the pits. We conclude that $PI(4,5)P_2$ controls the formation and dissolution of clathrin-coated pits while the exchange cycle is controlled by a phosphorylation-dependent release and a dephosphorylation-dependent rebinding of AP2.

1937

**Biophysical Studies of the Yeast Endocytic Scaffold Pan1 to Characterize Phosphorylation-regulated Conformations**

B. Wendland,[1] J. M. McCaffery[2]; [1]Biology, The Johns Hopkins University, Baltimore, MD, [2]Biology and the Integrated Imaging Center, The Johns Hopkins University, Baltimore, MD

The yeast endocytic scaffold protein Pan1 binds to endocytic factors that are required for both early and late endocytic events. We and others have shown that Pan1 binds to clathrin adaptor proteins (early cargo-selection and coat assembly stages) and to actin regulatory factors (late vesicle formation and scission stages). Some of these binding events and the actin polymerization activity are regulated by Prk1-dependent phosphorylation. Pan1 can also interact with itself through a central oligomerization domain to form dimers or higher order oligomers. The N- and C-terminal regions of Pan1 also interact; when the N-terminal region is phosphorylated by the Prk1 kinase, the C-terminal Arp2/3 stimulation activity is blocked. Here, we describe studies that address how Prk1 phosphorylation of Pan1 alters Pan1-Pan1 interactions to yield a range of Pan1 conformations. Electron microscopy of negatively stained purified Pan1 ± Prk1 phosphorylation allowed us to observe distinct morphologies of Pan1 complexes. We also have yeast two-hybrid evidence that Prk1 phosphorylation can have either positive or negative effects on interactions between specific domains of Pan1. Finally, Pan1 purified from *prk1Δ* cells is more prone to proteolysis than is Pan1 purified from wild-type cells, again consistent with the existence of distinct conformations. We are currently assessing Pan1 oligomeric status by equilibrium ultracentrifugation, and are monitoring Pan1 conformations using limited proteolysis and mass spec analyses. A thorough characterization of Pan1 conformations and interactions will help in developing specific models that explain how Pan1 regulates the temporal coordination of proteins mediating the early and

late stages of endocytosis.

1938

**Clathrin Trimer Stability**

S. Perez-Miller, M. W. Drazer, J. A. Ybe; Indiana University, Bloomington, IN

Clathrin is a scaffolding molecule that functions in intracellular trafficking and sorting events. The native clathrin molecule is a pinwheel shaped trimer with rod-like heavy chain 'legs' that interact to form closed baskets around budding vesicles. A clathrin light chain subunit binds along each leg of the trimer, but the function of the clathrin light chain in endocytosis is poorly understood. Additionally, while integrity of the trimer is essential for normal clathrin function, in some cases trimerization has been found to be compromised in the absence of light chains. Our objective is to characterize the role of the clathrin light chain C-terminus. We have used native gel electrophoresis to monitor the oligomerization state of recombinantly expressed bovine clathrin hub (residues 1073-1675) with and without light chains. Clathrin hub alone fails to run as a single species but when the hub is incubated with light chains, the smearing is drastically reduced and a single band is observed. Light chain binding also confers resistance to detergent denaturation of hub. Sequence comparison with a muscle-specific isoform of clathrin that does not bind light chains reveals several amino acid differences in the trimerization domain. We have found that a T1585L substitution in bovine clathrin hub increases trimer stability, as evidenced by a single band on a native gel. We conclude that both light chain binding and specific heavy chain residues are important determinants of clathrin trimer stability. Further, gel filtration chromatography data show that the isolated C-terminal third of light chain binds to the clathrin hub. Based on these data and recently published results from other groups, we have formulated a working model for how the C-terminal third of the light chain contributes to clathrin trimer stability that is currently being tested using biophysical and cell-based approaches.

1939

**Structural Requirements for Signaling Properties of Dynamin-2**

F. Soulet,[1] S. L. Schmid,[1] H. Damke[2]; [1]Department of Cell Biology, The Scripps Research Institute, La Jolla, CA, [2]Department of Biochemistry, University of Nevada Reno, Reno, NV

The multi-domain GTPase dynamin is essential for endocytic vesicle formation. Increasing experimental evidence supports additional roles for the dynamin GTPases in cellular signaling processes linking dynamin to actin dynamics, cytoskeletal rearrangements, kinase pathways and other signaling events. In mammalian cells dynamin exists in three isoforms with additional splice variants that might attribute to these differential functions and represent forms of specialization. We have previously shown that the ubiquitously expressed isoform dynamin-2 induces p53-dependent apoptosis, when overexpressed ≤5-fold relative to endogenous levels, whereas dynamin-1 does not. Mutants of dynamin-2 that are defective in GTP binding (and defective in endocytosis) do not trigger apoptosis suggesting that increased levels of dynamin-2:GTP rather than protein levels per se are required. Dynamin-2 is 70% identical with the neuronal isoform dynamin-1. With the design of chimeric molecules between dynamin-2 and dynamin-1 we have now addressed the structural and functional requirements responsible for the apoptotic potential of dynamin-2. Surprisingly, not the most divergent C-terminal proline/arginine rich domain (PRD) that interacts with many SH3 domain-containing partners implicated in both endocytosis and signal transduction, but the highly conserved GTPase domain of dynamin-2 is sufficient to trigger apoptosis within the full-length molecule. An assembly-defective mutant of dynamin-2 retains its ability to induce apoptosis suggesting that dynamin-2 can act as a signaling molecule independent on its state of self-assembly. It remains to be shown on which signaling pathways dynamin-2 impinges to ultimately cause apoptosis.

**COPI Subunits Constitute Novel Class E *VPS* Genes Essential for Protein Sorting to Multivesicular Bodies in *Saccharomyces cerevisiae***

G. Gabrielly, R. Kama, J. E. Gerst; Molecular Genetics, Weizmann Institute of Science, Rehovot, Israel

Earlier studies proposed a non-conventional role for COPI (coatomer) in endocytosis in mammalian cells. In this study, we examined the requirement for specific COPI subunits in the late steps of endosomal protein sorting in yeast. Initially, we found that carboxypeptidase Y (CPY) was partially missorted to the cell surface in mutants of the COPI B sub-complex (COPIb: Sec27, Sec28, and Sec33), which indicates an impairment in endosomal transport. Next, we observed an accumulation of integral membrane proteins destined for the vacuolar lumen (*i.e.* CPS1, Fur4, and Ste2) at a late endosomal compartment and at the limiting vacuolar membrane in these same mutants. In contrast, Snc1 v-SNARE recycling through early endosomes to the Golgi was unaffected. Labeling with a lipophilic dye, FM4-64, revealed the accumulation of an enlarged endosomal compartment next to the vacuole in mutants of Sec27 and Sec28. These phenotypes are characteristic of class E vacuolar protein sorting (*vps*) mutants, which are impaired in multivesicular body (MVB) protein sorting and biogenesis. Finally, we found a physical interaction between COPIb subunits and MVB-associated protein, Vps27. We propose that COPIb subunit genes are novel members of class E *vps* family and predict their role in protein sorting to MVBs.

1941

**Essential Role of RGS-PX1/Sorting Nexin 13 in Mouse Development and Organization of Endocytic Compartments**

M. G. Farquhar; Cellular and Molecular Medicine, University of California San Diego, La Jolla, CA

RGS-PX1 (also known as sorting nexin 13) is a member of both the regulator of G protein signaling (RGS) and sorting nexin (SNX) protein families. Biochemical and cell culture studies have shown that RGS-PX1/SNX13 is able to attenuate Gαs-mediated signaling through its RGS domain and to regulate endocytic trafficking and degradation of the epidermal growth factor receptor through its sorting nexin activity. To understand the functions of RGS-PX1/SNX13 in vivo, we generated mice carrying targeted mutations of *Snx13* and found that systemic *Snx13*-null mice were embryonic lethal around E12.5. *Snx13*-null embryos had significant overall growth retardation and defects in neural tube closure and blood vessel formation. The mutant placentas were hypoplastic and showed defective labyrinthine layer formation. Moreover, the visceral yolk sac (VYS) endoderm cells in *Snx13*-null embryos showed dramatic changes in the organization of endocytic compartments, presence of autophagic vacuoles and abnormal localization patterns of several endocytic markers, including megalin, an endocytic receptor for multiple nutrients and proteins, ARH, a coat protein that binds clathrin and megalin, LAMP2, a lysosomal protein, and LC3, an autophagy marker. These changes in endocytic compartments in the VYS endoderm suggest that *Snx13*-null embryos are defective in nutrient uptake and transport, which may

contribute to the other developmental abnormalities observed. Taken together, our findings demonstrate an essential role of SNX13/RGS-PX1 in mouse development and provide new insights into its cellular function in the organization of endocytic compartments.

1942

**Retrograde Transport of Bacterial Toxins Through the Recycling Endosome**

J. McKenzie,[1] T. Taguchi,[2] D. Sheff[1]; [1]Pharmacology, Carver College of Medicine, University of Iowa, Iowa City, IA, [2]Osaka School of Medicine, Osaka, Japan

Bacterial toxins from cholera and shigella are heterohexamers that rely on retrograde transport for activity. Each contains a toxic alpha subunit that is delivered to the cytoplasm. Five beta subunits bind cell surface glycolipids and carry the alpha subunit through endosomes, Golgi and ER for cytoplasmic delivery. Golgi entry is rapid, within 45 minutes. Golgi exit is relatively slow, 3-6 hours for complete transfer of shigella toxin B subunits (shiga B). We examined whether Golgi passage is required for ER delivery, or merely kinetically favored thus overshadowing a possible direct endosome to ER pathway. We used $AlCl_4$, an inhibitor of transferrin traffic from the recycling endosome to the basolateral plasma membrane. Surprisingly, treatment also inhibited retrograde traffic of both shiga B and cholera B subunits. Traffic of both into the Golgi was delayed up to 2 hours. Because treatment with fluoride ions disrupts the medial Golgi, this effect may result from Golgi disruption. Therefore, we generated cytoplasts from BSC-1 cells and followed the traffic of shiga B. In cytoplasts lacking Golgi apparatus, the shiga B recycled to the plasma membrane, and was in endosomal structures, but did not colocalize with the ER even after 3 hours. Addition of $AlCl_4$ resulted in strong colocalization of shiga B and transferrin in regenerated recycling endosomes. Together these data suggest that passage through the Golgi is obligatory for both shiga and cholera toxins. Both utilize an $AlCl_4$ sensitive pathway to exit the recycling endosome, and presence of an intact Golgi is not required for exit from the recycling endosomes. Indeed, the sensitivity of both basolateral and retrograde traffic to $AlCl_4$ and re-rerouting of shiga toxin in cytoplasts suggests that the retrograde pathway may share features, such as Rab6 isoform dependence, with the basolateral pathway.

**Syntenin-$PIP_2$ Interaction Controls Arf6-dependent Syndecan Recycling and Cell Spreading**

P. L. Zimmermann,[1] Z. Zhang,[1] G. Degeest,[1] E. Mortier,[1] I. Leenaerts,[1] C. Coomans,[1] J. Schulz,[1] F. N'Kuli,[2] P. Courtoy,[2] G. David[1]; [1]CME, Kuleuven, Leuven, Belgium, [2]Cell Unit, Université Catholique de Louvain, Brussels, Belgium

Syndecans are heparan sulfate proteoglycans that modulate the activity of several growth factors and cell adhesion molecules. PDZ domains in the adaptor protein syntenin interact with the intracellular domain of the syndecans and with the phosphoinositide $PIP_2$, which is involved in the regulation of the actin cytoskeleton and membrane trafficking. Here, we investigated the relevance of the syntenin-$PIP_2$ interaction for the biology of the syndecans. We found that the interaction of syntenin's PDZ domains with $PIP_2$ controls the ADP-ribosylation factor 6 (Arf6)-mediated recycling of syndecan upon cell stimulation. Syntenin defective for $PIP_2$ binding, dominant-negative Arf6 (Arf6 T27N), or dominant-negative phosphatidylinositol 4-phosphate 5-kinase, all block syntenin/syndecan in recycling endosomes. Multiple adhesion and signaling molecules that bind to the heparan sulfate chains of the syndecans are likely to be trapped in these endosomes. FGF receptor accompanies syndecan along the syntenin-mediated recycling pathway, in a heparan sulfate- and FGF-dependent manner. Additionally, we found that syndecans that cannot recycle via the syntenin pathway affect cell spreading. Blocking syntenin-dependent syndecan-recycling using syntenin defective for $PIP_2$ interaction, syntenin loss-of-function, or syndecan defective for syntenin interaction inhibits cell spreading. The effect on spreading depends on the heparan sulphate substitution of the syndecans, suggesting it results from the trapping of syndecan-cargo involved in cell adhesion/signalling rather than from the trapping of syndecan itself. We propose that the link made here between syndecan, heparan sulfate-ligands, syntenin, $PIP_2$ and Arf6-dependent membrane recycling identifies one piece of the molecular framework by which syndecans control cell surface dynamics and behavior.

1944

**A Gene Silencing Strategy to Identify Regulators of Endosomal Cycling**

T. Galvez, J. T. Jones, W. Heo, J. W. Myers, M. Kim, J. Liou, T. Meyer; Molecular Pharmacology, Stanford University, Stanford, CA

Various surface proteins including G protein-coupled receptors, protein tyrosine kinases, channels and transporters cycle between the plasma membrane and endosomal compartments. By regulating the cycling capacities and rates for a specific receptor, cells can control the density of functional receptors at its surface and subsequently the properties of the signal it receives. In order to identify pivotal regulatory players of the membrane recycling machinery, we monitored changes in the properties of this machinery in response to perturbations of the cellular signaling networks using systematic gene silencing. A library of 1920 diced small interfering RNAs (d-siRNAs) was designed to target proteins containing conserved signaling motifs as annotated in the National Center for Biotechnology Information databases. The effect of each silencing was tested on the transferrin receptor (TfR1) recycling pathway in HeLa cells. TfR1 and its ligand cycle in minutes between the cell surface and endosomes and constitute an archetypical model to study endosomal recycling. The perinuclear accumulation after a 10 min pulse of fluorescently-labeled transferrin was measured by automated fluorescence microscopy and image processing and used as the main parameter to detect d-siRNA-induced perturbations. In order to estimate the statistical confidence that a given d-siRNA has a significant effect, we developed a simple variation of ANOVA called *CAsH* (for Confidence Analysis of siRNA Hits) that subtracts the noise distribution of the screen from the actual distribution of the data. Using this parameter we found as expected that multiple hits were known to act in clathrin-mediated endocytosis or in the delivery of receptors to the plasma membrane. Other significant hits are involved in actin polymerization, phosphatidyl-inositol metabolism or PP2A activity. This approach constitutes a framework to investigate how the regulation of endosomal cycling is linked to other cellular functions.

1945

**Arrestins Interact with Multiple ARF-GEFs**

G. Laroche, E. Dupré, J. Parent; Rheumatology Division, University of Sherbrooke, Fleurimont, PQ, Canada

Arrestins have recently been found to mediate a variety of receptor signaling and regulatory processes and to bind to a growing list of signaling and endocytic proteins. Originally characterized as being involved in desensitization of G protein-coupled receptors, arrestins have been shown by numerous studies to have a larger role in the biology of these receptors. Activation of small GTP-binding proteins such as Rho and ARF6 was

shown to be regulated by arrestins. ARF6 and its guanine nucleotide exchange factor (GEF) ARNO are known to bind to arrestins. Here we describe novel interactions between arrestins and multiple GEFs of the ARF1 and ARF6 proteins. The GEFs studied include cytohesin-1, GRP1, EFA6, and ARF-$GEP_{100}$. Co-immunoprecipitation experiments of myc-tagged ARF-GEFs with HA-tagged arrestins carried out in HEK293 cells reveal an interaction between all of the ARF-GEFs studied with arrestin-2 and arrestin-3. However, there is specificity in these interactions. ARF-$GEP_{100}$ interacts equally well with both arrestin-2 and arrestin-3. On the other hand the interaction of cytohesin-1, GRP1, and EFA6 is very strong with arrestin-2 but drastically weaker with arrestin-3. Immunofluorescence microscopy shows that arrestins, GRP1, and cytohesin-1 are distributed uniformly in the cytoplasm. In contrast, EFA6 displays strong plasma membrane localization whereas ARF-$GEP_{100}$ is found both at the membrane and in the cytoplasm. Merging of the images demonstrates that arrestins co-localize in the cytoplasm with GRP1, cytohesin-1 and ARF-GEP100, and weakly with EFA6 in a location that appears just underneath the plasma membrane. Contrary to what we have shown before for ARNO, co-expression of GRP1 and EFA6 do not appear to affect agonist-induced internalization of the G protein-coupled receptor for thromboxane $A_2$ in HEK293 cells. The role of these novel interactions, their specificity, and the possible involvement of arrestins in ARF1 activation will be discussed.

1946

### Gq Directly Interacts with ARNO and Activates ARF6

P. Giguère,[1] M. Rochdi,[1] G. Laroche,[1] E. Dupré,[1] M. R. Whorton,[2] R. K. Sunahara,[2] A. Claing,[3] G. Dupuis,[4] J. Parent[1]; [1]Rheumatology Division, University of Sherbrooke, Fleurimont, PQ, Canada, [2]Department of Pharmacology, University of Michigan Medical School, Ann Arbor, MI, [3]Department of Pharmacology, University of Montreal, Montreal, PQ, Canada, [4]Graduate Program of Immunology, University of Sherbrooke, Fleurimont, PQ, Canada

G-protein coupled receptors are widely expressed hepta-helical receptors with pleiotropic effects which are tightly regulated. Here we report a novel aspect of their regulation by a direct molecular interaction between a heterotrimeric G protein and a guanine nucleotide exchange factor (GEF) for the small GTPases of the ADP-ribosylation factor family (ARFs), namely ARNO (ARF nucleotide binding site opener). Immunofluorescence microscopy in HEK293 cells showed that Gq and ARNO co-localized intracellularly in the basal state. On the other hand, the constitutively active Gq-R183C mutant localized to the plasma membrane and induced the translocation of ARNO from intracellular compartments to the plasma membrane. Interestingly, co-immunoprecipitation studies revealed that ARNO and ARF6 formed complexes preferentially with activated Gq compared to non-activated Gq. Binding experiments using purified proteins showed that Gq interacted directly with ARNO. Agonist treatment of the Gq-coupled thromboxane $A_2$ receptor triggered ARF6 activation, which was prevented by the sequestration of Gq. We previously demonstrated that internalization of this receptor required Gq signaling through a phospholipase Cβ- and protein kinase C-independent mechanism. Here we show that expression of ARNO and ARF6 promoted, whereas dominant negative mutants of these proteins inhibited the internalization of the thromboxane $A_2$ receptor. Taken together, our results indicate that stimulation of the thromboxane A2 receptor activates Gq which in turn leads to activation of ARF6 through ARNO, ultimately triggering internalization of the receptor. Thus in the present study, we elucidate for the first time how a heterotrimeric G protein can activate a small G protein of the ARF family. This mechanism could be a widely used signaling pathway involved in the regulation of intracellular trafficking events.

### Mutational Analysis of *Drosophila* Rab GDI and its Interaction with Gint3, a UBX-domain Containing Protein

D. J. Holtzman, A. K. Moore, A. Chen, B. E. Richardson, K. L. Ayres, N. F. Sangji, M. L. Keese, C. M. Cheney; Biology, Pomona College, Claremont, CA

Rab GTPases play multiple roles in vesicle transport. Rab GDP dissociation inhibitor (GDI) regulates rab placement by retrieving rabs from target membranes and delivering rabs through the cytoplasm to donor membranes. GDI plays a crucial role in ensuring that the correct rab is placed in the correct membrane. It is hypothesized that the GDI-rab complex must interact with a membrane bound receptor complex that triggers the release of rab from GDI. To identify proteins in such a complex, we have carried out screens for GDI interactors, using Drosophila as the model system, since the fly genome has a single GDI, but multiple rabs. In a yeast two-hybrid (Y2H) screen, using wild-type GDI in a pLexA vector as bait and screening a Drosophila cDNA library, a protein with a ubiquitin-like UBX domain was identified as a GDI interactor. This protein was named Gint3, for GDI interacting protein 3. Gint3 has a PUG N-glycanase-associated domain and a UBX ubiquitin-like domain, but no obvious transmembrane domain. Gint3 interacted with L319 mutant GDI, which has a mutation that alters the lipid-binding pocket of Domain II of GDI (Ricard et al, Genesis 31:17), but did not interact with a non-specific prey, human lamin C. Interaction was also seen when Gint3 was placed in the bait vector and GDI in the prey vector. GDI interacted with Gint3 in a LexA Y2H system as well as in a GAL4 Y2H system. Phylogenetic analysis of Gint3 and UBX domain proteins shows that Gint3 forms a distinct subfamily of UBX domain proteins with the highest bootstrap value. Supported by NSF-RUI grant 0212730 to CMC.

### RhoB Effector Mutants and their Effects on Post-Endocytic Traffic in Polarized MDCK Cells

C. Rondanino, W. G. Ruiz, C. J. Mazur, G. Apodaca; Medicine/ Cell Biology and Molecular Physiology, University of Pittsburgh, Pittsburgh, PA

Endocytic traffic is highly regulated in epithelial cells. RhoB, a member of the Rho family of GTPases, modulates post-endocytic events in many cells including polarized Madin-Darby Canine Kidney (MDCK) cells. In those cells, expression of a dominant active mutant of RhoB (RhoBV14) decreases transcytosis, receptor recycling and degradation while a dominant negative mutant of RhoB (RhoBN19) has a stimulatory effect. However, the mechanism by which RhoB mediates these processes is unknown. We hypothesize that RhoB acts through downstream effectors. We have stably expressed RhoBV14 bearing point mutations in the effector binding domain. Such mutations selectively disrupt RhoB binding to various known effectors: Rho-kinase, Rhophilin, Kinectin, Citron, mDia, and PKN. The effect of these mutants on post-endocytic traffic was measured. In cells overexpressing RhoBV14Y37 (which cannot bind any known RhoB effectors), we observed a significant slowing of IgA transcytosis and a decrease in the plateau level by 15% relative to control non-expressing cells. Transferrin recycling was also slowed but the absolute amount of recycled transferrin was not altered. These results suggest that unknown RhoB effectors are involved in the regulation of those pathways. Similar results were obtained with the mutant RhoBV14A39 that interacts specifically with mDia, suggesting that this protein has no regulatory role. Interestingly, in cells that express RhoBV14V39 that binds to both mDia and Rho-kinase, the extent of IgA transcytosis and

transferrin recycling was impaired by approximately 30% and 15%, respectively. We propose that RhoB acts through yet unknown effectors to modulate post-endocytic traffic in MDCK cells and that Rho-kinase could also be involved as well. We are currently conducting a yeast-two hybrid experiment to identify novel RhoB binding partners.

1949

### The *Tetrahymena thermophila* Phagosome Proteome

L. A. Klobutcher,[1] M. E. Jacobs,[1] L. DeSouza,[2] K. W. M. Siu[2]; [1]MMS Biology, University of Connecticut Health Center, Farmington, CT, [2]Department of Chemistry and Centre for Research in Mass Spectrometry, York University, Toronto, ON, Canada

In vertebrates, phagocytosis plays a role in the immune response, tissue development, and the removal of apoptotic cells. In lower eukaryotes, phagocytosis provides a means of ingesting other microorganisms to meet the nutritional needs of the cell. Research in a number of experimental systems indicates that phagocytosis is a multistep process that involves hundreds of genes and proteins, but the identities and functions of the proteins mediating phagocytosis are still incompletely understood. As a result, we have been analyzing the protein composition of phagosomes in the ciliate *Tetrahymena*. To purify phagosomes, the *Tetrahymena* cells were first fed latex beads. Following lysis of the cells, sucrose gradient centrifugation was employed to separate the bead-filled phagosomes from other cellular components. Proteins and/or tryptic peptides derived from the phagosomal preparations were then subjected to three different two-stage fractionation procedures followed by tandem mass spectrometry (MS/MS). The resulting mass spectra were compared to either conceptual translations of the entire *Tetrahymena* macronuclear genome sequence or the predicted total cellular proteome to identify proteins present in phagosomes. To date, more than 80 proteins with significant similarity to proteins of known function have been identified. This includes more than 25 proteins known to be associated with phagosomes in other experimental systems, providing an indication that *Tetrahymena* phagocytosis shares similarities with other organisms. In addition, 17 proteins proteins of unknown function have been identified, which are candidates for novel phagosome proteins. We are now beginning to utilize the strong genetic/molecular genetic tools available in *Tetrahymena* to generate strains with knockout or knockdown mutations in putative phagosome genes to obtain insight into their functions. In addition, strains with GFP-tagged versions of phagosome proteins are being generated to determine their cellular localization.

## Protein Targeting to the Endocytic Pathway (1950-1967)

1950

### Effector Binding Determines Rab GTPases Localization

D. A. Aivazian, R. L. Serrano, S. R. Pfeffer; Biochemistry, Stanford University, Stanford, CA

Rab GTPases regulate transport vesicle formation, motility, docking and fusion. Hypervariable domains are thought to specify the distinct localizations of Rab GTPases. We have found that the primary determinant of Rab localization is effector interactions, which need not involve hypervariable domain sequences. Effectors are proteins that bind preferentially to GTP-bearing Rabs. Rab9, Rab5 and Rab1 chimerae, containing heterologous hypervariable domains were generated; we quantitated their ability to bind a number of Rab effectors. In all cases, intracellular localization of the chimerae correlated with the capacity for specific Rab effector interaction. Moreover, intracellular concentrations of Rab effectors determined the localization of two different chimeric Rabs that could bind to the effectors of two different Rab proteins. These data rule out a simple model for an organelle-specific Rab receptor, and support the view that Rabs participate in complex and dynamic, protein:protein and protein:lipid, microdomain interactions that are important both for steady state Rab localization and the specialized functions of subcellular compartments.

1951

### Involvement of Rab5 and Rab11 in the Trafficking of H-Ras to Recycling Endosomes in CHO-K1 Cells

G. A. Gomez, J. L. Daniotti; Departamento de Química Biológica, CIQUIBIC (CONICET-UNC), Facultad de Ciencias Químicas, Universidad Nacional de Córdoba, Córdoba, Argentina

H-, N- and K-Ras are isoforms of Ras proteins, which undergo different lipid modifications at the C-terminus. These post-translational events make possible the association of Ras proteins both with the inner plasma membrane and to the cytosolic surface of endoplasmic reticulum and Golgi complex, which is also required for the proper function of these proteins. To better characterize the intracellular distribution and sorting of Ras proteins, constructs were engineered to express the C-terminal domain of H- and K-Ras fused to variants of green fluorescent protein. Using confocal microscopy, we found in CHO-K1 cells that H-Ras, which is palmitoylated and farnesylated, localized at the recycling endosome in addition to the inner leaflet of the plasma membrane. In contrast, K-Ras, which is farnesylated and non-palmitoylated, mainly localized at the plasma membrane. We demonstrate that sorting signals of H- and K-Ras are contained within the C-terminal domain of these proteins, and that palmitoylation on this region of H-Ras might operates as a dominant sorting signal for proper subcellular localization of this protein. Using selective photobleaching techniques, we demonstrate the dynamic nature of H-Ras trafficking to the recycling endosome from plasma membrane. We also provide evidence that Rab5 and Rab11 activities are required for proper delivery of H-Ras to the endocytic recycling compartment. Using a chimera containing the Ras binding domain of c-Raf-1 fused to a fluorescent protein, we found that a pool of GTP-bounded H-Ras localized on membranes from Rab11-positive recycling endosome after serum stimulation. These results suggest that H-Ras present in membranes of the recycling endosome might be activating signal cascades essential for the dynamics and function of the organelle. 1952

### The Dileucine Motif and AP-2 are Required for Efficient Endocytosis of $\beta_2$-adrenergic Receptors

H. O. Awwad, B. J. Knoll; Pharmacological & Pharmaceutical Sciences, University of Houston, Houston, TX

Agonist-activated $\beta_2$-adrenergic receptors ($\beta_2$ARs) recruit β-arrestin, a scaffolding protein, to form a β-arrestin-receptor complex. This complex then recruits adaptor proteins, mainly AP-2, at the plasma membrane for clathrin-mediated endocytosis. AP-2 is a heterotetrameric adaptor protein complex that binds to β-arrestin, clathrin, phosphoinositides and certain transmembrane proteins. The dileucine sorting motif is a recognition signal

for AP-2 binding. The fourth intracellular loop of $\beta_2$ARs has a conserved dileucine motif, at residues 339 and 340, known to be involved in receptor internalization. The role of AP-2 has been studied using dominant negative mutational analyses. However, the effect of silencing AP-2 by RNA interference on $\beta_2$AR internalization has not been studied yet. Our objective was to study the effect of AP-2 silencing on the internalization of $\beta_2$ARs and mutant $\beta_2$ARs with the dileucines changed to dialanines (LLAA). HEK293 cells stably expressing $\beta_2$ARs or LLAA $\beta_2$ARs were treated with short interfering RNA (siRNA) targeting the μ2 subunit of AP-2. By immunofluorescence microscopy, we show that silencing AP-2 inhibits agonist-induced $\beta_2$AR internalization, as well as transferrin internalization. LLAA $\beta_2$ARs showed reduced internalization in radioligand binding assays, which was further reduced upon treatment with siRNA targeting the AP-2. In addition, LLAA $\beta_2$ARs show reduced G-protein coupled receptor kinase (GRK) site phosphorylation and slower β-arrestin recruitment. The absence of either the dileucine motif or AP-2 complex alone reduces $\beta_2$AR internalization, however the absence of both almost abolishes $\beta_2$AR internalization in an additive manner. We conclude that both the dileucine motif and AP-2 complex are required for efficient $\beta_2$AR internalization. Supported by a grant from the American Heart Association, Texas Affiliate 0455072Y

**Identification of Sorting Determinants at the C-Terminal Cytosolic Tail of Mucolipin-1**

S. Vergarajauregui, R. Puertollano; Laboratory of Cell Signaling, NHLBI, National Institutes of Health, Bethesda, MD

Mucolipidosis type IV (MLIV) is an autosomal recessive lysosome storage disorder characterized by severe psychomotorretardation and oftalmological abnormalities, including corneal opacity, retinal degeneration, and strabismus. Unlike the situation in other lysosomal disorders, the accumulation of heterogeneous storage material observed in MLIV does not result from the block in the catabolic pathways, but is due to a transport defect in the late steps of endocytosis. MCOLN1, the gene mutated in MLIV patients, encodes a protein called mucolipin-1 that functions as a Ca2+ permeable channel and has been implicated in the biogenesis of lysosomes. However, it is important to note that very little is known about the factors that regulate the intracellular trafficking and final distribution of mucolipin-1. In this study we have analyzed the presence of sorting motifs in the C-terminal tail of mucolipin-1 by using a chimera consisting of the extracellular and transmembrane regions of Tac fused to the C-terminal cytosolic tail of mucolipin-1. We have found that the C-terminal tail of mucolipin-1 contains sorting information for location at early endosomes. This localization is dependent on a di-leucine motif, which mediates internalization of the Tac-MLN Tail chimera. Mutation of the di-leucine to alanines or depletion of AP2 from Hela cells caused retention of Tac-MLN Tail at the plasma membrane. Also, the C-terminal tail of mucolipin-1 fused to GFP associates with intracellular membranes. It seems that palmitoylation of three cysteine residues mediates recruitment of GFP-MLN Tail to membranes. Mutation of these cysteines to alanines inhibits internalization of Tac-MLN Tail. We concluded that the C-terminal tail of mucolipin-1 contains a di-leucine internalization motif that mediates the endocytosis of Tac-MLN Tail chimera through an AP2 dependent pathway and palmitoylation might play a role on mucolipin-1 trafficking by promoting endocytosis.

1954

**The FDNPVY Sequence of LDLR Is Not Required for VLDL Metabolism in Fibroblasts**

P. Michaely,[1] W. Li,[1] R. Anderson,[1] H. Hobbs,[2] J. Cohen[3]; [1]Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX, [2]Molecular Genetics, University of Texas Southwestern Medical Center, Dallas, TX, [3]Human Nutrition, University of Texas Southwestern Medical Center, Dallas, TX

The LDLR is the principal receptor that mediates the clearance of LDL and VLDL from the circulation. Internalization of LDL requires the $FDNPVY^{807}$ sequence on the LDLR cytoplasmic tail and mutation of the tyrosine to cysteine (Y807C) is associated with hypercholesterolemia. Here, we tested whether the FDNPVY sequence is also required for VLDL binding, uptake and degradation. Fibroblasts from individuals expressing either normal, Y807C or no LDLR ($LDLR^{-/-}$) were studied. Using $^{125}$I-VLDL assays, we show that the Y807C mutation had little effect on the ability of fibroblasts to bind or degrade VLDL. Uptake was examined by electron microscopy using colloidal gold labeled VLDL (VLDL-gold) and we observed that VLDL-gold accumulated in late endosomes of Y807C cells in a manner similar to that of normal cells. This internalization was specific to VLDL because LDL-gold did not accumulate in late endosomes of Y807C fibroblasts and $^{125}$I-LDL degradation was sharply reduced in these cells. Uptake and degradation of VLDL was LDLR dependent because we did not observe uptake or degradation of $^{125}$I-VLDL or VLDL-gold in $LDLR^{-/-}$ cells. We next examined the surface distribution of LDLR and the distribution of LDLR bound LDL and VLDL using LDLR immunogold, LDL-gold and VLDL-gold, respectively. We observed similar enrichment of VLDL in coated pits of both normal and Y807C cells, while only coated pits of normal cells were enriched with LDL and LDLR. We conclude that the FDNPVY sequence of the LDLR is not required for VLDL to be targeted to coated pits, internalized and degraded.

1955

**Biosynthetic and Endocytic Targeting to the Recycling Endosomal Compartment Involves a Critical Glutamic Acid Residue within the Cytoplasmic Tail of Prostate Specific Membrane Antigen**

J. J. Christiansen,[1] J. R. Goldenring,[2] A. K. Rajasekaran[1]; [1]Department of Pathology and Laboratory Medicine, University of California, Los Angeles, Los Angeles, CA, [2]Department of Surgery, Vanderbilt University, Nashville, TN

Prostate specific membrane antigen (PSMA) is a 100kDa glycoprotein with a highly restricted profile of tissue expression. In addition to the benign prostatic epithelium, PSMA is expressed in tumor-associated neovasculature and at increased levels in most cases of prostate cancer. We have previously demonstrated PSMA is targeted for clathrin-mediated endocytosis via a novel MXXXL motif and subsequently recycled back to the cell surface. The recycling of membrane proteins and receptors may either occur directly from the early endosomes or via a more indirect route. Some membrane proteins are first targeted to a tubulovesicular membrane compartment, referred to as the recycling endosomal compartment, or REC. The REC is a microtubule dependent structure proximal to the nucleus and associated with the centrosomes in both polarized and nonpolarized epithelial cells. The REC contains proteins internalized from both the apical and basolateral plasma membrane surfaces of polarized epithelial cells, however, the mechanisms and signals responsible for targeting of proteins to the REC is not well understood. In the current study, we demonstrate that PSMA is localized to the REC and that targeting to this compartment requires a critical glutamic acid residue within the cytoplasmic domain. Furthermore, our data indicate that while mutation of the PSMA endocytic motif effectively abolishes internalization from the plasma membrane, these mutant forms of PSMA continue to localize to the REC at steady state. Thus, we provide evidence that targeting to the REC can occur

independent of endocytosis and provide insight into the regulation and dynamic nature of this intermediate trafficking compartment.

1956

**The Endosome-Associated Protein Hrs is Hexameric and Exists to Increase Cargo Trafficking**

L. Pullan,[1] S. Mullapudi,[1] Z. Huang,[1] P. R. Baldwin,[1] C. Chin,[2] W. Sun,[3] S. Tsujimoto,[3] S. J. Kolodziej,[4] J. K. Stoops,[4] J. C. Lee,[2] M. N. Waxham,[3] A. J. Bean,[3] P. A. Penczek[1]; [1]Biochemistry and Molecular Biology, University of Texas - Houston Medical School, Houston, TX, [2]Human Biological Chemistry and Genetics, University of Texas Medical Branch, Galveston, TX, [3]Neurobiology and Anatomy, University of Texas - Houston Medical School, Houston, TX, [4]Pathology, University of Texas - Houston Medical School, Houston, TX

The first structure of the endosomal associated protein, Hrs, has been determined using cryo-electron microscopy and single particle analysis. Hrs physically interacts with a number of proteins, including eps15, SNX-1, and SNAP-25 that are involved in membrane trafficking. It also interacts with STAM1 forming a complex which binds ubiquitin moieties and acts as sorting machinery that recognizes ubiquitinated receptors and transfers them to further sequential lysosomal sorting/trafficking processes. Through the interaction with SNAP-25, Hrs is able to inhibit endosomal fusion. Analytical ultracentrifugation has revealed that Hrs exists as a hexamer in cells with no evidence for the monomeric state. The purified hexameric form of the Hrs was imaged using a 300 kV electron microscope and its 3-D structure was determined using single particle reconstruction method. First, using principal component analysis of the two-dimensional EM images we have determined that the symmetry of the hexameric structure is D3. Subsequently, we determined the three-dimensional EM density map that revealed that the structure of the hexameric Hrs is barrel-shaped with a central core and distinct caps on either end of the barrel, and is made up of three antiparallel dimers. With a slight rearrangement of its quaternary structure, the crystal structure of the FYVE and VHS domains fits into the Hrs end caps in the EM density map. This clearly indicates that the domains which interact with the endosomal membrane are located to facilitate the anchorage of Hrs to the membrane, thereby, initiating the functional processes of Hrs on the endosome. Based on our model, the location of the individual UIM domains of Hrs within the hexamer allows for increasing levels of ubiquitin binding and therefore allows for greater trafficking of cargo via endocytosis.

**Phosphatidic Acid Induces Endocytosis of Inactive EGF Receptors through the cAMP/PKA Pathway**

A. Silva, A. Norambuena, J. Valenzuela, A. González; Depto. Reumatología. Fac. Medicina. Centro de Regulación Celular y Patología, Fac. Ciencias Biologicas. P. Universidad Católica de Chile and MIFAB., Santiago, Chile

The endocytic pathway provides mechanisms for attenuating external stimuli as well as bestowing temporal and spatial determinants on the EGFR signaling system. Ligand-binding activates the intrinsic tyrosine-kinase activity of the receptor and induces endocytosis of active receptors. We have described that inhibition of basal PKA activity induces endocytosis of EGFR in the absence of ligand. Therefore, the endocytic pathway could also serve to control the permanency of empty EGFR at the cell surface through a mechanism sensitive to the activation status of the cAMP/PKA system. Phospholipase D (PLD) through its product phosphatidic acid (PA) participates in several vesicular trafficking processes, including the ligand-induced EGFR endocytosis, via activation of specific phosphatidylinositol kinases. However, PA also activates the phosphodiesterase (PDE) 4D3, from the PDE4 family of rolipram-sensitive PDEs that degrade cAMP. We found that: a) propranolol and disipramine used as inhibitors of the enzyme that degrades PA, provoked the expected increase in PA levels and decrease in cAMP levels and PKA activity, while increasing the endocytosis of inactive EGFR; b) Micelles of PA also induced EGFR endocytosis; c) The constitutive endocytosis of transferrin and the ligand-induced endocytosis of mu-opioid receptors did not respond to PA; c) forskolin and rolipram diminished the EGFR endocytosis induced not only by propranolol but, strikingly, also by EGF. These results indicate that a PDE4-mediated link between the PA and the cAMP/PKA systems constitutes a novel EGFR regulatory mechanism, that can reversibly control the relative distribution of empty and inactive EGFR between the cell surface and endocytic compartments. This mechanism is potentially amenable to modulation by the multiple factors that can increase the cellular PA levels, including stimuli to the EGFR itself (Financed by FONDAP grant: 13980001 and MIFAB).

**Regulation of EGF Receptor Downregulation by UBPY-mediated Deubiquitination at Endosomes**

E. Mizuno, T. Iura, A. Mukai, N. Kitamura, M. Komada; Department of Biological Sciences, Tokyo Institute of Technology, Yokohama, Japan

Ligand-activated receptor tyrosine kinases undergo endocytosis and are transported to endosomes, where they are sorted for lysosomal degradation. This “receptor downregulation” process is crucial to terminate the cell proliferation signals produced by activated receptors. At endosomes, ubiquitination of the receptors serves as a lysosomal sorting signal, which is recognized by a complex of two ubiquitin-binding proteins, Hrs and STAM. We have previously shown that the Hrs-STAM complex binds a functionally uncharacterized deubiquitinating enzyme UBPY (ubiquitin-specific protease Y)/USP8 (ubiquitin-specific protease 8). In this study, we examined the role of UBPY in the downregulation of epidermal growth factor receptor (EGFR). UBPY overexpression reduced the ubiquitination level of EGFR and delayed its degradation in EGF-treated cells. Immunopurified UBPY also deubiquitinated EGFR in vitro. UBPY bound to ubiquitinated EGFR in EGF-treated cells, whereas a UBPY mutant that cannot associate with the Hrs-STAM complex did not. In addition, the binding of UBPY to EGFR was reduced in Hrs-depleted cells, suggesting that the interaction with the Hrs-STAM complex is required for UBPY to interact with EGFR. Immunostaining of HeLa cells using anti-UBPY antibody showed that endogenous UBPY localized on exaggerated endosomes caused by the overexpression of Hrs or a dominant-negative mutant of SKD1, proteins that play roles in the endosomal sorting of ubiquitinated receptors. In addition, a catalytically-inactive UBPY mutant clearly localized on endosomes in normal as well as in Hrs-depleted cells, suggesting that the endosomal localization of UBPY is not mediated by the Hrs-STAM complex. Finally, the ubiquitination level of ligand-activated EGFR was elevated and its degradation was accelerated in cells in which endogenous UBPY was depleted by RNAi. These results suggest that UBPY deubiquitinates EGFR on endosomes and regulates the rate of EGFR downregulation.

1959

***FcRn* as a Regulator of *IgG* Trafficking: Analyses of Intracellular Sorting Events**

P. Prabhat*,[1,2] Q. Tang*,[1] Z. Gan,[1] Y. Chao,[1] R. J. Ober,[1,2] E. S. Ward[1]; [1]Center for Immunology, University of Texas Southwestern Medical Center, Dallas, TX, [2]Department of Electrical Engineering, University of Texas at Dallas, Richardson, TX

The Fc receptor, FcRn, plays a pivotal role in regulating the serum levels of immunoglobulin G (IgG) in mice, and much data support the concept that the human ortholog serves a similar function. FcRn also transports IgGs across cellular barriers to diverse body sites. The current model for FcRn function is that following uptake of IgGs into cells by fluid phase pinocytosis, IgGs bind to FcRn in early endosomes and are salvaged from lysosomal degradation (1). FcRn bound IgGs are subsequently trafficked to the cell surface and released by exocytosis (2). The question arises as to how FcRn acts as a salvage receptor in cells. The pH dependence of the IgG-FcRn interaction (tight binding at pH 6.0 that becomes progressively weaker as near neutral pH is approached) distinguishes this interaction from other classically studied receptor-ligand systems for which the trafficking pathways have been elucidated. In the current study we have used biotinylated IgG-quantum dot complexes in combination with live cell fluorescence imaging of FcRn-GFP transfected endothelial cells to analyze the sorting events in early endosomes. The use of quantum dots has allowed us to track intracellular processes for relatively long time periods, which in turn has led to insight in the molecular mechanisms of endosomal sorting. 1. **Analyses of the Involvement of the *Fc* Receptor, *FcRn*, in the Trafficking of Albumin in Human Endothelial Cells**

Q. Tang,[1] Z. Gan,[1] J. Zhou,[1] C. Vaccaro,[1] R. J. Ober,[1,2] E. S. Ward[1]; [1]Center for Immunology, University of Texas Southwestern Medical Center, Dallas, TX, [2]Department of Electrical Engineering, University of Texas at Dallas, Richardson, TX

Albumin is the most abundant serum protein that serves to regulate both the osmotic balance and transport a wide array of proteins, lipids and metabolites to different body sites. Despite the important functions of albumin, the mechanisms that maintain relatively constant serum levels of this protein are poorly understood. Recent studies in mice have suggested that the MHC Class I-related receptor, FcRn, plays a role in controlling albumin levels in an analogous way to that described for immunoglobulin G (IgG) (1). For IgG, FcRn has been shown to act as a salvage receptor that binds to pinocytosed IgG in early endosomes and salvages the bound ligand from lysosomal degradation (2). FcRn bound IgGs are subsequently trafficked to the cell surface and released by exocytosis (3). In the current study we have used live cell fluorescence imaging of FcRn-GFP transfected endothelial cells to analyze the intracellular trafficking of Alexa (546 or 647) labeled albumin. Triple color experiments have also been used to compare the intracellular routes taken by albumin with those followed by IgGs of different affinities for FcRn binding. Our studies provide insight into the processes that are involved in albumin trafficking. 1. Chaudhary, C. *et al., J. Exp. Med.,* **197**, 315-322 (2003). 2. Ober, R.J. *et al., J. Immunol.,* **172**, 2021-2029 (2004). 3. Ober, R.J. *et al., Proc. Natl. Acad. Sci. USA*, **101**, 11076-11081 (2004). Supported by grants from the NIH (R01 AI39167, R01 AI50747 and R01 AI55556).

**The Exocyst Complex Regulates Multiple Post-Endocytic Trafficking Pathways in Polarized MDCK Cells**

A. Oztan,[1] S. Hsu,[2] C. Yeaman,[3] G. Apodaca[1]; [1]Department of Medicine, University of Pittsburgh, Pittsburgh, PA, [2]Department of Cell Biology and Neuroscience, Rutgers University, Piscataway, NJ, [3]Department of Anatomy and Cell Biology, University of Iowa, Iowa City, IA

The exocyst is an octomeric complex that regulates delivery of newly synthesized proteins to the basolateral plasma membrane domain of polarized Madin-Darby canine kidney (MDCK) cells. In these cells, the exocyst has been variously localized to the lateral plasma membrane near the junctional complex, the trans-Golgi network, and transferrin-positive recycling endosomes. At present, it is unknown whether the exocyst is localized to additional endocytic compartments or whether it regulates transport within the endosomal system of polarized epithelial cells. Analysis of the distribution of the exocyst subunits Sec6, Sec8, and Exo70 in polarized MDCK cells by confocal microscopy confirmed that in addition to the lateral membrane, these proteins were partially localized to vesicles that are positive for the basolateral recycling marker transferrin. There was also a significant subapical pool of Sec6/Sec8/Exo70 that showed extensive colocalization with transcytosing IgA and the apical recycling endosome marker Rab11. Preliminary immunoisolation experiments confirm that Sec8 is found on Rab11-positive endosomes. Streptolysin-O (SLO)-permeabilized MDCK cells were used to analyze the involvement of the exocyst complex in endocytic trafficking pathways. Recycling of transferrin in this assay was inhibited 57.5 ± 4.0% by the addition of function blocking Sec8 antibodies, but was not effected by the addition of a non-specific control antibody. Furthermore, Sec8 antibodies inhibited IgA transcytosis 42.6 ± 1.9% and IgA recycling 27.5 ± 3.0%. In addition to the previously described role for the exocyst complex in regulating basolateral delivery of biosynthetic cargo, these results indicate that the exocyst complex of polarized MDCK cells is localized to endocytic recycling compartments where it regulates basolateral recycling, basolateral-to-apical transcytosis and apical recycling pathways.

1962

**Sorting Nexin 5 and Retromer Recruitment to the Maturing Macropinosome**

M. C. Kerr,[1] R. Leutterforst,[1] N. Hamilton,[1] M. Lindsay,[1] F. Simpson,[1] R. G. Parton,[1] P. A. Gleeson,[2] R. D. Teasdale[1]; [1]Institute for Molecular Bioscience, University of Queensland, Brisbane, Australia, [2]Bio21 Molecular Science and Biotechnology Institute, The University of Melbourne, Melbourne, Australia

Stimulation of cells with epidermal growth factor induces a change in the subcellular distribution of sorting nexin 5. Using a combination of real-time and immuno-fluorescence microscopy we have characterised the subsequent association of SNX5 with enlarged endocytic macropinosomes and tracked the progression of this endocytic compartment through its early stages of maturation using SNX5 as a marker. Initially SNX5 is recruited to distinct subdomains of the compartment as intense patches on the cytoplasmic face of the macropinosome. These patches then traverse the cytoplasmic face of the compartment in a directed manner before being incorporated into highly dynamic, often branched, tubular structures. Extension of the tubular subcompartment is dependent on the microtubule network. Concurrent with the extension and departure of the tubular elements is a marked reduction in the surface area and volume of the macropinosome. Characterisation of this compartment revealed its role in the early endocytic trafficking pathway from the plasma membrane to the early endosome. We demonstrate that the macropinocytic pathway characterised is epidermal growth factor receptor and transferrin receptor positive and is a novel site of membrane recruitment for the human retromer complex subunits; Vps26A, Vps29 and SNX1. Furthermore, we find that SNX5 interacts with the retromer complex via the formation of heteroligomers with SNX1 and cannot form homoligomers. This association represents the first observation of the retromer's involvement in macropinocytosis and provides a model for the characterisation of early-stage endosome maturation in real-time.

1963

**Membrane-associated Trafficking of Stat3 in the Cytoplasm: The Stat3 Signaling Endosome Hypothesis**

M. Shah, P. B. Sehgal; Cell Biology and Anatomy, New York Medical College, Valhalla, NY

Cytokine- and growth factor-initiated STAT signal transduction from the plasma membrane to the nucleus is a vital event in numerous cellular processes. Evidence from this lab and others has shown that IL-6/STAT3 signaling is initiated at the level of plasma membrane raft microdomains, but the cytoplasmic itinerary remains unclear. STAT signaling is widely represented as a free cytosolic process. We re-evaluated the question of membrane-associated trafficking of STAT3 in the cytoplasm. Cell fractionation, immunofluorescence and biochemical data showed constitutive as well as IL-6-enhanced association of cytoplasmic STAT3 as well as PY-STAT3 with vesicular components ("signaling endosome") which partially overlapped with markers of the caveolar/endolysosomal pathways [clathrin heavy chain (CHC), caveolin-1, Rab5, Rab7, LAMP1, LAMP2 and EEA1] in hepatocyte, endothelial, epithelial and smooth muscle cells. The endocytosis inhibitor phenylarsine oxide induced a dramatic increase in bulk STAT3 association with cytoplasmic membranes and between STAT3 and CHC. Additionally, the previously reported cytosolic 1-2 MDa STAT3 ("statosome II") complexes contained CHC, suggesting a clathrin-like cycling of STAT3 between cytosol and membrane elements. We employed a detergent dissection approach to determine the relative magnitude of membrane-associated versus free cytosolic PY-STAT3 signaling. Using this approach, approximately 70 % of IL-6-activated cytoplasmic PY-STAT3 was found to be associated with cytoplasmic vesicular elements ("STAT3 signaling endosomes), suggesting that the membrane-associated signaling is the major pathway. Inhibitors and expression constructs of proteins affecting raft/endolysosomal trafficking provided data indicating that this pathway included both a transcriptional activation component and a signal inhibitory component. These observations require a modification of our understanding of the cytoplasmic physiology of STAT3 to include vesicular trafficking.

1964

**A Lethal Mutation in the NEUZ/NHR Domain of Neuralized Alters Protein Subcellular Localization and the Ability to Colocalize with the Notch Ligand, Delta**

C. Commisso,[1,2] G. L. Boulianne[1,2]; [1]Developmental Biology, Hospital for Sick Children, Toronto, ON, Canada, [2]Medical and Molecular Genetics, University of Toronto, Toronto, ON, Canada

The Notch signaling pathway is involved in numerous developmental cell fate decisions and when signaling is disrupted a neurogenic phenotype results as a consequence of excess neural determination. The core pathway consists of the Notch receptor and its ligands, Delta and Serrate/Jagged. Neuralized is an E3 ubiquitin ligase thought to non-autonomously activate the Notch signal by targeting the Notch ligands for ubiquitin-mediated endocytosis. Neuralized is expressed as two isoforms, each containing a C-terminal RING domain and an internal repeat of the NEUZ/NHR domain, a conserved protein domain found in over 80 Neuralized-related proteins within the animal kingdom. We have previously shown that Neuralized functions as an E3 ubiquitin ligase *in vitro*, and that this function is dependent upon an intact RING domain. Here we show that a lethal, neurogenic allele of *neuralized* is a result of a mutation in a conserved residue of the NEUZ/NHR domain, affecting both of the Neuralized isoforms. The resulting mutant proteins exhibit altered subcellular localization in *Drosophila* S2 cells and *in vivo*. Other groups have shown that Delta and Neuralized are found in a complex and we have determined that Neuralized proteins normally colocalize with a wild-type or a membrane-tethered form of Delta in S2 cells. Here we show that the NEUZ/NHR mutants are defective in Delta colocalization. Taken together, this data suggests that the NEUZ/NHR domains may be facilitating protein-protein interactions that are important to subcellular localization and ubiquitin ligase target recognition. This is the first evidence of a possible function for the NEUZ/NHR protein domain and our current efforts include elucidating the specific protein-protein interactions that have been abrogated in NEUZ/NHR mutants, causing them to be mislocalized.

1965

**Localized PtdIns 3,5-$P_2$ Synthesis to Regulate Early Endosome Dynamics and Fusion**

O. C. Ikonomov, D. Sbrissa, A. Shisheva; Physiology, Wayne State University, Detroit, MI

Perturbations in the intracellular PtdIns 3,5-$P_2$ pool or the downstream transmission of PtdIns 3,5-$P_2$ signals often result in a gradual development of gross morphological changes along the pleiomorphic multivesicular endosomes, culminating with the appearance of cytoplasmic vacuoles. To identify the onset of PtdIns 3,5-$P_2$ functional requirements along the endocytic system, we characterized here morphological changes associated with early expression of the dominant-negative kinase-deficient form (K1831E) of the PtdIns 3,5-$P_2$-producing kinase PIKfyve, prior to formation of cytoplasmic vacuoles in transfected COS cells. Enlarged PIKfyve$^{K1831E}$-positive vesicles colocalizing with dilated EEA1- and Rab5a$^{WT}$-positive perinuclear endosomes were observed. This was dependent on the presence of active forms of Rab5 and the generation of PtdIns 3-P-enriched platforms on early endosomes. Because PIKfyve$^{WT}$ did not substantially colocalize with EEA1- or Rab5-positive endosomes, the dynamic PIKfyve-catalyzed PtdIns 3-to-PtdIns 3,5-$P_2$ switch was suggested to drive away PIKfyve$^{WT}$ from early endosomes toward later compartments. Late endosomes/lysosomes marked by ectopically expressed LAMP1 or Rab7 were dislocated from their typical perinuclear position upon PIKfyve$^{K1831E}$ early expression. Cytosols derived from cells stably expressing PIKfyve$^{K1831E}$ stimulated endosome fusion *in vitro*, whereas PIKfyve$^{WT}$-enriched cytosols had the opposite effect, consistent with PtdIns 3,5-$P_2$ production negatively regulating the endosome fusion. Together, our data indicate that PtdIns 3,5-$P_2$ defines specific endosome platforms at the onset of the degradation pathway to regulate the complex process of membrane remodeling and dynamics.

1966

**Pacsin 1 Tetramers are Targeted to Vesicles**

M. Milbrandt,[1] A. Halbach,[1] M. Mörgelin,[2] M. Plomann[1]; [1]University of Cologne, Centers for Biochemistry and Molecular Medicine Cologne (CMMC), Cologne, Germany, [2]Lund University, Department of Cell and Molecular Biology, BMC, Lund, Sweden

In eukaryotic cells complex regulatory mechanisms involving numerous proteins must operate to ensure the temporal and spatial specificity of intracellular membrane-trafficking pathways. We previously have identified the three members of the PACSIN protein family, which participate in rearrangements of actin networks during endocytosis. The isoform-specific expression patterns implicate a more general role for PACSINs in membrane traffic events, most of which occur at membranes of intracellular sorting compartments and vesicles. PACSINs bind to proteins involved in vesicle endocytosis and transport and act as linkers between the endocytic protein dynamin and N-WASP, thereby directing the actin propulsion

machinery to the site of vesicle fission. According to our model, dynamin remains attached to a released vesicle membrane and serves as anchoring site for PACSIN monomers, which oligomerise, recruit the propulsion complex to these sites and induce actin polymerisation. To address this hypothesis we have performed a series of experiments using recombinantly expressed PACSIN 1 to gain more insights into the oligomerisation of this protein in solution. PACSIN 1 dimers and tetramers interact via their N-terminal regions in a parallel orientation and form a barrel-like structure. In vivo two subpopulations of PACSIN 1 exist in microsomal and cytosolic fractions. In agreement with our model PACSIN oligomers are associated with vesicle membranes and can be localized to single sites on the vesicle surface as determined by ultrastructural analysis of negatively stained specimens in combination with immunogold labelled antibodies. We propose that PACSIN oligomers are required for vesicle removal from donor membranes.

1967

**Fc-receptor neonatal (FcRn) Mediates IgG Transport from the Apical or Basolateral Membrane of Polarized Epithelial Cells Intersects within a Common Endosomal Compartment**

S. Tzaban, E. Yen, M. Kothe, J. S. Wagner, W. I. Lencer; GI/Nutrition, The Children's Hospital, Harvard Medical School, Boston, MA

FcRn binds and traffics IgG bidirectionally across mucosal epithelial barriers where IgG acts in immune surveillance. The mechanism(s) of transport across polarized epithelial cells are unknown. Here we use polarized MDCK-II cells, stably expressing wild type FcRn (wt) or FcRn fused to green fluorescence protein (FcRn-GFP) to define the itinerary of FcRn-mediated IgG transport across polarized epithelial cells that model mucosal surfaces. Polarized MDCK-II cells stably expressing FcRn-GFP exhibit basolateral polarity of FcRn at the cell surface and transport IgG bidirectionally across the monolayer with the same efficiency as MDCK cells expressing wild type FcRn. At steady state, FcRn co-localizes with the transferrin receptor and the early endosome antigen 1 (EEA1) but not LAMP-1a, suggesting the sorting of FcRn to either early or common endosomes. In living cells, the FcRn-vesicles are strictly sorted away from the lysosomal compartment labeled with LysoTracker Red. Following uptake from either the apical or the basolateral surfaces, fluorophore-labeled IgG always co-localizes with FcRn. In contrast, chicken IgY that cannot bind FcRn is not internalized by these cells at all. Apically and basolaterally applied IgG meet in an apically located compartment that always localizes with transferrin. These results suggest that both the basolaterally- and apically-directed transcytotic pathways may meet in the common endosomal compartment. Whether these findings point to a common pathway remains to be determined.

## Protein Folding & Assembly in the Endoplasmic Reticulum II (1968-1984)

1968

**The Functions of ERp57 in the Folding and Assembly of MHC Class I Molecules**

Y. Zhang, D. B. Williams; Biochemistry, University of Toronto, Toronto, ON, Canada

Major Histocompatibility Complex (MHC) class I proteins consist of three subunits: the heavy chain (H chain), which is a transmembrane glycoprotein; a small soluble subunit termed $\beta_2$-microglobulin ($\beta_2$m), and an 8-9 residue antigenic peptide. Folding and assembly of class I molecules require multiple coordinated intra- and intermolecular events within the endoplasmic reticulum. The association of the thiol oxidoreductase ERp57 with free MHC class I H chains and with the class I peptide loading complex has suggested that this enzyme may participate in H chain disulfide formation/isomerization as well as in the loading of high affinity peptides. Here we present *in vivo* evidence that ERp57 does indeed participate in oxidative folding of the class I heavy chain. Depletion of ERp57 by RNA interference delayed H chain disulfide bond formation, slowed folding of the H chain $\alpha_3$ domain and caused slight delays in the transport of class I from the endoplasmic reticulum to the Golgi apparatus. In contrast, H chain-$\beta_2$m association kinetics were normal, suggesting that the interaction between H chain and $\beta_2$m does not depend on an oxidized $\alpha_3$ domain. Likewise, the peptide loading complex assembled properly except for the absence of ERp57. Peptide loading also appeared normal in the absence of ERp57 as evidenced by unaltered stability of cell surface class I molecules and by the normal production of complexes between the H-2K$^b$ molecule and the ovalbumin peptide, SIINFEKL. These studies constitute the first direct demonstration that ERp57 is involved in disulfide formation *in vivo* but do not support a role for ERp57 in peptide loading of class I molecules. Interestingly, depletion of another thiol oxidoreductase, ERp72, had no detectable effect on class I biogenesis, consistent with a specialized role for ERp57 in this process.

1969

**The FK506 Binding Protein Fkbp13 Interacts with and Stabilizes Presenilin**

D. L. van de Hoef, H. Wu, Y. Liu, G. Boulianne; Developmental Biology, Hospital for Sick Children, Toronto, ON, Canada

Presenilins were identified as causative factors in Familial Alzheimer's disease and also play an essential role in Notch signalling during development. Presenilins function in the multi-molecular γ-secretase complex, which cleaves type 1 transmembrane proteins including Notch and the beta-amyloid precursor protein (APP). To gain further insight into the function of Presenilins, we searched for *presenilin* interacting genes in *Drosophila*. Here we show that loss-of-function mutations in *Fkbp13* suppress phenotypes resulting from overexpression of *presenilin.* We also find that Fkbp13 binds directly to Presenilin and that Presenilin protein, but not RNA, is reduced significantly in *Fkbp13* null mutants. Finally, we show that FK506, which binds Fkbp13, also reduces Presenilin levels in addition to another component of the complex, Pen-2, thereby reducing γ-secretase assembly and activity *in vivo.* Together, our data demonstrate that Fkbp13 is an essential component of the Presenilin pathway. We propose that Fkbp13 is required to stabilize Presenilin protein allowing for formation of a functional γ -secretase complex.

1970

**Fluorescence-Detected Maintenance of the ER Membrane Permeability Barrier during the Co-Translational Integration of a Multi-Spanning Membrane Protein**

C. G. Jongsma, A. E. Johnson; Texas A&M University, College Station, TX

How is the permeability barrier maintained during the co-translational integration of a multi-spanning membrane protein (MSMP) at the translocon in the endoplasmic reticulum (ER) membrane? Previous work with a single-spanning membrane protein has shown that the aqueous translocon pore is sealed on the cytoplasmic side of the membrane by an ion-tight ribosome-translocon junction when the nascent chain is being transported into the ER lumen, and that this junction is opened for release of a nascent chain loop into the cytosol. However, junction opening does not occur

until the other end of the pore is first closed by the action of BiP after the transmembrane segment (TMS) of the nascent chain folds into an α-helix (or nearly so) far inside the ribosome nascent chain exit tunnel. The accessibility of the nascent chain to each side of the membrane was determined using cytosolic or lumenal iodide ions to collisionally quench the fluorescence of a probe incorporated into the nascent chain. Since the non-TMS segments of an MSMP are alternately directed into either the cytosol or the ER lumen, one would expect the nascent chain to alternate in its exposure to cytosolic or lumenal iodide ions as one TMS after another of a MSMP moves through the exit tunnel. Iodide ions were therefore added to fluorescent intermediates with different nascent chain lengths. Our studies reveal that an open ribosome-translocon junction is closed when the next TMS is synthesized by the ribosome. The length of nascent chain between the two TM segments appears to alter only the timing of the closure. (Supported by NIH grant GM26494 and the Welch Foundation.)

1971

### Proteomics and Pharmacology of CFTR Intracellular Interactions

A. V. Koulov,[1] X. Wang,[1] W. A. Kellner,[1] J. A. Coppinger,[1] J. R. Yates,[1] W. E. Balch[1,2,3]; [1]Cell Biology, The Scripps Research Institute, La Jolla, CA, [2]Molecular Biology, The Scripps Research Institute, La Jolla, CA, [3]The Institute for Childhood and Neglected Disease, La Jolla, CA

Cystic fibrosis (CF) is the most common hereditary disease in the Caucasian population, caused by mutations in the Cystic Fibrosis Transmembrane Regulator (CFTR) gene. From over 1000 mutations identified, deltaF508 in the NBD1 cytosolic domain of the protein is by far the most prevalent one, leading to folding defects and subsequent failure of the protein to engage the ER export machinery. To interrogate the direct interactions of CFTR within the export pathway, we have utilized mass-spectrometry-based multi-dimensional protein identification technology (MuDPIT). The focus of this study is to elucidate the interactions of CFTR with the protein machinery that couple folding to export. Using such a proteomic approach we have examined the role of Hsp90 and a dynamic complex of co-chaperones in the ER export of CFTR in normal and a disease state. Characterization of the effects of novel small molecules that modulate ER folding and export of mutant CFTR is anticipated to lead to discovery of new targets for future therapies.

1972

### Interaction of Wild Type and Mutant Human $Cl^-/HCO_3^-$ Anion Exchanger 1 with Molecular Chaperones

S. T. Patterson, D. B. Williams, R. A. F. Reithmeier; Biochemistry, University of Toronto, Toronto, ON, Canada

Anion Exchanger 1 (AE1, or Band 3) is an abundant red blood cell polytopic membrane glycoprotein responsible for the exchange of chloride and bicarbonate ions across the membrane as well as the anchoring to the cytoskeleton. Numerous point mutations and deletions have been identified leading to a loss of function as well as retention of AE1 in the endoplasmic reticulum (ER) during biosynthesis. Co-immunoprecipitation as well as peptide arrays were used to examine the interaction of AE1 with various chaperones. AE1 was expressed in a cell-free translation system using rabbit reticulocyte lysate supplemented with canine pancreatic microsomes and co-immunoprecipitated with antibodies to several chaperones. Wild type AE1, as well as the R760Q Hereditary Spherocytosis mutant and the Southeast Asian Ovalocytosis deletion mutant (Δ400-408) were shown to interact with the ER chaperones calnexin, calreticulin, and BiP, as well as the cytosolic chaperones Hsp70 and Hsp90. AE1 and the R760Q and SAO mutants were also expressed in HEK 293 cells and radiolabelled using [$^{35}$S]-methionine. Wild type and the mutant forms of AE1 were found to co-immunoprecipitate with calnexin, and pulse chase experiments showed a prolonged interaction of the mutants with calnexin. A peptide array generated using SPOT synthesis consisting of peptides corresponding to the various cytosolic and extracellular loops of AE1 was also used to study the binding of calnexin and calreticulin. Both chaperones were found to bind preferentially to the third and fourth extracellular loops. These results demonstrate the importance of molecular chaperones in the biosynthesis of AE1 and the retention of misfolded mutants in the ER. (Supported by the CIHR Strategic Training Program in the Structural Biology of Membrane Proteins Linked to Disease).

1973

### Folding, Assembly and ER Export of Yor1p, a Yeast ABC Transporter Homologous to Human CFTR

J. Barry, L. Kung, M. Dorrington, M. C. S. Lee, E. A. Miller; Biological Sciences, Columbia University, New York, NY

Eukaryotic cells dedicate significant resources to the deployment of proteins to the membrane compartments that comprise the secretory pathway. Cells must strike a precise balance between ensuring that only fully folded and properly assembled proteins are allowed to leave the endoplasmic reticulum (ER) and in avoiding the accumulation of misfolded proteins within the ER lumen, which can equally have detrimental consequences. We study the close relationship between protein folding and packaging into ER-derived transport vesicles using a model membrane protein, Yor1p, which functions as a plasma membrane drug pump in *Saccharomyces cerevisiae*. We have characterized two cytoplasmic di-acidic motifs that function as ER export signals and facilitate Yor1p capture into COPII vesicles. Mutations in these motifs cause ER retention without affecting the folding of Yor1p. In contrast, mutation of a conserved Phe residue (analogous to the predominant mutation associated with human cystic fibrosis) causes Yor1p to misfold, precluding its capture into COPII vesicles. We have undertaken several approaches to identify cellular components involved in the quality control of forward protein transport through the secretory pathway. Several of these quality control mutants show an improved ability to package the misfolded mutant of Yor1p into COPII vesicles. In some cases, mutant cells are better able to fold Yor1p and this improvement is linked to the ability to mount the unfolded protein response (UPR). Our results suggest that activation of the UPR can improve the ability of cells to handle misfolded proteins and suggest novel therapeutic targets for cystic fibrosis drug development.

1974

### Calnexin and Calreticulin Facilitate the Folding of ABCG5/G8 Sterol Transporter Leading to Increase the Cell Surface Expression

T. Kouno,[1] T. Okiyoneda,[1] A. Niibori,[1] K. Harada,[1] H. Kusuhara,[2] T. Sugiyama,[1] T. Shuto,[1] M. S. Suico,[1] Y. Sugiyama,[2] H. Kai[1]; [1]Molecular Medicine, Faculty of Pharmaceutical Sciences, Kumamoto, Japan, [2]Graduate School of Pharmaceutical Sciences, Tokyo Univ, Tokyo, Japan

ATP-binding cassette (ABC) G5 (G5) and ABCG8 (G8) hetero-dimerize and function as a sterol transporter that limits intestinal absorption and promotes biliary excretion of neutral sterols. Both G5 and G8 are N-glycosylated in the endoplasmic reticulum (ER) and interact with a lectin-like chaperone, calnexin, which is thought to facilitate the folding of G5/G8 heterodimer. To further investigate the role of calnexin in the biogenesis of G5/G8 heterodimer, we examined the effect of calnexin overexpression and knockdown on the biogenesis of G5/G8. Our results reveal that calnexin overexpression stabilized the immature forms of both G5 and G8 leading to the increase of G5/G8 heterodimer at the plasma membrane.

Moreover, a calnexin homologue, calreticulin, also stabilized the immature forms of both G5 and G8. Interestingly, calreticulin significantly increased the cell surface expression of G5/G8 heterodimer. Knockdown of either calnexin or calreticulin decreased the immature forms of both G5 and G8 leading to the decrease in expression of G5/G8 heterodimer. These results demonstrate that calnexin and calreticulin stabilize the immature forms of both G5 and G8 in the ER and facilitate the hetero-dimerization leading to the increase of cell surface expression

**The Role of Key Amino Acid Residues in *Staphylococcal* Nuclease Folding**

H. M. Chen, J. M. Wu, H. J. Fang; Institute of BioAgricultural Sciences, Academia Sinica, Taipei, Taiwan Republic of China

The role of key amino acid residues in *staphylococcal* nuclease folding H. M. Chen, J.-M. Wu and H.-J. Fang Institute of BioAgricultural Sciences, Academia Sinica, Taipei, Taiwan 115 R.O.C. *Staphylococcal* nuclease is a single domain protein with 149 amino acids. It has no disulfide bonds that make it a simple model for the study of protein folding. In this study, twenty mutants of this protein were generated each with a single base substitution of Gly for negatively charged Glu or Asp. The results using differential scanning microcalorimetry in thermal denaturation experiments, we identified two mutants, E75G and E129G, having approximately 43% and 44%, respectively, lower $\Delta H_{cal}$ values than the wild-type protein. Multiple interactions around E75 and E129 may generate a local area of stability. Furthermore, two mutants, W140A and K133A, and two truncated mutants, $SNase_{1-139}$ (W140O) and $SNase_{1-141}$ (E142O), were generated. Replacing Trp at 140 with an alanine (W140A) had greatly reduced secondary structure and conformational energy compared to the wild-type protein. Similar experiments with $SNase_{1-139}$ confirmed the unusually large contribution of the W140 to the stability and the structural integrity of protein. Based on these observations, this protein stability relies not only on those local stable segments formed by specifically charged amino acids, but also on the amino acid Trp at position 140.

**Analysis of Knock-in Mice Expressing a Mutant BiP with the Retrieval Sequence Deleted**

M. Kashio,[1] N. Mimura,[2] K. Kimura,[2] T. Aoe[1]; [1]Anesthesiology, Chiba University Graduate School of Medicine, Chiba, Japan, [2]Medicine and Oncology, Chiba University Graduate School of Medicine, Chiba, Japan

The endoplasmic reticulum (ER) provides a folding environment where secretory and transmembrane proteins interact with chaperones. Some membranous imperfect proteins are statically retained in the ER, while other membranous and soluble ones require transport to the Golgi complex and retrieval for ER quality control. BiP is a member of the Hsp70 family of proteins and is one of the most abundant ER chaperones, assisting in protein translocation, folding and degradation. When secreted from the ER in the company of imperfect proteins, BiP is recognized with a carboxyl terminal Lys-Asp-Glu-Leu (KDEL) sequence and retrieved by the KDEL receptor from the post-ER compartment. Yeast studies show that the deletion of retrieval motif from BiP/Kar2 is dispensable. Thus, the significance of the post-ER compartment for quality control in a single cell is unclear. In order to investigate the physiological significance of BiP and its retrieval in multi-cellular organisms in vivo, we established knock-in mice expressing a mutant BiP with the retrieval sequence deleted by homologous recombination.The embryonic fibroblasts derived from the homozygous mutant embryo expressed the mutant BiP instead of the wild-type and grew apparently as well as the wild ones. However, the homozygous mutant BiP mice were died early after birth, indicating that the retrieval of BiP is essential for surviving of mammals.

1977

**The Physiologic Deficits of Aging May Be Due to Declines in the Concentrations of the Endoplasmic Reticulum (ER) Chaperones**

J. L. Holtzman, R. R. Erickson, L. M. Dunning; Pharmacology, University of Minnesota, Minneapolis, MN

**Background:** In eukaryotes the ER chaperones are highly conserved proteins that catalyze the posttranslational processing of all secretory and membrane proteins. Recent studies from our laboratory have suggested that declines in the ER chaperones and N-glycosylation may be the central, biochemical defects underlying Alzheimer's disease. We propose that similar declines in the ER chaperones could account for some of the physiological deficits associated with aging in other organ systems. **Methods:** A single batch of rats were maintained in a "state-of-the-art" facility from age 21 days to death. At regular intervals 6 animals were removed, killed by $CO_2$, and hepatic microsomes prepared. At the end of the study, 6 ER chaperones were determined by immunoblotting. **Results:** After reaching maturity liver weights and total microsomal protein content did not change with age. On the other hand, constitutive levels of ERp55, ERp57, ERp72, BiP and calnexin declined 30-50% with age. Calreticulin was unaffected. BiP, ERp55 and ERp57 showed marked swings with peaks occurring in midwinter and midsummer. The heights of these peaks declined 73% with age. **Conclusions:** ER, posttranslational, protein processing is critical for cell function and survival. It appears to be capacity limited, especially for large, intrinsic membrane proteins, such as the CFTR. Hence, our data on the effect of aging on ER chaperone content even in a relatively well conserved organ, the liver, lend support to our proposal that the loss of ER chaperones may be a major factor in the physiological declines observed with aging. This loss would appear to be specific for ER chaperones, since others have reported that cytosolic chaperones, such as HSC70, are unaffected by age.

1978

**Consequences of Aging and Oxidative Stress on Endoplasmic Reticulum Protein Quality Control Machinery**

Z. Cabartova, E. L. Snapp; Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

Misfolded transmembrane and secretory proteins are a feature of several age-associated diseases. The translocation of proteins into the endoplasmic reticulum (ER) and folding are mediated by the translocon and ER chaperones. Oxidative damage of some chaperones in aged tissues suggests folding machinery dysfunction contributes to age-related protein misfolding. We are examining three age-related changes in the protein translocation and folding machinery. First, we are biochemically characterizing changes in ER chaperone and translocon component levels and oxidative damage to components in aging mouse liver. Second, we are mimicking these changes in cultured cells to assess consequences of oxidatively damaged chaperone and translocon component functionality. Finally, we are using the tissue culture system, coupled with biophysical imaging techniques, to investigate how oxidative damage affects the organization and dynamics of the translocon and lumenal chaperone complexes. By characterizing the age-related changes in the machinery responsible for the biogenesis of membrane and secreted proteins, we hope to gain new insights into the relationship between oxidative damage and ER function during aging.

1979

**Dynamic Interconversion of Proteasome Populations Identified by 2D BN-PAGE/SDS-PAGE**

T. Shibatani,[1] E. J. Carlson,[1] A. L. McCormack,[2] K. Früh,[2] W. R. Skach[1]; [1]Biochemistry, Oregon Health & Science University, Portland, OR, [2]Vaccine and Gene Therapy Institute, Oregon Health & Science University, Beaverton, OR

The proteasome is the major enzyme involved in proteolysis of cytosolic, nuclear, and misfolded ER proteins. Using 2D BN-PAGE/SDS-PAGE, we developed a single-step purification scheme which isolated 5 distinct proteasome populations in cytosolic extract. MS/MS analysis of 2D gel bands identified these complexes as 20S, single-capped and double-capped PA28-20S, hybrid PA28 and PA700 capped proteasome, and 26S proteasome. All populations were present in untreated cytosol. ATP depletion completely eliminated PA700 cap binding to the 20S core as reported previously, but had no discernable effect on PA28 interactions. In contrast, inhibition of 20S β subunit activity with MG132 stimulated formation of double capped PA28-20S core and hybrid proteasomes containing both PA28 and PA700 caps. Formation of double-capped PA28-20S proteasomes and hybrid proteasomes occurred quickly and was completed after 60-minute incubation at 37$^{o}$C with concomitant decrease of free 20S particles. *clasto*-Lactacystine β-lactone also stimulated the PA28-20S association but to a lesser extent than MG132. Interestingly, in the presence of MG132, 26S and hybrid proteasomes as well as single-capped and double-capped PA28-20S proteasomes remained stably associated with partially degraded products of an ER-associated degradation substrate. Our results demonstrate that BN-PAGE provides a powerful tool to isolate cytosolic proteasome populations. Proteasomes can exchange caps rapidly in response to cytosolic conditions. Furthermore PA28-20S proteasome, and hybrid proteasome populations preferentially accumulate when β-subunit activity is compromised, indicating that the PA28 might participate in diverse functions in addition to antigen presentation.

1980

**Targeting E2 Ubiquitin-Conjugating Enzymes for Degradation by the Proteasome: Mechanism and Implications in Protein Quality Control**

T. Ravid, M. Hochstrasser; MB&B, Yale University, New Haven, CT

Newly synthesized secretory proteins and endoplasmic reticulum (ER) resident proteins are subject to quality control mechanisms that verify proper folding prior to transport to their site of activity. Key players in this sorting system are components of the ubiquitin-proteasome system (UPS) that reside in the ER and covalently tag misfolded proteins with polyubiquitin chains, allowing retrotranslocation and degradation by the proteasome. Many mechanistic features of the UPS in the ER remain poorly understood. Our recent studies provide new insights into the regulation of ER-associated E2 enzymes of the ubiquitin system. Genetic studies in the yeast *Sacchromyces cerevisiae* identified several degradation pathways in the ER, which exhibit distinct substrate specificities. We had previously demonstrated that the E2 enzymes Ubc6 and Ubc7, together with the E3 Doa10, mediate the degradation of a subset of substrates that are either soluble nuclear or ER membrane proteins. We find that these E2 enzymes form a stable degradation complex with Doa10 at the ER membrane. Interestingly, both Ubc6 and Ubc7 are subject to degradation by the proteasome. However, whereas Ubc6 is degraded in the ER by a Doa10-dependent pathway, Ubc7 is ubiquitinated in a soluble cellular compartment by a distinct set of ubiquitinating enzymes. Structure-function analyses of the E2 enzymes demonstrate that the conserved cysteine in their active sites is essential, but their E2 catalytic activity is dispensable for degradation of the proteins. This implies that besides transferring ubiquitin to a substrate, the conserved cysteine in the E2 active site also plays an important role in the regulation of E2 enzyme degradation. The physiological function of this unique mechanism for ER-associated protein degradation and its mechanistic details are currently under investigation and will be discussed.

1981

**Heat Shock Protein 70-Interacting Protein (Hip) from Cold-Adapted and Sub-Tropical Teleosts**

S. Hann, H. Detrich; Biology, Northeastern University, Boston, MA

For Antarctic marine ectotherms, the cold Southern Ocean (-2 to +2°C) poses energetic challenges to protein folding. To help elucidate mechanisms that maintain efficient protein folding at low temperatures, we have initiated a comparative structural and functional analysis of Hip, the Hsp70/Hsc70-interacting, multi-motif cochaperone (39-45 kDa) that plays important roles in the biogenesis, transport, and degradation of cytoplasmic proteins. *hip* cDNAs were isolated from kidney or spleen of two Antarctic fishes, *Notothenia coriiceps* and *Chaenocephalus aceratus*, and from the kidney of the sub-tropical zebrafish, *Danio rerio*. The deduced Hip proteins were highly conserved both in amino acid sequence and in modular structure. However, one motif, the GGMP repeat (found in 5-6 copies in mammals), was present in 11-12 copies in the Antarctic fish Hip but only 1-2 in zebrafish Hip. Because GGMP repeat length is the major feature that differentiates the fish Hip proteins, we propose that this region is important for thermal modulation of Hip function. To test this hypothesis, we expressed recombinant wild-type *N. coriiceps* and *D. rerio* Hip and examined the temperature dependence of thermal denaturation and of self-oligomerization of the proteins. Wild-type *D. rerio* Hip melted with a $T_m$ of 49-50 $^{o}$C (monitored by CD at 222 nm), whereas *N. coriiceps* Hip was less stable ($T_m$ = 39-40 $^{o}$C). Denaturation analysis of GGMP-deletion variants of Hip should clarify the role of this motif in thermal stability. Preliminary analysis of wild-type *N. coriiceps* and *D. rerio* Hip by analytical ultracentrifugation suggests that the former self-associates to form a dimer whose association constant is greater than that of the latter. We conclude that the GGMP motif may be important for tailoring Hip function to environmental temperature. Supported by NSF grants OPP-9815381, -0089451, and -0336932 to HWD.

**Gene Expression and Phylogenetic Relationships Reveal a Complex Protein Disulfide Isomerase Family**

N. L. Houston,[1] T. Yang,[1] Q. Xiang,[1] R. Jung,[2] R. S. Boston[1]; [1]Botany, NCSU, Raleigh, NC, [2]Pioneer Hi-Bred International, A DuPont Company, Johnston, IA

Protein disulfide isomerases (PDIs) catalyze the formation of proper disulfide bonds and participate in ER quality control as part of the cellular ER-stress response. To identify plant PDI-like (PDIL) proteins, we performed a genome-wide search of *Arabidopsis thaliana* and identified 104 thioredoxin (TRX) domain containing proteins, 22 of which group with orthologs of known plant PDIs in a well-supported clade. Using the Arabidopsis PDIL sequences in iterative BLAST searches, we identified orthologous sets of plant PDIL sequences in rice (19) and maize (22) and resolved the phylogeny into 10 classes. Five classes (I-V) had the two TRX domains typically found in PDIL proteins in other higher eukaryotes

while the remaining five classes (VI-X) had a single TRX domain. RNA profiling and quantitative RT-PCR analyses of the maize PDILs (ZmPDILs) showed marked differences in expression within and among classes. The major PDI (ZmPDIL1-1), the class V PDIL (ZmPDIL2-3), and the class VI maize PDIL (ZmPDIL5-1) were up-regulated by ER stress. Subcellular fractionation and immunoblot analysis revealed that ZmPDIL1-1 but not ZmPDIL5-1 was localized to the intracellular membrane fractions. ER-stress induction in the absence of ER localization is suggestive of an unusual role for the PDIL5-1 family member.

1983

**Role of Hsp90 in the Exocytic Pathway**

P. G. LaPointe, C. Gurkan, W. E. Balch; Molecular and Cell Biology, The Scripps Research Institute, La Jolla, CA

Packaging of protein cargo molecules into COPII vesicles at the ER is regulated through a balance between folding, cargo selection and degradation. Several lines of evidence suggest that the Hsp90 chaperone system contributes to cargo folding pathways including the cystic fibrosis transmembrane conductance receptor (CFTR). Our objective is to identify and characterize the role of the Hsp90 chaperone system in protein folding and ER export. Using yeast two-hybrid screens and proteomics we have identified Hsp90 co-chaperones involved in ER export. One of these is the conserved protein, Aha1, which has been previously been shown to interact with Hsp90 and accelerate its ATPase activity. We now report that hAha1 is itself a novel GTPase/ATPase with a peptide binding activity. Moreover, these two activities localize to two distinct domains of the protein. siRNA depletion of hAha1 results in a marked increase in the secretion of protein cargo proteins as well as an increase in ER stability of misfolded cargo molecules including the Δ508 variant of the CFTR protein. Our results suggest that hAha1 is potentially involved in regulating the presentation of client molecules to the Hsp90 complex for folding and export.

1984

**Plant UBX-domain Containing (PUX) Proteins Regulate the Function of *Arabidopsis* CDC48**

D. M. Rancour, S. Park, S. Y. Bednarek; Biochemistry, University of Wisconsin-Madison, Madison, WI

CDC48/p97 is a conserved and essential hexameric AAA-ATPase that functions as a molecular chaperone in numerous diverse cellular activities. CDC48/p97 activity is recruited to specific functions through its interaction with adapter proteins. Our working hypothesis is that AtCDC48 and the *Arabidopsis* homolog of syntaxin5/Sed5p, SYP31, mediates events important for plant cytokinesis. Using affinity chromatography and MALDI-TOF mass spectrometry we have identified two uncharacterized plant UBX-domain containing proteins, PUX1 and PUX2, which interact with AtCDC48. UBX-domains are ubiquitin-like protein folds that function as interaction domains for CDC48/p97. PUX1 is a soluble protein that co-fractionates with non-hexameric AtCDC48 from plant cell extracts and inactivates AtCDC48 through hexamer disassembly. The UBX C-terminus of PUX1 contains the primary determinants necessary for interaction with AtCDC48. Two null insertion mutant alleles of PUX1 have been identified and show no gross morphological abnormalities, however, these plants surprisingly display accelerated growth rates. We propose that PUX1 elicits its negative effect on growth by promoting the inactivation of AtCDC48 function *in vivo*. In contrast to PUX1, PUX2 is a peripheral membrane protein that interacts with AtCDC48 *in vitro* and co-fractionates with membrane-associated but not soluble AtCDC48 *in vivo*. Biochemical reconstitution and immunolocalization data suggested that PUX2 facilitates the interaction of SYP31 and AtCDC48 during interphase and cytokinesis, thereby regulating an AtCDC48 membrane-associated function. Deletion analysis of PUX2 protein domains revealed the requirement of its PUG domain and not its UBX-domain for interaction with AtCDC48. Sequence analysis of PUX2 suggested that divergence in amino acid composition of the UBX-domain might be responsible for the inability of the domain to interact with AtCDC48. These studies provide the first evidence that the PUG domain may be an alternate interaction domain for AtCDC48.

## Tissue-Specific Gene Expression (1985-2002)

1985

**Human Dental Pulp Cell Culture and Cell Transplantation Using Alginate Scaffold**

S. Kumabe, F. Aikawa, M. Nakatsuka, H. Imbe, Y. Iwai; Oral Anatomy, Osaka Dental University, Hirakata-shi, Japan

[Purpose] We research stem cells in human dental pulp (HDP), because our preliminary study observed that cultured HDP cells induced hard tissue formation. The present study examines the transplantation of cultured cells using alginate as a scaffold.[Materials & Methods] The HDP tissue was obtained from extracted tooth, and cultured 13 passages. We added beta-glycerophosphate to examine cell differentiation, and examined ALPase activity related with tissue mineralization. Then, for studying differentiation of odontoblast, the expression of dentin sialophosphoprotein (DSPP) mRNA was studied by reverse transcriptase polymerase chain reaction (RT-PCR). For the investigation of the effect of scaffold, we mixed cultured cells and 1.5% alginate solution to form a cell cluster, which was then transplanted to the subcutaneous layer of 7-week old immunodeficient mice. Super soft X-ray (SOFTEX) films were taken to identify mineralization of the transplanted cell cluster. After 6 weeks, the tissue was removed, embedded in paraffin and type I & III collagen was immunohistochemically studied. Fine structure of the tissue was studied by the conventional TEM. [Results] Fibroblast-like cells were observed in the 13th passage samples. Diachronic increase of ALPase activity and expression of DSPP mRNA were increased by adding beta-glycerophosphate. Mineralized nodules were observed in cultured cells. Formation of hard tissue was observed within the transplanted cell cluster using alginate scaffold. Type I & III collagen antigen reaction was observed in the mineralized tissue surrounded and interposed with many fibroblast-like cells. [Discussion] The 13th passage cultured cells differentiated odontoblast-like cells. Expression of DSPP mRNA and formation of X-ray opaque tissue containing type I & III collagen indicated that transplanted cells commenced formation of certain dentin-like substance. [Conclusion] The present study suggests that alginate is an effective scaffold for dental pulp cells to produce dentin-like tissue.

1986

**Optimization of Spider Silk Glands for the Elicited Production of a Tissue-Specific Fibroin Product**

A. Garcia, I. Cajigas, B. Marrero, X. Cajigas, S. Medina, J. Rodriguez, G. Arroyo, G. C. Candelas; Biology, University of Puerto Rico, San Juan, Puerto Rico

Our studies have revealed that fibroin production by the large ampullate glands of the spider *Nephila clavipes* is the culmination of a series of time

and tissue-specific events, which optimize the glands for their highly demanding function. The latter is attained through a series of transient bouts of activities which enrich the gland's protein synthesis machinery. The processes are reproducible in terms of their timing and also relative intensities. The earliest of these events, one of considerable magnitude, provides the glands with a variety of small RNAs: two isoforms of 5S rRNA, a tissue-specific alanine tRNA, and members of the U subset of small RNAs which constitute the spliceosome complex. Isoforms of U1 and U2 generated have been proven not to be intermediates of RNA processing. The second event, which generates the fibroin template, is followed by an event of rather limited magnitude which attains selective enrichment of the gland's tRNA population by generating the tRNAs cognate to the fibroin's predominant amino acids: glycine, alanine and proline; an adaptive tRNA population shift. The last of the transient events, and one of considerable magnitude, attains the culmination of the elicited process through the massive production of the full size fibroin. Of special interest is the generation of a tissue-specific alanine tRNA of considerable intensity. Although its function is not, as yet, known it is a feature in the fibroin production strategy of the silkworm *Bombyx mori.*

1987

**Detection of HLA-E and HLA-G Expression in Human Placental Tissue**

H. Hutter, M. Siwetz, A. Blaschitz, G. Dohr; Institute of Cell Biology, Histology and Embryology, Medical University of Graz, Graz, Austria

Nonclassical MHC class Ib human leukocyte antigen E (HLA-E) and HLA-G molecules differ from classical ones by specific patterns of transcription, protein expression, and immunotolerant functions. HLA-G can be expressed as four membrane-bound (HLA-G1 to -G4) and three soluble (HLA-G5 to -G7) proteins upon alternative splicing of its primary transcript. In this study, we used a set of monoclonal antibodies (mAbs) called HCA2, 4H84, MEM-G/1, -G/9, MEM-E/2, and -E/6 recognizing HLA-G or HLA-E. The patterns of reactivity of these mAbs were analyzed on transfected cells by Western blotting and immunocytochemistry. MEM-G/1 recognizes (similar to the 4H84 mAb) the denatured HLA-G heavy chain of all isoforms. MEM-G/9 mAb react exclusively with native HLA-G1 molecules. MEM-E/2 and -E/6 mAbs bind the denatured and cell surface HLA-E molecules, respectively. These mAbs were then used to analyze the expression of HLA-G and HLA-E on cryo-preserved and paraffin-embedded serial sections of placental tissue. Single and double-immunolabeling with the respective mAbs revealed the presence of HLA-G and HLA-E in extravillious cytotrophoblast. In comparison, however, the levels of HLA-E expression seem to be much lower than those of HLA-G. In addition, we found a strong expression of HLA-E in endothelial cells using mAb MEM-E/2. The presence of HLA-G and HLA-E in specific cell populations of the placenta suggest an interacting functional role of these molecules in maternal-placental immune recognition.

1988

**Cdx2, Gata-4 and Hnf-4α Lead to Expression of an Intestinal Epithelial Phenotype in Fibroblasts**

J. Babeu, C. R. Lussier, F. Boudreau; Anatomy and Cell Biology, University of Sherbrooke, Fleurimont, PQ, Canada

The intestinal epithelium is an excellent model to study the molecular mechanisms during cellular differentiation. The epithelial stem cells located at the bottom of the intestinal crypts constantly divide to generate cells that will differentiate into four cell lineages. This differentiation is tightly regulated during cellular migration up to the villi. Literature supports the idea that restricted expression of many intestinal specific gene in differentiated cells is due to the specific combination of transcription factors. However, little is known about the exact molecular mechanisms that ultimately lead to intestinal epithelial cell differentiation. In the light of recent observations, we followed the hypothesis that Cdx2, Gata-4 and Hnf-4α could act as a transcriptional complex and induce cells to specialize into intestinal epithelial cells. To test this hypothesis, we first generated fibroblastic cell lines (NIH-3T3) that can conditionally over-express different combinations of Cdx2, Gata-4 and Hnf-4α transcription factors. We then characterized these inducible cell lines by Western blot analysis. NIH-3T3 cell lines that showed the best controlled expression for each factors were chosen to further investigate. RT-PCR analysis revealed that the combination of Cdx2, Gata-4 and Hnf-4α resulted into the induction of expression of the intestinal epithelium specific genes intestinal-fatty-acid-binding-protein (IFABP), intestinal trefoil factor 3 (ITF3) and apolipoprotein A-IV. We also found by electronic microscopy that NIH-3T3 with combined expression of Cdx2, Gata-4 and Hnf-4α changed morphology with the increase in cellular dimension, appearance of microvilli and beginning of polarization. In conclusion, our results suggest that ectopic combination of HNF-4α, Cdx2 and GATA-4 can initiate a program of intestinal epithelial cell determination within the mesenchymal context. Further studies will be necessary to document the targets of these transcription factors during the acquisition of the intestinal epithelial phenotype.

1989

**Functional Characterization of the Liver-enriched Transcription Factor CREB-H**

K. Chin,[1] J. Wong,[2] I. Ng,[2] D. Jin[1]; [1]Biochemistry, The University of Hong Kong, Pokfulam, Hong Kong Special Administrative Region of China, [2]Pathology, The University of Hong Kong, Pokfulam, Hong Kong Special Administrative Region of China

We have previously characterized transcription factor LZIP/CREB3 to be a growth suppressor targeted by hepatitis C virus oncoprotein. In search of proteins closely related to LZIP, we have identified a liver-enriched transcription factor CREB-H/CREB3L3. LZIP and CREB-H represent a new subfamily of bZIP factors. CREB-H activates transcription by binding to cAMP responsive element, box B, and ATF6/UPRE-binding element. Interestingly, CREB-H has a putative transmembrane domain and it localizes ambiently to the endoplasmic reticulum. Proteolytic cleavage that removes the transmembrane domain leads to nuclear translocation and activation of CREB-H. CREB-H activates the promoter of hepatic gluconeogenic enzyme phosphoenolpyruvate carboxykinase. This activation can be further stimulated by cAMP and protein kinase A. CREB-H transcript is exclusively abundant in adult liver. In contrast, the expression of CREB-H mRNA is aberrantly reduced in hepatoma tissues and cells. The enforced expression of CREB-H suppresses the proliferation of cultured hepatoma cells. Taken together, our findings suggest that the liver-enriched bZIP transcription factor CREB-H is a growth suppressor that plays a role in hepatic physiology and pathology.

1990

**Characterization of Two New Members of the *XK* Gene Family: XPLAC and XTES**

G. Calenda, J. Peng, C. M. Redman, Q. Sha, X. Wu, S. Lee; Membrane Biochemistry Laboratory, Lindsley F Kimball Research Institute of the New York Blood Center, New York, NY

XK, a putative membrane transporter, is a component of XK/Kell complex of the Kell blood group system. The substrate of XK is unknown but

absence of the protein results in neuromuscular abnormalities known as McLeod syndrome. We have cloned two XK homologues, *XPLAC* (AY589511) and *XTES* (AY989815), which form the *XK* gene family sharing 33% or higher amino acid identities. XK and XPLAC are present from human to fish. Gene linkage analysis demonstrates that *XK* is the primary copy from which *XPLAC* is duplicated. Currently *XTES* is found only in primates, suggesting *XPLAC/XTES*-splitting is the latest gene duplication event. Phylogenetic analysis revealed that the *XK* gene family is distantly related to at least 5 other vertebrate genes down to fish. However, less homologous proteins are present in nematodes and chordates. Ced-8 in *C. elegans* shares 19% amino acid identity with XK but it is more closely related to the 5 distantly related genes than to the XK gene family. Ced-8 has been reported to be involved in apoptosis (Stanfield, GM., Horvits,R., *Molecular Cell*. 2000; 5:423-433). Unlike ubiquitously expressed XK, XPLAC is mostly expressed in placenta and adrenal gland while XTES expression is limited to testis. Transfection of XPLAC and XTES cDNAs in COS-1 cells produced proteins of about 42 and 40 kDa, respectively, which are smaller than the predicted sizes of 53.6 (XPLAC) and 53.4 kDa (XTES). Immunohistochemistry of human placenta revealed that XPLAC is present in syncytiotrophoblasts. RT-PCR of a human trophoblast cell line, BeWo, showed the presence of XPLAC mRNA. Immunofluorescence detected XPLAC on the plasma membrane of BeWo cells. Cell surface biotinylation showed that XPLAC is on the plasma membrane of transfected COS-1 cells as well. Supported by NIH grants, HL54459 and HL075716

1991

**Aggrecan Upstream Regulatory Element P3 Directs Expression Exclusively to Maturing Chondrocytes**

K. Doege, F. Galiano; Pathology, LSU Health Sciences Center, Shreveport, LA

Aggrecan is a large chondroitin-sulfate proteoglycan expressed primarily in cartilage, where it is a major and essential component of the extracellular matrix. Stimulation of aggrecan synthesis is one of the goals in tissue engineering of cartilage, while depletion of aggrecan either by catabolic processes or altered cellular metabolism is one of the hallmarks of degenerative joint disease. Progress in understanding aggrecan gene regulation was recently achieved by identification of a regulatory element 12 kb upstream of the promoter which conferred cartilage-specific expression in transgenic mice. This element, (P3), appeared to direct expression to a subset of cartilages. The object of the current study was to determine the developmental course of expression driven by the P3 element, and relate it to the endogenous aggrecan gene expression pattern. Transgenic mice bearing the P3-driven lacZ transgene were bred, and litters were harvested at stages E14.5 and E16.5 p.c. The embryos were fixed and embedded in paraffin, and processed for in situ hybridization on tissue section using radioactive antisense cRNA probes. The transgene was monitored using a probe for the lacZ reporter, while other probes were also generated for aggrecan, type II collagen, type X collagen, Sox9, and Cbfa1. The results showed that aggrecan and type II collagen have very similar expression domains, while the P3-driven reporter was restricted to maturing cartilage of the lower proliferative/upper hypertrophic zone. This is the zone of highest expression for the endogenous aggrecan gene, and overlaps with type X collagen expression. Both Sox9 and Cbfa1 are expressed in this region also. These results confirm that the aggrecan regulatory apparatus is composed of combinatorial elements which may give restricted patterns of expression individually, but must be assembled together to reconstitute the entire endogenous expression pattern.

1992

**Identification of Two Repressor Elements Responsible for Cell-Specific Expression of an Osteoclastic Protein-Tyrosine Phosphatase (PTP-oc) Within its Intronic Promoter**

J. Yang, M. Amoui, K. H. W. Lau; Musculoskeletal Disease Center, J. L. Pettis Memorial VAMC, Loma Linda, CA

PTP-oc plays an important role in osteoclast functions. Although PTP-oc shares the same gene with a renal receptor PTP, GLEPP1, it is a distinct gene driven by a cell-specific, intronic promoter. To identify regulatory elements responsible for cell-specific expression of PTP-oc, we performed deletion and site-directed mutagenesis analyses on the pGL3-murine PTP-oc intronic promoter reporter construct. The pGL3-PTP-oc promoter construct showed strong basal promoter activity in osteoclastic cells, RAW264.7 cells, but was inactive in non-osteoclastic cells (TE85 osteoblastic cells, HepG cells, and skin fibroblasts). Deletion analyses performed with 13 pGL3-PTP-oc promoter deletion constructs identified two regulatory regions (-931/+116 and -491/+116, respectively). Internal deletion of each of these two regions from the promoter alone each led to >90% reduction in promoter activity. Simple alignment analysis between the human and mouse promoter sequences revealed no homology. When potential transcription factor binding regions (identified with the TESS program) of human promoter sequence was aligned against the murine promoter, at least 9 conserved domains were identified within the regulatory regions of the promoter. Site-directed mutagenesis analyses of each conserved domain revealed that at least two sites (potential binding site for IK-1/2 and IL6-RE-BP, respectively) contained repressor sites, since mutation of each site led to a significant increase in basal transcription activity in RAW264.7 cells. Importantly, each of the two mutated promoter constructs was equally active in non-osteoclastic cells as was in RAW264.7 cells, indicating that these two repressor sites were responsible for cell-specific expression of PTP-oc. In conclusion, we have identified two repressor elements responsible for cell-specific expression of PTP-oc within its promoter.

1993

**Multiparametric Gene Expression Profiling of Umbilical Cord Blood Multi Lineage Progenitor Cell Line**

N. Forraz,[1] M. Baradez,[2] C. P. McGuckin[1]; [1]Regenerative Medicine, Clinical Laboratory Sciences, University of Newcastle, Newcastle upon Tyne, United Kingdom, [2]Stem Cell Therapy Programme, Kingston University, Kingston upon Thames, United Kingdom

OBJECTIVES: Development of reproducible tissue engineering protocols calls for reliable access to sufficient numbers of immature homogeneous cell groups. High definition microarray analysis was used to phenotype the umbilical cord blood (UCB) cell line: Multi Lineage Progenitor Cell line (MLPC -BioE, MN, USA). Multiparametric gene expression analysis compared MLPCs to UCB mononucleated cells (MNCs), PrepaCyte-purified cells, CD133+ progenitor cells, lineage-restricted stem cells (Lin-) and a bone marrow mesenchymal stem cell (BMMSCs) in order to span a range of cell groups at various stages of differentiation. METHODS: RNA samples were hybridized to the PIQOR 942 gene Human Stem Cell Microarray platform (Miltenyi Biotec, CA, USA). MLPCs were compared to each cell group above with full pathway and signal network bioinformatics analysis. RESULTS: MLPCs phenotypic expression profile was significantly different (>1.4 fold down- or up-regulated) by 631 genes to the other five cell groups. MLPCs were particularly different to mature cell populations (MNCs and PrepaCyte) with downregulation of 65 genes associated with active protein synthesis (e.g. ribosomal sub-units), 18 genes linked with phosphate metabolism (kinases and phosphatases),

123 genes regulating proliferation and cell cycling (cyclins, cyclin-dependent kinases, check point proteins); reflecting a high degree of stemness, immaturity and quiescence. Comparison to stem and progenitor cell subsets (CD133+, Lin-) highlighted MLPCs' multipotential with downregulation of 12 different cluster of differentiation surface marker genes (e.g. epithelium, endothelium) and upregulation of 80 genes involved in nucleic acid binding and/or transcription factor activity regulating differentiation of tissues from all three germ layers. CONCLUSION: Stem cell-specific microarray phenotyping charaterized MLPC line as homogeneous group of extremely immature cells with exciting capabilities for tissue engineering applications.

1994

**Megakaryocytopoiesis and Zinc Finger Protein 24 (ZNF24)**

A. Hughes,[1] I. B. Sundell,[2] K. Tsubata,[1] J. Wooden,[1] J. A. Reems,[1] D. M. Gilligan[1]; [1]Puget Sound Blood Center, Seattle, WA, [2]Cellular and Medical Pharmacology, UCLA, Los Angeles, CA

Differentiation of megakaryocytes from hematopoietic stem cells is a complex process that occurs within human bone marrow. Megakaryocytes are large cells (50-70 micrometers) that are hyperdiploid (8N to 64N) due to incomplete cytokinesis. The final event of differentiation is platelet production, whereby each megakaryocyte produces hundreds of platelets. Given that the regulation of megakaryocyte differentiation and platelet production is not well understood, microarray analysis was performed on human hematopoietic stem cells (CD34+/CD38lo) that were induced to undergo megakaryocytic differentiation with thrombopoietin during a ten day culture period (Shim, et al., 2004). Among the genes identified to significantly increase in expression levels when comparing uncultured CD34+/CD38lo to day 10 culture derived cells was ZNF24. The mRNA level for ZNF24 showed an increase of 5.8$\pm$1.9 (mean$\pm$SEM; n=3) fold by microarray analysis, with a p-value of less than 0.001 (array performed in triplicate from three different cultures). Results were verified by real-time RT-PCR and analysis of hematopoietic lineages demonstrated lack of expression of ZNF24 in myeloid or lymphoid cells, with low levels of expression in erythroblasts and human hematopoietic stem cells cultured in the presence of erythropoietin. ZNF24 expression was also detected in cultures of murine megakaryocytes. We have expressed ZNF24 recombinant protein in E. coli and purified it using a 6xHis tag. Recombinant protein was used to generate an antibody in chickens and this antibody reacts strongly with a band of 50 kDa, the predicted size for the gene product. Confocal immunofluorescent microscopy demonstrates strong expression of ZNF24 in nuclei of human culture derived megakaryocytes. Since ZNF24 is a member of the large Kruppel-like family of transcription factors that play a variety of roles in regulating cellular differentiation, further studies will test the hypothesis that ZNF24 has a role in the regulation of megakaryocyte differentiation.

1995

**EST Analysis of Genes Expressed in Hemocytes of Manila Clams *(Ruditapes philippinarum)* Infected with *Perkinsus olseni***

S. K. Cho, Y. Kim, J. Kim, K. Choi, M. Cho; Cheju National University, Jeju, Republic of Korea

To investigate the patterns of genes expressed in Manila clams (*Ruditapes philippinarum*) infected with the protozoan parasite *Perkinsus olseni*, we constructed a cDNA library and generated 1,850 clones (expressed sequence tags). The 1,850 expressed sequence tags (ESTs) were compared to sequences in the GenBank database. Of these, 1,151 clones (62.2%) were unknown and are likely to represent newly described genes, while 699 clones (37.8%) were identified based on matches to sequences in the database. In all, 53 contigs and 376 singletons were formed. The identified ESTs could be grouped into seven functional categories: cell signaling/communication (14.9%), cell structure (9.0%), cell defense/immunity (11.3%), metabolism (17.9%), replication (1.9%), unknown functions (10.9%), and others (34.2%). In these categories, a total of 79 ESTs, such as C-type lectin, lysozyme, and cystatin B, were related to 29 functional immune genes in Manila clams infected with *Perkinsus olseni.* Lectins were the largest group of immune-function ESTs found in the Manila clams. A phylogenetic tree of these ESTs was constructed from a sequence alignment by the Jotun-Hein method (Megalign, DNAstar). The resulting phylogenetic tree showed that the Manila clam C-type lectin was more closely related to that of purple sea urchins than to that of scallops. The expressions of lectins in the hemocytes were analyzed by RT-PCR using gene specific primers. Hemocyte from *Perkinsus*-infected clam expressed different set of lectins from that of *Vibrio*-infected one. Here, we suggest various lectins are involved in Manila clam innate immunity and different challenges induce expression of a different set of lectins.

1996

**Possible Functional Consequences of Microgravity-Induced Changes in Gene Expression in Activated T-Lymphocytes**

N. E. Ward,[1] N. R. Pellis,[2] S. Risin,[3] D. Risin[2]; [1]Cell Science, Wyle Laboratories, Houston, TX, [2]NASA/JSC, Houston, TX, [3]UT Medical School, Houston, TX

Exposure to both true and modeled microgravity causes a decline in cellular immune function. The purpose of this study was to identify associated gene expression changes and possible gravity sensitive genes by applying microarray chip analysis. CD3- and IL2-activated T-cells were cultured in 1g (static) and modeled microgravity (NASA Rotating Wall Vessel bioreactor) conditions for 24 hours. Microarray analysis was performed utilizing Affymetrix Gene Chips that allow testing for 18,400 genes. Exposure to modeled microgravity resulted in altered expression of 89 genes, 10 genes showed up-regulation and 79 down-regulation. Up-regulated genes included IL7-receptor which plays a role in lymphocyte development and blocking of apoptosis during T-cell differentiation and activation. Also up-regulated were several heat shock protein family members functioning together as molecular chaperones, stabilizing existing proteins from aggregation, and mediating folding of newly translated proteins. Down-regulated genes involved in various roles in the induction of apoptosis included granzyme B, beta-3-endonexin, and Apo-2 ligand. Proteasome activator subunit 2, part of the immunoproteasome which processes MHC peptides was also down-regulated. Also down-regulated were three proteasome beta family members which cleave peptides, several genes potentially affecting the integrity of the cellular cytoskeleton such as CD2 associated protein, tubulin, and pericentrin 1, genes affecting DNA repair such as nudix and FEN1, and genes affecting several metabolic pathways such as glucose 6-phosphate dehydrogenase in the pentose phosphate pathway. (Supported by NRA OLMSA-02 and NSCORT NAG5-4072 grants).

1997

**Production Mechanisms of Plasma Glutathione Peroxidase from Bovine Adipocyte**

H. Aso,[1] T. Yamasaki,[2] K. Tahara,[2] S. Takano,[2] M. Inoue-Murayama,[3] T. Minashima,[1] T. Kanaya,[1] S. Ito[3]; [1]Cellular Biology Laboratory, Tohoku

University, Sendai, Japan, [2]R & D Center, BML Inc., Kawagoe, Japan, [3]Laboratory of Animal Genetics, Gifu University, Yanagido, Japan
Despite the well-known ability of glutathione peroxidases (GPx) to metabolize hydrogen peroxide, the exact role of this enzyme family under physiological and oxidative stress conditions is still not clearly defined. A plasma-secreted form of GPx (pGPx) is a member of this family, and kidney is a main producer of pGPx. We identified the large part of isolated genes as pGPx, which were subtracted the proliferating stage from the adipogenic differentiating stage of a bovine intramuscular preadipocyte (BIP) line. Therefore, we analyzed the production mechanisms of pGPx in bovine adipocyte. During adipogenic differentiation of BIP cells, the expression of pGPx genes was increased from 2 days and reached to the peak at 4 days after stimulation. The production of pGPx protein to the culture supernatant was detected at 6 days after stimulation and produced by dexamethason. The addition of octanate enhanced its production by dexamethason. In BIP cells, the peak of expression of C/EBP-gamma genes were about 6.4-fold at 2 days after stimulation, however, the expression of the GPx1 genes was hardly detected during adipogenesis. In 3T3-L1 cells and human preadipocytes, GPx1 gene was usually expressed at the proliferating and the differentiating phases. These data suggested that there might be a different production pathway of GPx between spices. The protein of pGPx was greatly produced in kidney and in intraperitoneal fat, but was weakly detected in lung, heart, spleen and small intestine. We considered that the transcriptional control of pGPx in ruminants might to be carried out by C/EBP-gamma, and that the expression of pGPx might be a characteristic phenomenon in bovine adipogenic differentiation.

1998

**Value of Microarray Analysis of Gene Expression for the Study of the Mechanism of Ischaemia/Reoxygenation in the Human Myocardium**

H. A. Vohra, M. F. Chowdhry, M. Galiñanes; Cardiovascular Sciences, Leicester University, Leicester, United Kingdom
OBJECTIVE We have previously shown that the degree of cell death by apoptosis and necrosis in the human myocardium depends on both the ischemic insult and the period of reoxygenation, that injury is exacerbated by diabetes and reduced by ischemic preconditioning (IP) and caspase-3 inhibition (C3i). Here we investigate changes in gene expression induced by ischemia (I) and reoxygenation (R) and the effect of cardioprotective interventions such as IP and C3i in the diabetic and non-diabetic human myocardium. METHODS Gene Chip ® microarrays were used to analyse mRNA isolated from right atrial appendage (n=3 specimens from different subjects/group) at the end of 90 minutes I and after 120 minutes R. Affymetrix Suite 4.0 and DNA-chip analyser 1.3 were used for data analysis. Changes in gene regulation were considered significant if hybridization intensity was more than 2-fold different from non-ischaemic controls. RESULTS Genes encoding for pro-inflammatory cytokines (e.g. TNF-α, IL-1, IL-6, interferon-α) were down-regulated by I, whereas heat-shock proteins were unaffected by I but were up-regulated by R. A number of specific genes transcribing for pro- and anti-apoptotic proteins were down- or up-regulated, changes that may contribute to promote or counteract apoptosis. The Bcl-2 related gene was down-regulated by >6-fold by I and R but was attenuated by C3i (1.2-fold) and reversed by IP (3.1-fold up-regulation). Specific inflammatory, cell cycle, growth-related and cell death genes were up- or down-regulated by diabetes and I and R resulted in gene expression changes that were not observed in non-diabetics. CONCLUSION Use of microarray analysis and gene expression can be an important tool to understand the complexity of I and R injury, the role played by disease states such as diabetes and the mechanism of cardioprotection.

1999

**Nkx25 Knockdown Using RNAi Resulted in Sarcomere Disorganization**

H. Kasahara,[1] C. Martinov,[1] M. Marks,[1] H. Aoki[2]; [1]Physiology and Functional Genomics, University of Florida, Gainesville, FL, [2]Yamaguchi University, Ube, Yamaguchi, Japan
The homeobox transcription factor, Nkx2.5, is a well-characterized early cardiogenic marker in embryonic heart development. While Nkx2.5 expression continues in the heart throughout adulthood, its function in postnatal hearts is not well understood. We knocked-down Nkx2.5 using adenovirus-delivered RNAi in cultured rat neonatal cardiomyocytes. Depletion of Nkx2.5 expression (more than 90 %) was associated with altered cardiomyocyte cell shape with sarcomere disorganization. Expression of two Z-disc localized proteins, muscle LIM protein (MLP) and T-cap (titin cap protein), were markedly downregulated early after Nkx2.5 downregulation, suggesting that their expressions are dependent on Nkx2.5 expression. To understand the transcriptional regulation of the MLP gene, a 2kb promoter region of mouse MLP gene was analyzed in a luciferase reporter construct. Addition of this promoter region to pGL3-luciferase basic reporter vector caused a more than 50-fold induction of luciferase activity in cardiomyocytes compared to only 2- to 3-fold induction in non-myocytes (relative to pGL3 basic vector luciferase activity). These results indicate that this 2 kb proximal promoter region of the MLP gene contains strong cardiomyocyte-specific transcription factor binding sites. Five consensus Nkx2.5 binding sites are located in this region, which suggests direct involvement of Nkx2.5 on MLP gene expression. Our findings suggest that in the postnatal heart, Nkx2.5 is involved in transcriptional regulation of sarcomeric protein expression and maintenance or maturation of sarcomere organization.

2000

**New Technologies for Gene Expression Analysis from Blood**

P. Whitley, S. Motori, J. Kemppainen, J. Gonzoles, B. Setterquist, C. D. Buchanan, G. Latham; Ambion, Austin, TX
Blood is used extensively as a diagnostic tissue to indicate a variety of health problems including infection, inflammation, cancer and autoimmune disease. However, abundant globin transcripts in the blood greatly reduces array sensitivity and causes a progressive distortion of gene expression profiles in a manner that is dose dependent. Several cutting-edge technologies have converged to enhance the success of microarray experiments from blood. In particular, we have optimization sample stabilization, RNA isolation, globin mRNA reduction and RNA amplification from whole blood. These advances result in >95% removal of globin transcripts and increase the percent of detectable genes on Affymetrix arrays by more than 50%.

2001

**Methylation Profiling Using a Human Chromosome 1 Minimal Tiling Path Array**

E. Ramos,[1,2] C. De Bustos,[3] R. K. Tran,[4,5] U. Menzel,[3] S. McGrath,[2,5] C. F. Langford,[6] E. E. Eichler,[2,5] L. Hsu,[7] S. Henikoff,[4,5] J. P. Dumanski,[3] B. J. Trask[1,2]; [1]Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA, [2]Department of Genome Sciences, University of Washington, Seattle, WA, [3]Department of Genetics and Pathology, Uppsala University, Uppsala, Sweden, [4]Division of Basic Sciences, Fred

Hutchinson Cancer Research Center, Seattle, WA, [5]Howard Hughes Medical Institute, Seattle, WA, [6]Welcome Trust Sanger Institute, Cambridge, United Kingdom, [7]Division of Public Health, Fred Hutchinson Cancer Research Center, Seattle, WA

DNA methylation is a major epigenetic modification that plays an important role in gene expression and genomic imprinting. Aberrant methylation can lead to a number of diseases, including cancer. In mammals, some CpG islands, regions of dense CpG sequence, are involved in regulating transcription of many genes. Consequently, methylation at key CpGs can lead to the inhibition of transcription. Classical approaches investigate methylation patterns on a locus-by-locus basis. CpG islands associated with genes of interest are targeted for analysis. More recently, high-throughput methods have emerged to analyze the methylation state of a genome using microarrays of gene- or CpG island-specific oligonucleotides or PCR products. Here, we describe our approach, which yields a comprehensive methylation profile of a human chromosome at ~100 kb resolution, as it employs an array ~2100 clones (BACs, PACs, cosmids and fosmids) that represent a minimal tiling path covering the euchromatic portions of chromosome 1. We have found differences in methylation between different tissues from a normal human tissue panel. Interestingly, some hypomethylated clones contain genes that are tissue specific. We believe that this global view of methylation will aid in making gross comparisons among tissues or tumor samples, as well as point to specific CpG islands for more in-depth analysis. The approach can also be expanded to profile a variety of diseases associated with aberrant methylation. Identifying abnormal promoter methylation in diseases such as cancer would have a powerful impact on our understanding of the gene expression changes that contribute to the disease process.

2002

**Metaplasia of Hepatocytes into Pancreatic Acinar Cells During Mouse Liver Regeneration**

A. Tsou,[1] Y. Chau,[2] C. Liu,[1] C. Lin,[3] Y. Lu,[1] M. Hsu[4]; [1]Institute of Biotechnology in Medicine, National Yang-Ming University, Taipei, Taiwan Republic of China, [2]Institute of Anatomy and Cell Biology, National Yang-Ming University, Taipei, Taiwan Republic of China, [3]Institute of Bioinformatics, National Yang-Ming University, Taipei, Taiwan Republic of China, [4]Institute of Biochemistry and Molecular Biology, National Yang-Ming University, Taipei, Taiwan Republic of China

Hepatocytes rarely divide but rapidly regenerate upon severe tissue losses by chemical or physical injuries. Numerous reports revealed observation of pancreatic cell phenotypes in the cultured hepatocytes, in animal livers and in patients with liver tumors embedded in a cirrhosis background. In addition, acute pancreatitis was known to occur in patients after liver transplantation. The molecular mechanism dictating the mutual interaction between adult liver and pancreas, however, is uncertain. In a global transcriptome study we detected activation of a cluster of 39 pancreatic exocrine genes during mouse liver regeneration induced by partial hepatectomy (PHx). Syn-expression of selected genes at early $G_1$ phase of liver regeneration was confirmed by qRT-PCR. Amylase from regenerating liver is *Amy2* by nucleotide sequence alignment. Amylase protein expression showed a portal-to-central vein gradient and peaked at early $G_1$ phase of liver regeneration as revealed by immunohistochemistry and western blot analysis. The observation that *Ptf1a* is specifically up-regulated suggests a possibility that hepatocytes may be induced to undergo metaplasia into pancreatic exocrine cells. Electron microscopic (EM) analysis of regenerating hepatocytes detected the granular structure similar in morphology to that of pancreatic zymogen granule and prominent rough ER structures characteristic of pancreatic acinus which were not found in control liver tissues. To examine whether pancreas is injured by the altered blood flow in hepatectomy, we examined the morphology of mouse pancreas after liver resection. EM analysis showed autophage structure and abnormal mitochondria in the pancreas during liver regeneration. The rough ER structure characteristic of pancreatic exocrine cells was also significantly decreased in the pancreas following hepatectomy. Liver-to-pancreas metaplasia during PHx-induced liver regeneration may constitute an early induction signal of liver regeneration and a signal to trigger recovery of pancreatic acinar cells from PHx-induced damages.

## Chromatin & Chromosomes II (2003-2020)

2003

**Comparative Proteome Analysis of Human Metaphase Chromosomes**

H. Takata, S. Uchiyama, N. Nakamura, S. Kobayashi, S. Matsunaga, K. Fukui; Biotechnology, Osaka University, Osaka, Japan

Chromatin was composed of DNA and many kinds of proteins and it takes a condensed structure called chromosome during mitosis. Although this chromosomal higher order structure is essential for cell division, protein components of chromosome and mechanism of chromosome condensation remain controversial. In this study, we aim to identify proteins which are essential for formation of the higher order structure by using comparative proteome analysis. Chromosomes were isolated from two different human cell lines, Ball-1 and HeLa S3, using polyamine procedure. Chromosomal proteins were extracted using an acetic acid method. Proteins were subjected to one-dimensional (1D) SDS-PAGE and two-dimensional electrophoresis (2DE). We use a radical free and highly reducing method (RFHR) for 2DE. RFHR method is useful to separate basic proteins, thus the method is more effective to detect chromosomal proteins that interact with DNA in chromosome. By CBB staining, about 200 spots were detected from the isolated chromosome protein with high reproducibility. Proteins were identified by mass spectrometry, MALDI-TOF MS or LC-MS/MS, and more than 100 proteins were identified from each cell line. Almost all chromosomal proteins were occupied by histone proteins and the amount of non-histone proteins is only 1/10 of histone proteins based on the information of quantitative analysis of identified proteins. By comparison of the amount between BALL-1 and HeLa S3, we identified some proteins whose amounts were conserved in both cell lines. These results suggest that some non-histone proteins are essential for chromosome higher order structure.

2004

**Molecular Analysis of Mitotic Chromosome Condensation Using a Quantitative Time-Resolved Fluoresence Microscopy Assay**

P. S. Maddox, N. Portier, A. Desai, K. Oegema; LICR, UCSD, La Jolla, CA

Chromosomes condense during mitotic entry to facilitate their accurate segregation. We have developed a quantitative method to monitor the kinetics of condensation in living cells by measuring progressive changes in the fluorescence intensity distribution of green fluorescent protein (GFP) fused to a core histone. In *C. elegans* and *Drosophila* embryos, condensation occurs during prophase in two temporally distinct steps that we term primary and secondary condensation. In *C. elegans*, where the histone variant CENP-A forms centromeric chromatin that runs along the entire length of each holocentric chromatid, both centromeric chromatin and condensin contribute to condensation. We show that preventing the assembly of centromeric chromatin results in a condensation defect that is kinetically distinct from condensin inhibition, and that the role of centromeric

chromatin in condensation is independent of its requirement for directing kinetochore assembly. Depletion of Aurora B, the mitotic histone H3 kinase reported to control condensin distribution on metaphase chromosomes, has no effect on condensation kinetics. In contrast to the SMC subunits of condensin, HCP-6, the CAP-D3 subunit of *C. elegans* condensin, requires CENP-A to localize to chromosomes, suggesting that it functions as a centromeric chromatin-specific adaptor for condensin. However, a quantitative comparison of HCP-6-depleted, SMC-4-depleted and CENP-A-depleted embryos indicates that HCP-6 and SMC-4 are of equal functional importance during condensation. This result suggests that the difference between the targeting of HCP-6 and SMC-4 to metaphase chromosomes reflects a change in chromosome architecture that occurs after prophase condensation.

2005

**Comparative Structural Biology of the Genome: Nano-scale Imaging Single Nucleus from Different Kingdoms Reveals the Chromatin Built Up on a 40 nm Structural Unit**

T. Kobori,[1] M. Kodama,[2] K. Hizume,[1] S. H. Yoshimura,[1] T. Ohtani,[3] K. Takeyasu[1]; [1]Graduate School of Biostudies, Kyoto University, Kyoto, Japan, [2]Kyoto University, Kyoto, Japan, [3]National Food Research Institute, Tsukuba, Japan

Eukaryotic genome is organized into the nucleus through several compaction steps. Core histones are well conserved among eukaryotes, form a 'beads-on-a-string' structure of nucleosomes together with DNA. Linker histones are also found in eukaryotes, and contribute to establish thicker 30-40 nm chromatin fibers. Interestingly, however, the linker histones do not always play a role in the genome packaging in some eukaryotes. Nevertheless, relationship between the genome structure and function seems to be generally conserved among eukaryotes. In this study, we comparatively analyzed the chromatin dynamics with different intrinsic properties; genome size, histone composition, and inter-nucleosomal distance. Namely, the nuclei isolated from human HeLa cells, chicken erythrocytes, and yeast *Schizosaccharomyces pombe* were structurally studied using a nanoscale imaging technique, atomic force microscopy (AFM). For this, we adopted the 'on-substrate' lysis procedure, which successively removes the nuclear membrane and the nucleoplasm while the chromatin and nuclear scaffold remain on the substrate, and, thus, allow us to look at the chromatin architectures in the nucleus at nano-scale. Our comparative structural analyses identified a common fundamental structural unit of the interphase chromosome. The high-salt treatment, which removed the nucleoplasm, caused a release of 40 nm fibers from the nuclei of all eukaryotic cells tested. The 80-100 nm bead structures were also observed on the surface of nuclei after the high-salt treatment. No structural population other than the 40 nm fiber and the 80 nm beads was clearly found, suggesting that the 40 nm fiber would fold directly up to the 80-100 nm beads regardless of eukaryotic species.

2006

**Older Human Cells Show More Complex Aneuploidy than Younger Cells after DNA Damage by Cobalt Chrome Particles**

D. Ladon, I. Papageorgiou, I. D. Learmonth, C. P. Case; Dpt. of Orthopaedic Surgery, University of Bristol, Bristol, United Kingdom

Humans are exposed to metals from the environment, industry and surgical implants. This study has explored whether cellular age influences the cytogenetic response to metal exposure (in this case cobalt-chrome alloy (CoCr) particles). Human primary fibroblasts at PD 5 (young) and PD35 (middle aged) were treated with CoCr particles (38.5 mg/ml) for 24 hours, harvested after 1, 2 and 15 days and karyotyped with M-FISH. 60 metaphases were analysed in each sample and in triplicate. Although the mitotic index (1000 cells/sample 3hr colchicine) of the resting young and older control cells was approximately the same (9-12%), there was a difference after short term metal exposure. The mitotic index was reduced in young cells to 2% at 1 and 2 days after exposure but was absent at this stage in older cells. By 15 days the mitotic index had partially recovered in both young and older cells (6%). The total incidence of structural and numerical chromosome aberrations was approximately the same after metal exposure of young and older cells (in metaphases that could be scored). There was little difference in the type of structural aberrations (deletions, fragments, translocations). However the type of aneuploidy was different. At day 15 the younger cells mostly showed loss of a chromosome (58% <46, 10% >46 5%>60) whilst older cells mostly showed a gain, often involving more than 60 chromosomes (7% <46, 47% >46, 29% >60). 30% of metaphases in older cells with more than 60 chromosomes showed evidence of a lack of cohesion and/or premature sister chromatid separation. This was only seen in 2% of metaphases in young cells. We conclude that cellular age in culture has a significant effect on the cytogenetic response to a mutagenic agent.

2007

**Fundamental Structure of Bacterial Chromosome Identified by Atomic Force Microscopy and the Reconstitution of Nucleosome-like-structure with Hu**

J. Kim,[1] K. Hizume,[1] S. Yoshimura,[1] R. Ohniwa,[1] C. Wada,[1] A. Ishihama,[2] K. Takeyasu[1]; [1]Department of Responses to Environmental Signals and Stresses, Graduate School of Biostudies, Kyoto University, Kyoto, Japan, [2]Division of Molecular Biology, Nippon Institute for Biological Science, Tokyo, Japan

In the *Escherichia coli* genome structure, one of the main structural proteins is Hu, which is known as histone-like protein. However, the molecular mechanisms of Hu for the formation of genome structure remain unclear, so it is not known weather there is beads-on-a-string structure like eukaryotic genome. In this study, we have tried to reconstitute the fundamental structure with 3 Kbp plasmid DNA (pBluescriptII) and Hu, and analyzed by AFM, to understand the mechanism of genome packing. As the reconstitution of eukaryotic nucleosome structures, salt-dialysis experiment was performed; DNA and proteins were mixed in the buffer containing 2 M NaCl and dialyzed against the buffer without NaCl. Dialysis was carried out until NaCl concentration became 50 mM, and subjected to AFM observation. As the results, a relaxed circular DNA which had a bead with a diameter 25 nm was observed, although the supercoiled plasmid was used for the reconstitution. Contour length was measured to be 930 nm, which is 70 nm (200 bp) shorter than 3 Kbp DNA. From the volume measurement of the volume of the beads and the length of DNA, 200 bp of DNA and 10 to 20 of Hu dimers seem to form this. These results suggest that the Hu could form the nucleosome like structure which has bead shape and resolve DNA supercoiling. When we just mixed DNA and Hu in low-salt buffer without dialysis process, beads structure was never observed. We had reported that 80-nm and 40-nm fiber structures were fundamental structure of the intact prokaryotic genome. From the combination of the observations of intact nucleoid and reconstituted Hu-DNA complex, we propose a structural model of the molecular mechanism of the fundamental structure of nucleoid.

**Localization and Dynamics of Chromosomal Proteins in Human Cells**

D. No,[1] S. Matsunaga,[2] S. Uchiyama,[2] K. Fukui,[2] T. Azuma,[3] M. Nakagawa,[3] N. Ohmido[1]; [1]Graduate School of Cultural Studies and Human Science, Kobe University, Kobe, Japan, [2]Laboratory of Dynamic Cell Biology, Department of Biotechnology, Graduate School of Engineering, Osaka University, Suita, Japan, [3]Division of Biosignaling, Research Institute for Biological Scienses, Tokyo University of Science, Noda, Japan

Chromosomes are essential for accurate segregation of replicated genomic DNA to daughter cells. It is not well-defined, which proteins contribute to the higher order structure and precise function of human chromosomes. To understand which proteins are important in chromosome structure and function, proteome analysis of isolated human chromosomes were carried out and listed 107 proteins could possibly relate to chromosome (Uchiyama, *et al.*, 2005). To identify the specific localization of these proteins on chromosome, we have generated polyclonal antibodies against candidate proteins and performed immunofluorescent staining using three types of chromosome samples of chromosomes in cells, hypotonic treated cells, and isolated chromosome from HeLa S3 cells. As the results of indirect immunofluorescent staining, FtsJ homolog 3 was localized to chromosome peripheral region on isolated chromosomes and spread chromosomes samples, FtsJ homolog 3 was localized at periphery of chromosomes and also on spindle body at metaphase and anaphase cells. These results show that FtsJ homolog 3 is a novel chromosomal protein. It is known that *ftsj* deletion results in a growth defect and altered ribosome profile in *E. coli* (Caldas, *et al*., 2000 and Bügl, *et al*., 2000). FtsJ is well-conserved as the heat shock protein from bacteria to human. Therefore, our data on FtsJ homolog 3 localizing on chromosomes and spindle body suggest that FtsJ homolog 3 might be also thought to be functional protein through cell cycle.

2009

**Mugsy, a *Drosophila* Nucleostemin-Like GTPase**

R. Rosby,[1] V. Robinson,[2] P. DiMario[1]; [1]Biological Sciences, Louisiana State University, Baton Rouge, LA, [2]Molecular and Cell Biology, University of Connecticut, Storrs, CT

Nucleostemin is a nucleolar GTPase implicated in stem cell and cancer cell proliferation (Tsai and McKay, 2002, 2005; Mistelli, 2005). We have identified a nucleostemin-like protein in *Drosophila* (CG3983 in cytological region 89E11 of chromosome 3R). The predicted protein that we call Mugsy is 581 amino acid residues in length. It displays 33.7% identity and 64.2% similarity to mammalian nucleostemin. Initial hydrolysis assays indicate the protein binds and hydrolyses GTP efficiently, despite its permuted GTPase motifs. The cDNA encoding the GFP-Mugsy was ligated into pUAST, a P element-containing transformation vector with yeast GAL4 upstream activation sequences. We prepared six homozygous transgenic lines that we crossed to the *daughterless-GAL4* driver line. Induced GFP-Mugsy localized primarily to nucleoli in all tissues examined. A small percentage also localized to the nucleoplasm. The interesting localizations were in larval salivary gland nuclei where GFP-Mugsy localized to the giant nucleoli as expected, but also to the condensed bands in the polytene chromosomes. This localization is similar to that of a modulo, another nucleolar protein known to localize to polytene bands, and to suppress position effect variegation (Perrin et al., 1998, 1999).

2010

**The Role of RNAi in Gene Silencing: Investigating VIG and Its Homologue CG11844**

K. D. Grim, S. C. R. Elgin, E. Gracheva; Lab of Dr. Sarah Elgin, Biology, Washington University in St. Louis, St. Louis, MO

We are studying the RNAi pathways in *D. melongaster*, in particular RNAi induced transcriptional silencing. Mutations in the RNAi genes *piwi, aubergine*, and *homeless*, have been shown to impact the formation of heterochromatin and the generation of histone H3 dimethylated at lysine 9 (H3K9me2) (Pal-Bhardra et al. 2004, Science 303, 669). A protein complex that has been implicated as playing a role in both RNAi-induced transcriptional and post-transcriptional silencing is the RISC complex (ribonuclease-containing RNA-induced silencing complex). A member of the RISC complex, VIG (Vasa Intronic Gene), is associated with heterochromatic regions of the polytene chromosome as shown by immunofluorescent staining (B. Brower-Toland, S. Elgin, unpublished data). However, mutations in VIG have no impact on a variegating *yellow* transgene. A search of the genome has identified a close homolog of VIG, putative gene CG11844, a locus with no characterized mutant alleles. Knock-down experiments in Drosophila Kc cells and VIG mutant flies demonstrate that the total H3K9me2 level does not change in a VIG deficient background; however when both VIG and CG11844 are knocked down in Kc cells, the H3K9me2 level drops. To evaluate the function of the CG11844 gene product in heterochromatin formation and thus transcriptional silencing *in vivo*, we are generating *D.melongaster* mutants deficient in CG11844 using 'Ends-In' targeting and deletion (method described in Xie and Golic, 2004, Genetics 168, 1477). A construct carrying sequences flanking the CG11844 gene, as well as a *hs-white* marker and the required restriction sites and FRT elements, has been prepared and will be injected into flies. The results should help us to further understand the mechanisms directing heterochromatin formation and maintenance. [Supported by NIH grant GM073190 to SCRE.]

2011

**Spatial Arrangement and Dynamics of Chromosomes in *S cerevisiae***

D. A. Bressan,[1] S. Jain,[1] E. Kim,[2] S. Haase,[2] J. Martin,[3] J. Kondev,[3] J. W. Sedat,[2] J. E. Haber[1]; [1]Rosenstiel Center and Department of Biology, Brandeis University, Waltham, MA, [2]Department of Biochemistry and Biophysics, University of California, San Francisco, CA, [3]Department of Physics, Brandeis University, Waltham, MA

The Recombination Enhancer(RE) is a cis-acting region located proximal to *HML* on the left arm of yeast chromosome III which controls donor preference during mating-type (*MAT*) switching. *MAT***a** preferentially recombines with *HML* on the left arm, whereas *MAT*alpha prefers *HMR* on the right arm. We marked several different chromosomal loci on chromosomes III and V using *lacO* and *tetO* arrays to which LacI- and TetR-fluorescent proteins bind. Using live-cell 3D deconvolution fluorescence microscopy, we found that the movement of *lacO* sequences adjacent to *HML* are strongly constrained in both *MAT*alpha and RE-deleted *MAT***a** strains, compared to *MAT***a** cells. In contrast, movement of *lacO* arrays adjacent to *HMR* or on the left arm of chromosome V is mating type-independent. *HML* is more strongly constrained in *MAT***a** re- and less constrained in *MAT***a** $RE^+$ compared with other sites. These data support models in which donor preference reflects the constitutive tethering of the left arm of chromosome III and that RE acts to relieve this tethering in *MAT***a** cells. Although the donor loci are not pre-paired with *MAT* prior to HO induction, we observed a mating type- and RE-dependent difference in the 3D configuration of *MAT*, *HML* and *HMR*. Kinetic analysis of synapsis between *MAT* and *HML* following double-strand break(DSB) induction by HO cleavage at *MAT* in wild-type and recombination-defective

mutants enables us to see the real-time dynamics of homology search that is the prelude to DSB repair. Recent imaging of the *MAT* and *HML* loci and the spindle pole body revealed both mating type- and locus-dependent differences in dynamic behavior of these regions. To study the rapid diffusion between different sites on chromosome III, we are analyzing images collected by a novel high-speed fluorescence deconvolution microscope developed by the laboratory of John Sedat.

2012

**Displacement of the Bromodomain Protein Brd4 from Chromosomes is Required for the Recovery from Anti-Microtubule Drug Induced Mitotic Arrest**

A. Nishiyama, K. Ozato; LMGR, NIH/NICHD, Bethesda, MD

Brd4 is a mammalian bromodomain protein that belongs to the conserved BET family. Brd4 associates with chromosomes during the entire course of mitosis through binding to acetylated histone H3 and H4. Mitotic cells are particularly susceptible to anti-microtubule drugs. To study the functional significance of Brd4-chromosome association, we examined the effect of anti-microtubule drugs. We found that Brd4 was displaced from mitotic chromosomes in response to all anti-microtubule agents tested, including the reversible agent, nocodazole. However, after nocodazole withdrawal, Brd4 was reloaded onto chromosomes, which coinciding with the resumption of mitotic progression. Several JNK inhibitors inhibited displacement of Brd4 from chromosomes induced by nocodazole. The JNK inhibitor also reversed Brd4 displacement when added following nocodazole, indicating that Brd4 displacement is a transient response and is controlled by JNK activation. We also found that cells treated with the JNK inhibitor were deficient in resuming mitosis after nocodazole removal, suggesting that Brd4 displacement has a functional role in restarting mitosis after drug withdrawal. Furthermore, we show that Brd4 heterozygous (Brd4+/-) cells are defective in reloading Brd4 onto chromosome after nocodaozole withdrawal, although Brd4 displacement by nocodazole was normal in Brd4+/- cells. Similar to JNK inhibitor treated cells, Brd4+/- cells were impaired in resuming mitotic progression after nocodazole removal, and showed increased chromosome missegregation and reduced cell division. Together, our study shows that Brd4 undergoes a dynamic movement from and to chromosomes after addition and removal of anti-microtubule agents. Brd4 dynamics triggered by these agents may represent a cellular response against drug induced mitotic stress, and may have a key role in facilitating the recovery from drug induced mitotic stress.

2013

**Linker Histone Dynamics, Structure, and Function in Interphase and Mitotic Sperm Chromosomes Assembled in Xenopus Egg Extracts**

B. S. Freedman, T. J. Maresca, R. Heald; Molecular and Cell Biology, UC Berkeley, Berkeley, CA

Classic electron microscopic and nuclease digestion experiments have established that linker histones bind to nucleosomal arrays and compact them into a thicker chromatin fiber. It is unclear how these experiments, which were assayed at the scale of chromatin under processed conditions, relate to the *in vivo* organization of entire chromosomes. We recently addressed this issue using physiologically active *Xenopus* egg extracts and sperm nuclei that progress through the cell cycle. We found that replicated, mitotic chromosomes assembled in extracts depleted of the embryonic linker histone H1M (or B4) had a distorted morphology and were about twofold longer than normal (Maresca TJ *et al.*, 2005). Thus, H1M helps compact whole chromosomes, which is consistent with the classical role for linker histones at the smaller scale of nucleosomal chromatin. Currently, we are using this roughly physiological, vertebrate system to investigate several aspects of linker histone function: (1) To extend our findings from mitotic to interphase chromosomes, we are using fluorescence microscopy to measure nuclear size, chromosome morphology, and chromosome length (by FISH) in nuclei assembled with or without H1M. (2) H1M must first be loaded onto DNA during interphase in order to compact mitotic chromosomes. To understand the molecular mechanism underlying this loading step, we are therefore performing H1M immunoprecipitations to identify binding partners. We are also comparing the binding dynamics of H1M to chromosomes during interphase versus mitosis. (3) H1M has two major domains, a globular head and a highly basic, unstructured carboxyl tail. We are substituting these domains for the full-length protein to evaluate their separate contributions to chromosome morphology. We are also engineering phosphorylation-state H1M mutants, to investigate the long-standing mystery of why many linker histones are phosphorylated during mitosis.

2014

**A Novel Chromosome Compaction Step in Anaphase Revealed by Quantitative Fluorescence Microscopy in Living Cells**

F. Mora-Bermudez,[1] D. Gerlich,[1,2] J. Ellenberg[1]; [1]Gene Expression and Cell Biology/Biophysics, European Molecular Biology Laboratory (EMBL), Heidelberg, Germany, [2]presently at: Institute of Biochemistry, ETH, Zurich, Switzerland

Chromatin structure changes dramatically during mitosis, when chromosomes compact and congress in order to be correctly segregated to daughter cells. Despite its importance, this dynamic organization of chromatin *in vivo* remains poorly understood. To address mitotic chromatin compaction, we developed a set of quantitative assays based on fluorescence microscopy of intact mammalian cells stably expressing GFP-tagged core histones. First, we measure changes in the total volume occupied by fluorescent chromatin through mitosis, using high-resolution 4D confocal imaging. Second, pixel intensity statistics of fluorescent chromatin are analyzed. Both assays show that the majority of mitotic compaction occurs during prophase. Surprisingly, after sister chromatid segregation, in late anaphase, chromosomes reach a compaction level even higher than in metaphase. To characterize this unexpected late compaction step, we developed a photoactivation assay to label confined regions in single chromosomes. Quantitative analysis shows that, at the time of the anaphase recompaction, protruding chromosome arms shorten by further compaction toward the rest of the chromatin mass, rather than by relocation within the anaphase. To identify the forces underlying this event, we tested whether microtubules are required. In untreated cells, compaction of all chromosomes was completed within 12 minutes after segregation. In cells were microtubules were acutely depolymerized by nocodazole immediately after segregation, 83% of measured chromosomes failed to fully compact with normal timing. This suggests that anaphase microtubules not only segregate and direct chromosomes to daughter cells, but may also participate in their recompaction, to form a single mass of chromatin before nuclear envelope reassembly. We are currently further characterizing this novel compaction event and are probing the possible involvement of chromatin-intrinsic factors.

2015

**Ubiquitination at DNA Breaks**

L. Postow, H. Funabiki; The Rockefeller University, New York, NY

Double strand DNA breaks induce two separate pathways: the DNA damage checkpoint response and double strand break repair. In mammalian cells, the most common repair mechanism is nonhomologous end joining (NHEJ). Both the checkpoint response and NHEJ can be reconstituted in extracts made from the eggs of the frog *Xenopus laevis.* Using *Xenopus* egg extract, we developed a system to biochemically identify proteins bound to damaged DNA structures. Such proteins are likely involved in either the checkpoint response or repair. Biotinylated DNA was conjugated to magnetic streptavidin-coated beads, and proteins binding these DNA-coated beads were analyzed. Many of the proteins that bound to these DNAs were well-known damage response proteins, including Ku70, Ku80, the DNA-PK catalytic subunit, Werner's helicase, and RPA. By mass spectrometry, we also found ubiquitin and several subunits of the 26S proteasome. In addition, the majority of the polyubiquitin conjugated to these DNA-bound proteins has the K48 branch point characteristic of proteins targeted to the proteasome. These results suggest that some proteins bound to the damaged DNA are ubiquitinated in higher eukaryotes, and moreover that some of these ubiquitinated proteins are subsequently degraded by the proteasome. We are investigating which damage-bound proteins are ubiquitinated, and the role of this ubiquitination in the damage response.

**Cak1p/CDK Interactions with Ctf7p-dependent Sister Chromatid Cohesion**

A. Brands, R. V. Skibbens; Biological Sciences, Lehigh University, Bethlehem, PA

High fidelity chromosome segregation requires that sister chromatids become paired or tethered together during S-phase. An essential step in chromatid pairing, termed cohesion establishment, involves Ctf7p/Eco1p (herein Ctf7p)(Skibbens et al., 1999; Toth et al., 1999). At present, there is no molecular mechanism known that coordinates cohesion establishment to S-phase. To understand how Ctf7p establishment activities are regulated, we performed a genome-wide synthetic lethal screen using the conditional *ctf7-203* allele to identify mutations in essential factors not present in most micro-array and high-throughput screens. To date, we identified 10 non-sectoring strains - representing new candidates for cohesion establishment factors. We cloned the first of these as a novel *cak1* allele. Cak1p is a serine/threonine kinase that phosphorylates Cdc28p - the major Cyclin-Dependent Kinase or CDK in budding yeast (Espinoza et al., 1996; Kaldis et al., 1996). Importantly, Cak1p is required for timely S-phase progression, potentially coordinating Ctf7p function to Cak1p/Cdc28p activation. Similar to the temperature sensitivity of *cak1* alleles (Cross and Levine, 1998), we find that the synthetic lethality of *cak1 ctf7* double mutants is bypassed by *cdc28* hypermorphs. These data suggest that cohesion establishment is tightly regulated by CDK activity.

2017

**Construction of the Cytogenetic Map of Maize Chromosome 9 by FISH and Integration of Pachytene Chromosome Structure and Recombination Frequency**

C. Wang, L. Harper, W. Cande; Department of Molecular and Cell Biology, University of California at Berkeley, Berkeley, CA

Meiotic recombination takes place during early prophase I of meiosis and genetic maps are based on the percentage of recombination between markers. However, recombination events are is not evenly distributed throughout the genome. To correlate the gene positions and chromosome structure with recombination frequency and linkage maps, we developed a novel high-resolution single copy FISH technique in maize to map genes on pachytene chromosomes for construction of a cytogenetic map. Since pachytene is the stage in which recombination is completed and most recombination occurs within genes, placement of genetically mapped gene on pachytene chromosomes by FISH will not only integrate chromosome structure and the genetic map, but also provide biological information about the global positions of genes, distribution of recombination events, and may shed light on the process of meiotic homologous pairing. We optimized our FISH procedure and successfully mapped nine single-copy genes on chromosome 9 that had been previously genetically mapped. All probes were directly labeled with fluorophores, and the smallest probe used was 3.1 kb. Two loci, *bz1* and *tac7077*, which are less than 1 cM apart, can be distinguished as two distinct signals. The centromere region 0.3 cM on the genetic map spans ~30% of short arm of chromosome 9; however, the distal region of 9S that represents almost 36 cM on the genetic map is only 25% of short arm. We found that the dramatic reduction of recombination between markers around the centromere corresponds to the pericentric heterochromatic region.

2018

**The Nuclear Envelope and Sister Chromatid Cohesion Factors Play a Direct Role in Telomere Length Homeostasis**

L. M. Antoniacci, R. V. Skibbens; Biological Sciences, Lehigh University, Bethlehem, PA

The nuclear envelope plays key regulatory mechanisms in both the spatial organization of chromatin within the nucleus and gene transcription. Mps3p/Nep98p (herein termed Mps3p) is an integral nuclear envelope protein with a single transmembrane domain that is recruited to the spindle pole body half bridge. Previous studies reported that Mps3p is essential for spindle pole body duplication (Jaspersen et al., 2002; Nishikawa et al., 2003). More recently, Mps3p was shown to perform a critical function in sister chromatid cohesion (Antoniacci et al., 2004). Here, we provide new evidence for a novel regulatory mechanism in which a telomerase-assembly component, Est1p, associates with Mps3p - suggesting that Est1p is sequestered to the nuclear envelope. We also report that Ctf7p/Eco1p (herein termed Ctf7p), previously found to interact with Mps3p, also physically and genetically interacts with Est1p and functions in telomere length regulation. Importantly, *mps3* and *ctf7* mutant cells exhibit similar telomere length increase defects - opposite that of telomere length decrease defects reported for *est1* mutant cells. These findings reveal a nuclear envelope-based balancing act in which associated factors promote telomere growth and shortening - altering telomere homeostasis.

2019

**Bimodal Dynamic Behavior of the Origin Regions of the Two *Vibrio cholerae* Chromosomes**

A. Fiebig, K. Keren, J. A. Theriot; Biochemistry, Stanford University, Stanford, CA

Chromosome partitioning is an essential process for all cells. Eukaryotic cells use the mitotic apparatus and regulatory checkpoints to faithfully segregate their chromosomes. Less is known about how bacteria accomplish the same task. Although most bacterial genomes are contained on a single circular chromosome, numerous bacterial species encode essential genes on more than one chromosome. These studies focus on *Vibrio cholerae*, a human pathogen whose genome is divided between two circular chromosomes. We used fluorescent repressor-operator systems to visualize the origin region of both chromosomes in live cells. Time-lapse analysis revealed important similarities and differences in the behavior of the two origins ($ori_I$ and $ori_{II}$). Both exhibit two modes of behavior we term "at home" and "traveling" that are correlated with progress through the

cell cycle. When at home, both origins move randomly within an ellipsoidal caging domain and their movements are comparable over 20-1500 second time scales. The home positions, however, are distinct. Home for $ori_I$ is near but not at the pole, while $ori_{II}$ is near the mid-cell and after segregation near the quarter-cell. Furthermore, each origin employs unique mechanisms to maintain the home position. The positioning mechanism for $ori_I$ measures absolute distance while that for $ori_{II}$ measures relative distance from the pole. During segregation, origins travel to find and establish a new home. $ori_I$ segregates asymmetrically from the old pole and $ori_{II}$ segregates symmetrically from the mid-cell. In both cases movement is directed, speed is comparable, and cell growth accounts for about half of the motion observed. Thus while the home positions, mechanisms to maintain the home position, and pattern of segregation differ, the local dynamic behavior of the origins of the two *V. cholerae* chromosomes are similar both at home and while traveling.

2020

**Telomere Shortening in Skeletal Muscle from MDX Mice**

T. C. Lund,[1] S. A. Nelson,[2] R. W. Grange,[3] D. A. Lowe[2]; [1]Department of Medicine, University of Minnesota, Minneapolis, MN, [2]Department Physical Therapy and Rehabilitation, University of Minnesota, Minneapolis, MN, [3]Dept. of Human Nutrition, Foods and Exercise, Virginia Polytechnic Institute and State University, Blacksburg, VA

Telomeres are the DNA sequences at the ends of chromosomes that keep tally of the number of cell divisions. Prior studies have shown that when telomeres become too short, chromosomes break and cell senescence or apoptosis occurs. Muscular dystrophy (MD) is a common X-linked neuromuscular disease in which the lack of the protein, dystrophin, causes muscle fiber damage. While previous studies have shown satellite cells are maintained in dystrophic muscle, they are reduced in number and this likely contributes to the pathogenesis of MD . We hypothesize that this is in part due to significant telomere shortening in these cells. Furthermore, our study stands out as the first to evaluate the diaphragm muscle for telomere dynamics. DNA was isolated from diaphragm and tibialis anterior muscles from mdx and wildtype mice aged 20, 40, 80, 100, 240, and 600 d (n=2-6 per age). Telomere length was determined by Southern blot. We found that telomere length was not different between muscles from 20, 40 or 80 d mdx and wildtype mice ($P>0.05$). Telomere length in diaphragm muscles from 100 and 600 d mdx mice was 84 +/- 3.8% and 59 +/- 1.4% of that from age-matched wildtype mice ($P<0.05$). In tibialis anterior muscles, telomere shortening was not evident in 100 d mdx mice (103 +/- 3.4% of wildtype) but in 600 d mice it was 68 +/- 2.3% of wildtype ($P<0.05$). These findings indicate that muscle satellite cells undergo telomere erosion and conceivably have a more finite life span in vivo than previously appreciated. Although considered to have stem cell characteristics, satellite cells in mdx muscle are perhaps under so much pressure to divide that they succumb to telomere erosion limiting their lifespan and their ability to repair damage muscle.

## Mammalian Development (2021-2046)

2021

**Embryonic Genome Activation in Porcine**

H. Odaman-Mercan,[1] M. Misirlioglu,[1] H. Sagirkaya,[2] M. Crenshaw,[1] E. Memili[1]; [1]Animal and Dairy Sciences, Mississippi State University, Mississippi State, MS, [2]Veterinary Faculty, Uludag University, Bursa, Turkey

The embryonic genome activation (EGA) is the most critical event of early mammalian embryogenesis. Still not well-understood in the porcine, EGA is remarkable with regard to the number of embryonic genes that must be activated, maternal messages that must be degraded, and the dramatic reprogramming of embryonic gene expression setting the stage for events associated with first differentiation and implantation. The objective of this study was to define timing of transition from maternal to embryonic control of development, and transcriptional patterns of two developmentally important genes, Glut1 and Hsp70, in preimplantation porcine embryos. In three groups, in vitro fertilized porcine oocytes were cultured in NCSU23 medium supplemented with 0.4% BSA at 39ºC, 5% $CO_2$. Presumptive zygotes (Group I) and 2- to 4-cell embryos (Group II) were cultured with specific inhibitor of mRNA synthesis α-amanitin (50 µg/ml) between 5 and 36 hours post insemination (hpi) and 36 and 48 hpi, respectively. Following α-amanitin exposure, the embryos were washed three times with TL-HEPES and then transferred into the NCSU23 medium without α-amanitin. Embryos in the Control Group were cultured without α-amanitin. While the control embryos reached to the blastocyst stage, α-amanitin treated embryos both in Groups I and II were arrested at the 8- to 16-cell stage. Glut1 and Hsp70 gene expressions, in the three groups were determined by quantitative RT-PCR relative to the transcripts of housekeeping gene β-Actin. In Group I, Glut1 and Hsp70 gene expressions were not different from that of Control Group. However, Hsp70 gene in Group II was significantly down-regulated as compared to Control Group ($p<0.001$). These results indicate that embryonic gene expression is essential for cell cleavage beyond 8- to 16-cell stage, and Glut1 and Hsp70 are maternal until 2-cell stage with Hsp70 being both maternal and embryonic at the 4-cell stage.

2022

**Reset of the *Saccharomyces cerevisiae* Aging Clock by Meiosis during Prophase Recombination Period**

V. Lukose,[1] S. DeSantiago,[2] L. Cahoon,[1] M. Wu,[1] K. Lancaster,[1] B. Rockmill,[3] L. L. Mays Hoopes[1]; [1]Biology and Molecular Biology, Pomona College, Claremont, CA, [2]Molecular Biology, Pomona College, Claremont, CA, [3]Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT

Asymmetric replicative aging occurs during budding or mitosis in *Saccharomyces cerevisiae.* The bud is reset to 0 g (generations) while the mother cell gains 1 g per mitosis. Meiosis was not previously known to reset yeast aging. We found that meiosis resets the aging clock. **Methods:** We magnetically sorted 8 g BR19191-8B wild type cells using Pierce EZ-Link Sulfo NHS LC biotin and Miltenyi anti-biotin beads, and induced meiosis on potassium acetate sporulation medium. **Results:** The cells germinating from these ascospores had life spans nearly as long as young cells, much longer than 8 g cells. All four spores were reset. We next examined resetting in meiotic mutants. Ndt80 initiates a transcription wave at pachytene (prophase I), after most recombination/repair. Mutant *ndt80* cells stall at pachytene but they can be 'returned to growth' by restoring rich medium. The 8 g *ndt80* cells 'returned to growth' are already reset; therefore, meiotic resetting occurs before pachytene. We also examined *spo11* homozygous diploids, which cannot form the first double strand break (DSB) required to initiate recombination. We found that *spo11* does not reset its aging clock during meiosis. **Conclusion:** We conclude that resetting occurs between the time of DSB formation and Ndt80 expression during prophase I. We hypothesize that DSB formation and DNA recombination may be involved in the resetting.

2023

**Increased Protein Arginine Methylation during the Myoblast Fusion**

S. Kim,[1,2,3] S. Kim,[2] C. Uhm[1,2,3]; [1]Anatomy, Korea university, Seoul , Korea, Republic of Korea, [2]Brain Korea 21 Biomedical Sciences, Seoul, Republic of Korea, [3]Korea Lung Tissue Bank, Seoul, Republic of Korea
